of acetone and alcohol, forming large white needles, which melted to a deep red liquid at 158.1–158.6° cor. The yield was 11 g. or 53.5% of the theoretical.

Anal. Calcd. for $C_{30}H_{34}O_3S_2$: C, 71.2; H, 6.72; S, 12.6. Found: C, 71.8; H, 6.41; S, 12.75.

Reaction of "Anhydro-*p*-methoxypropiophenone Disulfide" with Copper Chromite.—Two grams of the sulfur compound was dissolved in 40 ml. of dry xylene and 10 g. of finely ground copper chromite was added. The mixture was stirred and refluxed for two and one-half hours. After cooling, the mixture was filtered and the xylene removed by vacuum distillation. The residue of brown oil was dissolved in about 10 volumes of hot methanol and cooled, giving yellowish crystals which were recrystallized from methanol in yellow needles, m. p. 112.3–112.8° cor. The yield was 0.85 g., or 66% of the theoretical.

Anal. Calcd. for $C_{29}H_{30}O_2S$: C, 74.1; H, 6.18; S, 9.87. Found: C, 74.5; H, 6.19; S, 9.71.

Demethylation.—The procedure given by Kharasch[9] for demethylation of stilbestrols was used: 1.07 g. of the dianisylthiophene was dissolved in 25 ml. of ethylene glycol, 2.5 g. of potassium hydroxide added, and the mixture sealed in a glass bomb under a pressure of 0.5 mm. of mercury. It was kept at 225° for eighteen hours. When cool it was opened, and the contents diluted with 2 volumes of water and filtered. When 8 ml. of concentrated hydrochloric acid was added, the solution set to a gel immediately. It was digested on a steam-bath, filtered and washed with water and dried. It was recrystallized with difficulty from benzene or toluene. After two recrystallizations from benzene, the gray material darkened at 185°, melted at 194–196°. The yield was 0.61 g., 61% of the theoretical. The compound is a phenol, as the deep yellow color with ferric chloride and the solubility in base indicate.

Anal. Calcd. for $C_{18}H_{16}O_2S$: C, 73.0; H, 5.41; S, 10.81. Found: C, 72.5; H, 5.37; S, 10.83.

Acetylation.—The 2,4-di-*p*-hydroxyphenyl-3,5-dimethylthiophene was readily acetylated by heating 0.1 g. with 0.1 g. of fused sodium acetate in 2.5 ml. of acetic anhydride on a steam-bath for one hour. The mixture was then poured over ice and stirred until the oil had solidified. The amorphous solid was centrifuged out and recrystallized three times from ethyl alcohol, giving fine white needles of the diacetate, which softened at 121°, but melted at 125.9–126.9° cor.

Anal. Calcd. for $C_{22}H_{20}O_4S$: C, 69.5; H, 5.26; S, 8.42. Found: C, 69.7; H, 5.29; S, 8.25.

Formation of the Thiophene in Two Steps.—Approximately 2 g. of "Anhydro-*p*-methoxypropiophenone disulfide" was refluxed in 30 ml. of xylene for three hours. The solution became deep purple in color. The xylene was distilled off under vacuum, and the residual brown oil was taken up in ethanol and stored in the refrigerator. No crystals were obtained in twenty-four hours, although both 2,4-di-*p*-anisyl-3,5-dimethylthiophene and "anhydro-*p*-methoxypropiophenone disulfide" are readily crystallized from alcohol. A few drops of the alcohol solution decolorized an acetone solution of potassium permanganate, indicating unsaturation. The alcohol solution was refluxed for two hours with copper chromite. Upon cooling the filtered alcohol solution, yellow needles were obtained, m. p. 112–113.5°. Mixed with 2,4-di-*p*-anisyl-3,5-dimethylthiophene, the melting point was 112–113°.

Summary

A new method for the synthesis of 2,4-diarylthiophenes, in yields of 65 to 85% based on the reaction of "anhydroketone disulfides" with copper chromite, is described.

The mechanism of this reaction is discussed.

Four new compounds, "Anhydro-*p*-methoxypropiophenone disulfide," 2,4-di-*p*-hydroxyphenyl-3,5-dimethylthiophene, and its dimethyl ether and diacetate, are characterized.

Acetylenic Ethers. IV.[1] Hydration

BY THOMAS L. JACOBS AND SCOTT SEARLES, JR.

It has been shown[2] that acetylenic ethers add water more rapidly than vinyl ethers but less rapidly than ketene acetals. The hydration is acid catalyzed and the rate has been followed quantitatively for several vinyl ethers.[3,4,5] It was of interest to carry out similar experiments with several acetylenic ethers for comparison.

Experimental

A dilatometric method was used to follow the hydration because it has been employed successfully to study the vinyl ethers[3,4,5] and because methods of analysis for acetylenic hydrogen or for the unsaturation of the triple bond are relatively inexact and have not been applied with success to acetylenic ethers. Butyl acetate was isolated[2] in 67% yield by heating butoxyacetylene with distilled water. In dilute solutions containing traces of acid this hydration is the only significant reaction; both the polymerization of the acetylenic ether and the hydrolysis of the ester are slow enough to be neglected. In aqueous alcohol the reaction is accompanied by marked volume contraction. The concentrations of the solutions studied were 0.025 to 0.03 molar.

The acetylenic ethers used in this work were carefully refractionated samples.[2,6] The ethoxyacetylene may have contained a little water and traces of water may have been introduced into all the ethers when samples were being sealed in small bulbs since for this operation the bulbs were embedded in dry-ice and open to the air.

The dilatometer was similar to that described by Leutner[7] and used to study the hydration of vinyl ethers.[3,4,5] The measuring bulb had a volume of 110 ml. and the capillary was 25 cm. long, had a diameter of 0.36 mm. and was uniform within 1% over the calibrated portion.

The acetylenic ethers are not very soluble in water and

measurements were made in 12.5 and 42.7% by weight alcohol and water.[8] The rate of hydration of ethoxyacetylene and butoxyacetylene was followed most accurately and conveniently at *p*H 6 to 7. The solutions were weakly buffered and the acetylenic ethers were dissolved by crushing the bulbs containing the samples under a known amount of the solvent containing the basic portion of the buffer. This solution was transferred to the mixing chamber of the dilatometer in the thermostat and stirred until the temperature was constant. A dilute, thermostated solution of the acidic portion of the buffer was then transferred to the mixing chamber and the solution stirred and forced several times into the measuring chamber and back. The measuring chamber was finally filled to the desired capillary height using mercury to seal the stopcock as described by Leutner[7] and readings were taken at regular intervals.

The hydration of phenoxyacetylene was followed conveniently at *p*H 2; hydrochloric acid was used and the solution was not buffered.

It was necessary to allow considerable time for thermostatting after the sample bulbs were broken because the heats of solution of acetylenic ethers in aqueous alcohol are rather large. When a bulb containing 0.151 g. of ethoxyacetylene was broken in 140 ml. of 12.5% alcohol (*p*H 7.4) at 24.8° in a Dewar flask the temperature drop was 0.120°. Using a value of 1.026 cal. per g. degree as the specific heat of the solvent[9] and neglecting the heat capacity of the Dewar flask, the heat of solution of one mole of ethoxyacetylene in 64.9 liters of 12.5% alcohol is −7.9 kcal.

Measurements were carried out at 25.0° in a thermostat controlled by a large mercury regulator. The maximum temperature variation during a run was 0.003° and in some experiments it was as little as 0.001°. It was not possible to correct the capillary reading accurately for temperature variations since the changes were not synchronous. A preferable procedure is to use the readings of a second dilatometer containing only the solvent to correct the measurements.[10] Due to the war, it was not possible to obtain more of the capillary tubing of the correct size to construct another dilatometer. In 12.5% alcohol when the temperature changes were random and fairly rapid a variation of 0.001° altered the capillary height 0.05 to 0.1 mm. and the maximum effect on the capillary reading lagged behind the temperature change by 0.1 to 0.8 minute. Any sustained shift in the temperature altered the reading 3 or 4 times as much. In 42.7% alcohol the capillary reading varied 4 or 5 times as much as in 12.5% alcohol and the rate constants are correspondingly less reliable. However, the volume changes which occur with acetylenic ethers during hydration are larger than with vinyl ethers. The dilatometer capillary in work with the latter[3,4,5] had a diameter of only 0.05 mm.

The *p*H's of the solution were measured with a Model G Beckmann *p*H meter which makes use of a glass electrode. Dole[11] reported that in dilute alcohol there is practically no error in the voltage of the glass electrode and this was found to be true for 12.5% alcohol solutions. In solutions containing more alcohol there is an error depending upon the amount of alcohol present[11] and in addition the electrode is somewhat erratic.[12] The readings were found to be unreliable if the instrument was used in alcohol solution continuously for fifteen minutes or longer, but such treatment did no damage to the electrode, for correct values were obtained on standard aqueous buffers immediately after such erratic behavior in alcohol. Figure 1 gives the relationship between *p*H readings of hydrochloric acid solutions in 42.7% ethanol and the log $1/H_3O^+$ of identical concentrations of the same acid in water. The graphical mean of the deviations is 0.16 *p*H unit with a possible variation of 0.05 *p*H unit. Such a variation corresponds to an uncertainty in the hydrogen ion concentration of ±12%. This is present only in the rate determinations on ethoxy- and butoxyacetylene in 42.7% alcohol, since with phenoxyacetylene, the hydrochloric acid concentrations were known accurately.

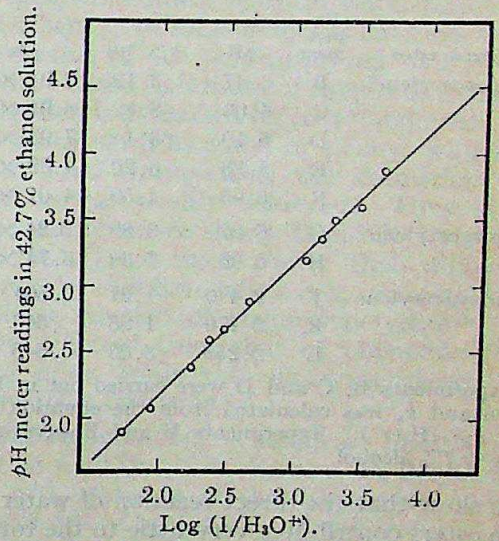

Fig. 1.—The relationship between *p*H readings in 42.7% ethanol solutions and log $(1/H_3O^+)$ in water solutions of identical concentration.

Either phosphate or acetate buffers were used with the alkoxyacetylenes and the exact concentrations of the salts were not known. In the phosphate buffers the concentration of disodium acid phosphate was approximately 1×10^{-4} *M* and of monosodium acid phosphate 1 to 2.5×10^{-3} *M*. This corresponds to an ionic strength of 1.3 to 2.8×10^{-3} *M*. The concentration of sodium acetate in the acetate buffer was approximately 4.5×10^{-3} *M* and of acetic acid 1.5 to 3×10^{-3} *M*.

Calculations, Results and Discussion

The hydration was found to be first order with respect to acetylenic ether and to hydronium ion. Since the latter acts as a catalyst only, the rate law at any given *p*H was $-dc/dt = kc$. The equation may, therefore, be written in its integrated form as

$$\log \frac{(h_\infty - h)}{(h_\infty - h_0)} = -\frac{kt}{2.3}$$

where h_0, h_∞ and h are the capillary readings at the beginning and end of the reaction and at time t. The specific rate constant, k, was evaluated graphically by plotting log $(h_\infty - h)$ against t in minutes and determining the slope of the curve. Accurate experimental values of h_∞ were not obtained due to the difficulty of maintaining a constant temperature for a sufficiently long period of time, but by a trial and error method an empirical h_∞ was chosen which gave most nearly a straight

(8) Dilute alcohol was chosen as the solvent because it was used by Skrabal[3] in his studies of the vinyl ethers. The 12.5% by weight ethanol was prepared conveniently by mixing 800 ml. of distilled water and 150 ml. of the azeotropic mixture of water and ethanol which is 95.57% by weight ethanol. The ethanol was a carefully refractionated sample. The 42.7% by weight ethanol was prepared by mixing equal volumes of water and 95.57% ethanol. Only ethoxyacetylene was sufficiently soluble to be studied in the more dilute alcohol.

line. The method of Guggenheim[13] which eliminates h_∞ was also applied to the data. The points did not fall as accurately on a straight line as in the first method since random errors in the individual readings are magnified. However, the rate constants as determined by the two methods always agreed within 2%. Table I summarizes the results and Fig. 2 gives the experimental curves from which the values of k were obtained for runs C, E, H, and K. The other runs give equally good lines.

TABLE I

Acetylenic ether	Experiment	pH	$k \times 10^2$	k_a
Ethoxyacetylene[a]	B	6.47	3.12	8.91×10^3
	C	6.03	8.42	8.91×10^3
	D	5.10	63.1	7.93×10^3
	E	5.85	6.20	4.39×10^3
	F	5.95	4.50	4.01×10^3
Butoxyacetylene	G	6.27	3.89	7.24×10^3
	H	5.96	7.39	6.74×10^3
Phenoxyacetylene	J	2.470	1.91	0.564
	K	2.470	1.85	.546
	L	2.255	3.03	.545

[a] Experiments B, C and D were carried out in 12.5% alcohol and k_a was calculated from the equation $k_a = (k - k_w)/(H_3O^+)$. Experiments E and F were carried out in 42.7% alcohol.

To show that the direct reaction of water with these esters contributes very little to the total reaction rate one experiment was carried out on ethoxyacetylene in 12.5% alcohol at pH 8.97. The reaction was less than a third complete in sixty hours and the determination was much less accurate than experiments in acid solution. From the slope of the curve, k was found to be 1.1×10^{-4}. This represents the sum of the rate constant of acid catalyzed hydration, $k_a(H_3O^+)$ and the rate constant of hydration by water, k_w. Since $k_a = 9 \times 10^3$ and $(H_3O^+) = 1.1 \times 10^{-9}$, $k_w = 1.0 \times 10^{-4}$. The hydration by water should be independent of the acid concentration and k_w was therefore subtracted from k in the calculation of k_a for experiments in 12.5% ethanol (Experiments B, C, and D). The value of k_w in 42.7% alcohol was not determined because it was less than in 12.5% alcohol and the variations of capillary reading with temperature were so large.

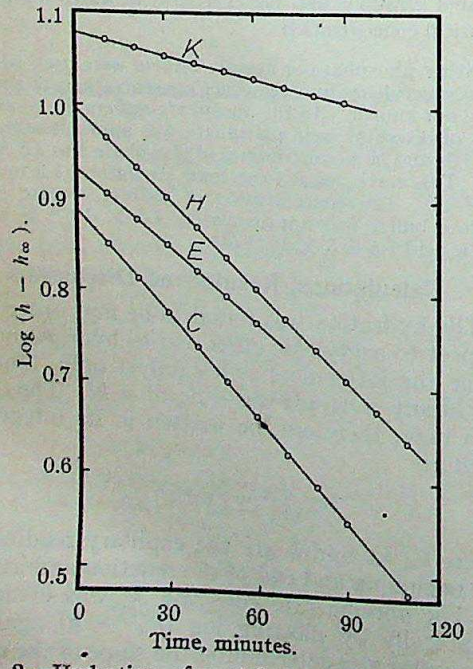

Fig. 2.—Hydration of acetylenic ethers at 25°: C, ethoxyacetylene in 12.5% ethanol; E, ethoxyacetylene in 42.7% ethanol; H, butoxyacetylene in 42.7% ethanol; K, phenoxyacetylene in 42.7% ethanol.

The hydrolysis of saturated ethers is believed to proceed through an oxonium intermediate of the type $[RO(H)R]^+$ and cleavage of one of the alkyl-oxygen bonds.[14,15] A. Skrabal[16] and R. Skrabal[4] have formulated the reaction mathematically to permit calculation of the rates of hydrolysis of unsymmetrical ethers from the rates of symmetrical ones. This treatment does not hold for vinyl ethers and R. Skrabal[4] believed that this was due to a different mechanism of hydrolysis, probably the addition of water to the double bond of the vinyl group as Paul[17] suggested earlier. No direct evidence for this addition could be obtained because the hemiacetal produced is hydrolyzed more rapidly than the vinyl compound.[16] The hydrolysis of ethynyl ethers appears to be similar to that of vinyl ethers, but in this case the compound obtained by the addition of water to the triple bond is the enol form of an ester. This rearranges to the ester which hydrolyzes very much less rapidly than the acetylenic ether.[18] A mechanism which is consistent with the observed kinetics may be formulated as follows

(1) $ROC{\equiv}CH + H_3O^+ \longrightarrow (ROC{=}CH_2)^+ + H_2O$

(2) $(ROC{=}CH_2)^+ + H_2O \longrightarrow (ROC(OH_2){=}CH_2)^+$

(3) $(ROC(OH_2){=}CH_2)^+ + H_2O \longrightarrow ROC(OH){=}CH_2 + H_3O^+$

(13) Guggenheim, *Phil. Mag.*, [7] **2**, 538 (1926).

(17) Paul, *Bull. soc. chim.*, [5] **1**, 971 (1934).

(18) The rate constant, k_a, for the acid catalyzed hydrolysis of ethyl acetate in water at 25° is 6.5×10^{-3} min.$^{-1}$ moles^{-1} liters [Dawson and Lowson, *J. Chem. Soc.*, 2146 (1928)] and the constant for the reaction with base in water at 25° is 6.76 min.$^{-1}$ moles^{-1} liter [Terry and Stieglitz, THIS JOURNAL, **49**, 2216 (1927)]. It has been shown by Caudri [*Rec. trav. chim.*, **48**, 422 (1929)] that in aqueous alcohol the rate constant for the reaction with base decreases as the amount of alcohol increases (in 10% and 20% alcohol by volume k has values of 6.23 and 5.70, respectively, compared with a value of 6.54 which he obtained in water). At a pH of 6 the pseudo first order rate constant for the over-all hydrolysis in water is 7.4×10^{-8} min.$^{-1}$. This is negligible compared with the pseudo first order rate constant of 8.7×10^{-3} for ethoxyacetylene at pH 6 in 12.5% alcohol at 25°.

(4) $ROC(OH)=CH_2 \longrightarrow ROC(=O)-CH_3$

The first step involves the transfer of a proton to the β-carbon atom and is probably the same as the first step in the acid catalyzed hydration of an ordinary ethylenic bond,[19] a reaction which shows the same kinetics and for which hydronium ion appears to be the only acid with an appreciable effect on the rate. This specific acid catalysis seems to hold for the acetylenic ethers as well since the values of k_a obtained from different runs on the same compound by dividing k by the hydronium ion concentration are the same even when the concentration of other acids such as dihydrogen phosphate ion or acetic acid are varied several fold. The question of the rate determining step remains open. An alternative mechanism which may be important in 42.7% alcohol involves the formation of a ketene acetal. This would be converted

(2) $(ROC=CH_2)^+ + C_2H_5OH \longrightarrow$

$$\left(\begin{array}{l} RO \\ C_2H_5O-C=CH_2 \\ \quad | \\ \quad H \end{array}\right)^+$$

(3)

$$\left(\begin{array}{l} RO \\ C_2H_5O \end{array}\!\!>\!C=CH_2 \right)^+ + H_2O \longrightarrow$$

$$\begin{array}{l} RO \\ C_2H_5O \end{array}\!\!>\!C=CH_2 + H_3O^+$$

rapidly to the ester, possibly to some extent through the ortho ester.

Table II lists the average values of k_a for vinyl and ethynyl ethers, for diethyl ether and for two olefins.

TABLE II

RATE CONSTANTS FOR ACID CATALYZED HYDRATIONS OR HYDROLYSES AT 25°

Compound	k_a (min.$^{-1}$, moles^{-1} l.)	Solvent
Diethyl ether[3]	1.46×10^{-11}	Water
Ethyl vinyl ether[5]	1.73×10^{2}	Water
Isopropyl vinyl ether[4]	5.20×10^{2}	Water
Divinyl ether[3]	5.0×10^{-1}	Water
	2.9×10^{-1}	25% alc. (by vol.)
Ethoxyacetylene	8.6×10^{3}	12.5% alc. (by wt.)
	4.2×10^{3}	42.7% alc. (by wt.)
Butoxyacetylene	7.0×10^{3}	42.7% alc. (by wt.)
Phenoxyacetylene	5.5×10^{-1}	42.7% alc. (by wt.)
Isobutylene[19]	2.3×10^{-2}[a]	Water
Trimethylethylene[19]	1.3×10^{-2}[a]	Water

[a] These are the values for k_a at an ionic strength of 0.05 N. For isobutylene the extrapolated value at zero ionic strength is 2.2×10^{-2} (min.$^{-1}$, moles^{-1}, l.).

All of the differences in rate constants are in the directions expected if step (1) is rate determining. Vinyl ethers hydrate more rapidly than alkenes because of the extra stabilization due to resonance in the intermediate onium ion and hence in the transition state as well. The effect is larger when

(1) $ROCH=CH_2 + H_3O^+ \longrightarrow$

$$\left\{\begin{array}{l} R-O-\overset{+}{C}H-CH_3 \\ R-\overset{+}{O}=CH-CH_3 \end{array}\right\} + H_2O$$

the double bond is replaced by a triple bond since the ability of the latter to take part in such resonance is greater.[20] This does not permit a direct prediction of the relative rates of hydration of ethynyl and vinyl ethers, but only of the former relative to alkynes; however it is not surprising that acetylenic ethers hydrate more readily than vinyl ethers. No measurements have been made of the rates of the acid-catalyzed hydration of alkynes. When the ability of oxygen to enter such conjugation is decreased by its attachment to another group such as vinyl or phenyl which permits crossed conjugation, the transition state would be less readily achieved. Thus divinyl ether hydrates more slowly than ethyl vinyl and phenoxyacetylene more slowly than alkoxyacetylenes. In this connection it is interesting that the dipole moment of phenoxyacetylene[21] is not greatly different from that of phenetole or diphenyl ether while the alkoxyacetylenes have higher dipole moments.[21]

Acknowledgments.—Thanks are due to Dr. S. Winstein and Dr. J. B. Ramsay of the Department of Chemistry of the University of California at Los Angeles for many helpful suggestions throughout the course of this work. Part of the preliminary work on the problem was done by Mr. L. R. Pollack. We also wish to thank Mr. Harry L. Masser of the Southern California Gas Company for a scholarship granted to the junior author.

Summary

The rates of the acid catalyzed hydration of ethoxy-, butoxy- and phenoxy-acetylene have been measured at 25° in dilute alcoholic solutions by a dilatometric method. The reaction is first order with respect to ether and hydronium ion concentration and consists in the addition of water to the triple bond yielding an ester. The hydration is very similar to that of vinyl ethers, but proceeds more rapidly. A mechanism consistent with the kinetics is proposed.

LOS ANGELES, CALIFORNIA RECEIVED JANUARY 11, 1944

Unsaturated Synthetic Glycerides. VI.[1] Polymorphism of Symmetrical Monoöleyl-disaturated Triglycerides[2]

BY B. F. DAUBERT AND T. H. CLARKE

Since studies on the polymorphic phases of glycerides, both natural and synthetic, have been excellently reviewed recently by Ferguson and Lutton,[3] no detailed reference to past investigations will be made in this report.

While much of the earlier and basic work concerning the abnormal melting behavior of fats was confined to simple triglycerides and complex glyceride mixtures of natural fats, it remained for Malkin and associates[4,5,6] to establish a foundation upon which the polymorphism of glycerides could be studied and understood. The latter investigators, on the basis of their experimental work mainly with synthetic compounds, indicate that mixed triglycerides can exist in at least four different modifications (which they designate by Greek letters as β, β', α and γ, each with a characteristic melting point.

Transition point data for the polymorphic forms of synthetic glycerides containing unsaturated acids, only recently synthesized, have not been published. The purpose of the present paper, therefore, is to report the experimental data for a series of symmetrical monoöleyl-disaturated triglycerides.[7]

In this and future publications dealing with polymorphism in glycerides we shall refer to the different polymorphic forms for the unsaturated synthetic glycerides by the use of Roman numerals, *e. g.*, Form I, Form II, etc. Form I will always refer to the highest melting or most stable form.

Experimental

Methods and Apparatus.—The measuring system consisted of an eight-junction copper–constantan thermel, a Leeds and Northrup type K1 potentiometer and a type R galvanometer with a glass scale reading device. The thermel was about 1.5 mm. in diameter and the active section about 7 mm. in length. The ends of the thermel were enclosed in thin-wall glass tubes. The thermel was calibrated against a platinum resistance thermometer from 100 to −79° using the Callender equation above 0° and the van Deusen equation below 0°, in order to determine the temperature of the thermometer at a given point. The Na_2SO_4–$Na_2SO_4 \cdot 10H_2O$ point and the freezing point of mercury (−38.89°) were checked to within ±0.02°. The maximum sensitivity of the system was 0.02° per cm. of scale deflection when the scale was placed at a distance of one meter from the galvanometer mirror. The change in microvolts was 300, on the average, over the temperature range involved.

A sample of the synthetic glyceride (0.7 to 1.0 g.) was weighed into a small glass vial and then the end of the thermel was inserted to a depth of about 25 mm. The vial was then inserted into a small vacuum flask so that a 1-cm. clearance around the vial was available. The small vacuum flask could be lowered into any one of a series of liter vacuum flasks serving as warming or cooling baths. Within reasonable limits any desired rate of warming or cooling could be obtained.

During the determination of a cooling or warming curve, the setting of the potentiometer was changed by even increments and the time recorded when the galvanometer image crossed the zero point on the scale. The magnitude of the increments on the potentiometer dial depended upon the rate of cooling or warming. On a time basis the most rapid practical rate was a reading every six seconds. During a very slow rate of change of temperature, the time interval between readings was as long as two minutes.

For the purpose of checking technique and determining the accuracy of the apparatus, transition points were redetermined for 1-monostearin and 1-monomyristin. Comparison of the results with those previously reported by Malkin and Shurbagy[5] are tabulated in Table I.

TABLE I

TRANSITION POINTS FOR POLYMORPHIC FORMS OF 1-MONOSTEARIN AND 1-MONOMYRISTIN

Form	1-Monostearin, °C.	1-Monomyristin, °C.
I	81.8	71.0
Malkin's β	81.5	70.5
II	78.0	67.5
Malkin's β'	79.0	67.5
III	75.4	55.3
Malkin's α	74.0	56.0
IV	48.5	21.3
Malkin's γ	47.5	24.0

Discussion of Cooling and Warming Curves.—The type of warming curve obtained on heating a sample of a synthetic glyceride depends entirely on its previous history, *i. e.*, the manner by which it was cooled and subsequently stored. This observation, pointed out by other investigators, has been verified in the present study.

Since it was not possible under our experimental conditions to observe the transformations of the different forms of the synthetic glycerides, transition point is used in preference to melting point to indicate the temperature at which the change occurred.

Types of cooling and warming curves for 2-oleyl-1,3-dimyristin, resulting from many thermometric measurements and typical for the series of symmetrical monoöleyl-disaturated triglycerides, are shown in Figs. 1 and 2. In these figures the temperature scale is entirely accurate, but certain liberties have been taken with the time axis so that a complete set of curves could be drawn on a single chart. Approximate time intervals are indicated (see below) for certain sections of the curves.

The cooling of a melted sample resulted in its solidification in one of three forms depending on the rate of cooling. Very rapid cooling (three to five minutes) brought about solidification in Form IV (curve CC′, Fig. 1). Subsequent warming of the cooled glyceride (curve C′C″) produced a pronounced change of slope 0.2 to 0.6° below the transition point of Form IV (this behavior was checked many

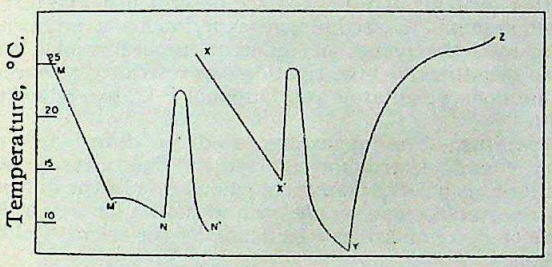

Fig. 2.—Types of cooling and warming curves for 2-oleyl-1,3-dimyristin.

times and seemed very specific) followed by a very sudden rise to the transition point of Form III and a slower rise to the transition point of Form I. The presence of Form II was not indicated on this warming curve. If the rapidly cooled sample (curve CC′) was held slightly below the transition point of Form IV for some time (thirty to forty-five minutes) indicated in curve CD, a rise in the curve occurred, indicating a slight heat evolution. This heat evolution was apparently caused by the conversion of Form IV to some higher temperature form or forms, for subsequent warming (curve DD′) gave only a slight indication of the presence of Form III, a definite change in slope, and then a good transition point for Form I. Again the presence of Form II was not indicated.

A somewhat slower rate of cooling (eight to twelve minutes) of the original melted sample resulted in solidification of the sample in Form III (curve AA′). Immediate warming gave changes of slope corresponding to the transition points from Form III, Form II and Form I (curve A′A″). As in the case of curve CD, if the sample solidified in Form III was held for some time (thirty to forty-five minutes) as indicated in curve A′B, conversion occurred to the higher temperature forms as shown by curve BB′, wherein a small but definite break occurred at the transition point of Form II followed by a marked change of slope at the transition point of Form I. If the cooled samples at points B or D were held at those temperatures for a longer period of time (sixty to seventy-five minutes), subsequent warming indicated practically complete conversion to Form I.

Very slow cooling (twenty to twenty-five minutes) of the melted sample of 2-oleyl-1,3-dimyristin resulted in solidification of Form I (curve XX′Y, Fig. 2). The liquid supercooled to point X′; the temperature then rose very rapidly to a point between the transition points of Form I and Form II as the heat of solidification was evolved and then decreased rapidly. Warming of the sample (curve YZ) showed a transition point of Form I only. Curve MM′NN′ would seem to indicate the possibility of crystallization of more than one form at a time from a melted sample. Upon cooling, solidification occurred in Form III at M′ on the curve. The sample continued to cool for several degrees to point N and then suddenly increased to a temperature between the transition points of Form I and Form II with no indication of the presence of Form III.

Important factors determining the shape of the curves, time of cooling and warming, etc., are the nature and size of the sample, and the temperature gradient between the sample and surroundings. We believe we have studied a sufficient number of rates of cooling and warming to show that the transition point temperatures, in the main, are not rate dependent. The determination of the transition point of Form IV on a warming curve did show slight rate dependence. The transition point approached that found for Form IV on cooling curves (which were not rate dependent) as the warming rate was increased.

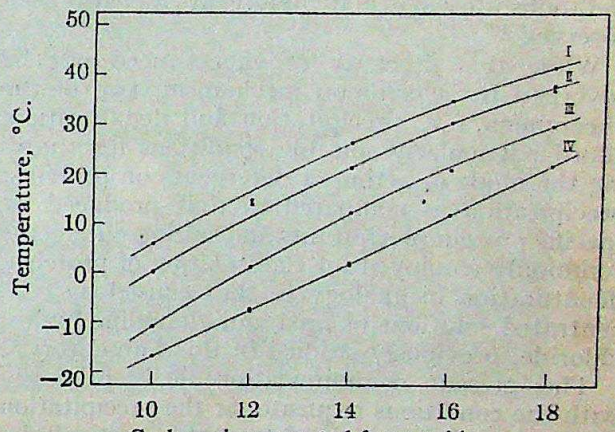

Fig. 3.—Transition point curves for the polymorphic forms of symmetrical 2-oleyl-1,3-diacylglycerols.

The transition points for the polymorphic forms of each member of the series of symmetrical monoöleyl-disaturated triglycerides are given in Table II. A single value is given wherever a transition point could be duplicated to within ±0.1°. The relationships between the various polymorphic forms are shown in Fig. 3. While the consistency of the data is apparent, one anomaly, however, is to be noted. For 2-oleyl-1,3-dilaurin, no transition point clearly defining either Form I or Form II was obtained. Three values, all lying between the curves for Form I and Form II were experimentally obtained, none of which clearly characterizes either form. The capillary melting point for Form I (16.0 to 16.5°) would fall close to the curve for the melting points of other members of the series.

The Precipitation of Proteins by Synthetic Detergents[1a]

BY FRANK W. PUTNAM AND HANS NEURATH

Synthetic detergents are capable of reacting with proteins to produce precipitation[1,2,3,4] and denaturation,[1,2,5,6] the inactivation of some viruses[7,8] and enzymes,[9] the fragmentation of certain natural pigment-protein complexes,[2,10] and the catalytic hydrolysis of protein amide and peptide bonds.[11] The inhibition of bacterial metabolism by synthetic detergents has also been observed.[12]

While this diversity of effects need not be governed by a common mechanism, two of the phenomena, *i. e.*, precipitation and denaturation, afford particularly suitable conditions for studying the mode of action of detergents on proteins: precipitation as compared to that produced by specific protein precipitants and salting-out agents commonly employed for the isolation of proteins; denaturation in analogy to that caused by concentrated solutions of urea and guanidine hydrochloride, previously studied in this Laboratory.[13]

The present communication deals primarily with the conditions requisite for the precipitation of proteins by anionic detergents, particularly, the precipitation of crystalline horse serum albumin by sodium dodecyl sulfate, and with the properties of the protein-detergent complex.[14] The effects of anionic detergents on the denaturation and regeneration of proteins will be the subject of subsequent papers.

Experimental

Materials and Methods

Serum Albumin.—Crystalline horse serum albumin was prepared by low temperature precipitation of the globulins with ammonium sulfate (2.1 *M*) at *p*H 6.4, followed by room temperature precipitation of the albumin at its isoelectric point (*p*H 4.8) by 2.3 *M* ammonium sulfate, the procedure being analogous to that already described for the preparation of bovine serum albumin.[17] The four-times crystallized albumin had a carbohydrate content of 0.10% and corresponded approximately to Kekwick's Fraction B. The preparation was electrophoretically homogeneous at *p*H 7.6.

Other proteins investigated are described in the text.

Detergents.—In preliminary experiments a number of commercial detergents of different type formulas were used. Quantitative investigation was restricted to purified sodium dodecyl sulfate[18] and Duponol P C, free of sodium sulfate.[19]

Apparatus.—The apparatus used in diffusion,[20] viscosity,[21] and electrophoresis studies[22] has already been described, as has the manner of calculation of the diffusion constant, molecular asymmetry and molecular weight.[20,21] Nitrogen determinations were made by the micro-Kjeldahl method.

Preliminary Observations

The action of a number of commercial detergents[19,23,24] on several purified proteins was investigated qualitatively in the following manner: to Wassermann tubes containing 2-cc. aliquots of 2% protein in phosphate buffer *p*H 7.7, or in acetate buffer *p*H 4.2, were added serially from another tube 2 cc. of tenfold dilutions (0.0002–2.0%) of an aqueous solution of the detergent. Thorough mixing was accomplished by repeated pouring back and forth.

It was observed that with anionic detergents precipitation was restricted to the acidic *p*H and that with all types of detergents maximum precipitation occurred at 0.1–1.0%, increasing detergent concentrations resulting in dispersion of the precipitate.

p*H* Region of Precipitation.—In order to investigate further the effect of *p*H on precipitation, a series of buffers hydrochloric acid–sodium chloride, sodium acetate or phosphate) differing by 0.1 or 0.2 *p*H unit, was prepared.[25]

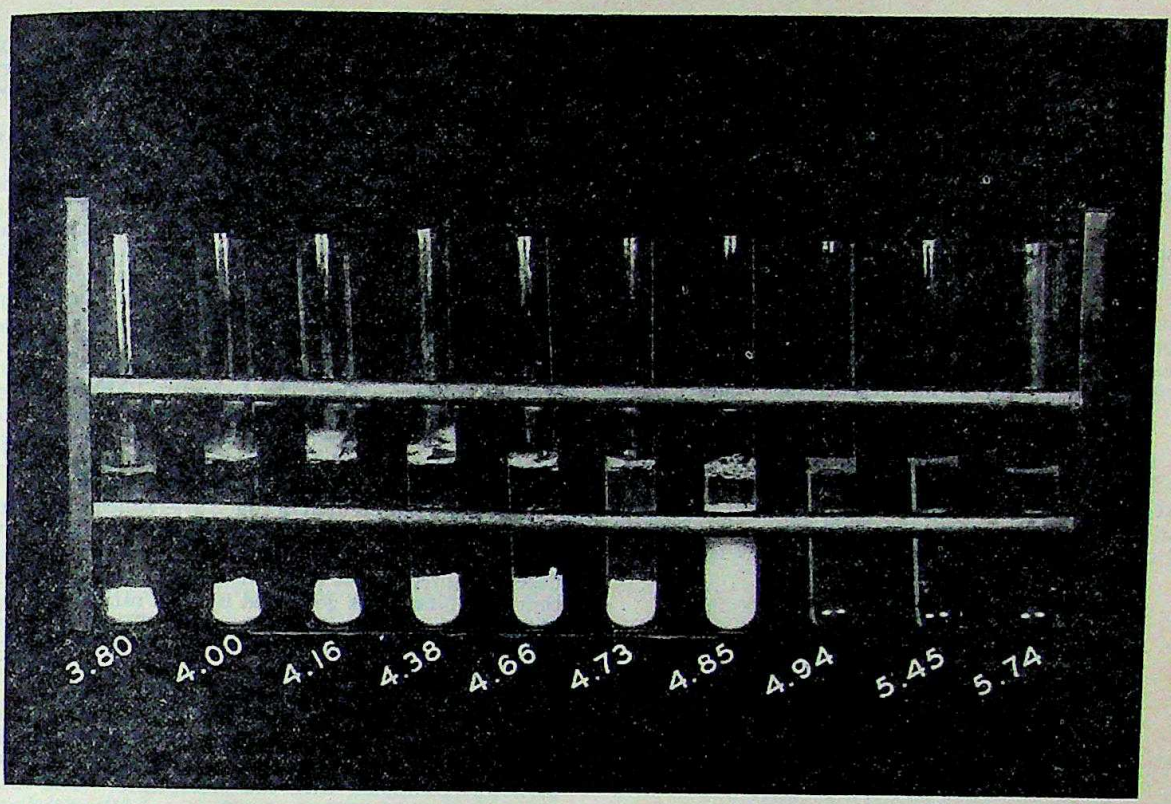

Fig. 1.—pH region of precipitation. The test-tubes contain 40 mg. of crystalline horse serum albumin and 10 mg. of purified sodium dodecyl sulfate in 4 cc. of 0.1 N sodium acetate buffer of the pH indicated. Photographed without centrifuging two hours after mixing. Since up to pH 4.85 the protein was completely precipitated, in all of the tubes, the heights of the precipitates are indicative only of the rate of sedimentation.

The protein was dissolved in the buffers and sufficient sodium dodecyl sulfate (SDS) was then added to ensure complete precipitation. The final pH was determined on the supernatant with the glass electrode since slight changes in pH occurred incidental to mixing.

Serum Albumin.—The test tubes depicted in Fig. 1 contain 40 mg. of crystalline horse serum albumin to which had been added 10 mg. of SDS, the solutions being 0.1 N with respect to sodium acetate, in a total volume of 4 cc. The isoelectric point of horse serum albumin in this buffer is reported to be pH 4.75[26] while precipitation ceases at pH 4.85.

Except in the region of the isoelectric point, settling is very rapid. Within less than one hour a compact pellet is formed from which the supernatant solution may be decanted readily without prior centrifugation. The photograph taken after standing for two hours after mixing is evidence of this fact. Since all the protein was precipitated in the pH range 3.80–4.85, the heights of the precipitates are indicative only of the rate of sedimentation.

Other Proteins.—Other proteins investigated in a similar manner were: pepsin, β-lactoglobulin, horse serum pseudoglobulin GI, and crystalline beef serum albumin, obtained as already described,[16,21] egg albumin, made available through the courtesy of Dr. A. R. Taylor of the Duke Medical School; and crystalline human carboxyhemoglobin prepared according to the method of Cannan and Redish.[27] All preparations were found to be homogeneous in diffusion or electrophoresis, except for hemoglobin which was not investigated.

As revealed by the data given in Table I, all these proteins are precipitated only in the cationic form, the maximum pH at which precipitation ensues closely approximating the isoelectric point except for hemoglobin. Agreement between the isoelectric point and the maximum pH of precipitation is most satisfactory for proteins which are isoelectric within the acetate buffer range. In the case of pseudoglobulin GI, a small amount of precipitate which formed above the isoelectric point redissolved spontaneously on standing overnight. Likewise, in the case of pepsin, a small amount of precipitate was observed at

TABLE I

COMPARISON OF ISOELECTRIC POINT, AND MAXIMUM pH FOR PRECIPITATION OF PROTEINS BY SDS

Protein	I. P.	Ref.	Maximum pH for precipitation
Pepsin	2.7	(28)	about 2.7
Egg albumin	4.6	(29)	4.6
Horse serum albumin	4.75	(26)	4.85
Beef serum albumin	4.8	(30)	4.8

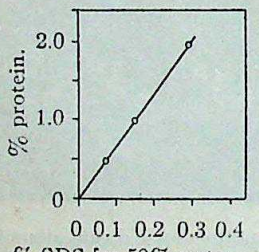
reactions exceeding the isoelectric point; however, acidification of the supernatant solutions yielded additional precipitation only in tubes initially at *p*H 2.75 or higher.

The conclusion derived from these experiments is that *anionic detergents precipitate proteins only when the latter are in the cationic form*[33] and that the maximum *p*H at which precipitation occurs closely approximates the isoelectric point.

Analytical Investigations

Quantitative investigations of the influence of the following factors on the precipitation of crystalline horse serum albumin by purified SDS was undertaken: (1) the protein-detergent weight concentration ratio, (2) *p*H, and (3) temperature and salt concentration. SDS was chosen because (a) it is available in the pure anhydrous form, (b) it is nitrogen free, and (c) its presence may readily be detected and its removal effected by the addition of barium salts.

1. Protein-Detergent Weight Concentration Ratio.—The effect of varying detergent concentration on the precipitation of a given amount of serum albumin was studied at three different protein concentrations (4.80, 9.80 and 19.72 mg. per cc.), in the presence of 0.1 *N* sodium acetate, *p*H 4.5, at room temperature. One-half hour after mixing the tubes were centrifuged and aliquots of the filtered supernatant solutions were analyzed for nitrogen, the amount of protein precipitated being obtained by difference.



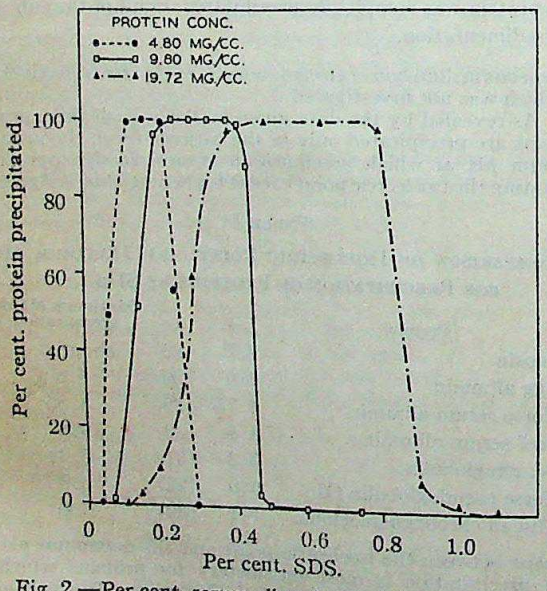


Fig. 2.—Per cent. serum albumin precipitated at *p*H 4.5 in 0.1 *N* sodium acetate plotted against concentration of sodium dodecyl sulfate. The initial protein concentration of the solution is denoted as follows: - - - - 4.80 mg. per cc., —— 9.80 mg. per cc., and ·—· 19.72 mg. per cc. The small graph represents the linear relation between the protein concentration and the per cent. SDS required for 50% precipitation.

In Fig. 2 the per cent. of total protein precipitated is plotted against the final concentration of SDS.

Taking the middle curve representing a protein concentration of 9.80 mg. per cc. as an example, three distinct regions may be discerned: (a) that of *protein excess* where the protein is incompletely precipitated; (b) the *equivalence zone* where complete precipitation is achieved; and (c) the region of *detergent excess*, in which the precipitate initially formed may be partly or completely dispersed by shaking. At a given protein concentration, the transition between these regions with increasing concentration of SDS is abrupt. Therefore, to ensure 100% precipitation an optimal protein-detergent concentration ratio must be observed. Since the equivalence zone is fixed within the limits of the protein-detergent weight ratio (5:1 to 2.5:1), its width varies directly with protein concentration.

If the data represented in Fig. 2 are reduced to a common basis by plotting the protein-detergent weight ratio as abscissa against the per cent. protein precipitated as ordinate, the three curves very closely superimpose, indicating that precipitation is governed by this ratio. This is also illustrated by the small inset graph of Fig. 2 in which the per cent. SDS required to precipitate 50% of the albumin is plotted against the protein concentration, the figures being interpolated from the larger graph in Fig. 2.

Qualitative tests for SDS made by the addition of barium chloride to the supernatant solutions indicated that below the region of detergent excess nearly all of the SDS was combined with the precipitate. The maximal concentration of SDS that will completely precipitate a given amount of horse serum albumin at room temperature corresponds approximately to the total acid-binding capacity of the protein. The average value obtained by interpolation from the curves in Fig. 2 is 145 moles of SDS per g. of protein $\times 10^5$. This correlation suggests that anionic detergents may act to precipitate proteins by combining stoichiometrically with the positively charged groups of the protein. However, since precipitation is already complete at a detergent concentration corresponding to about one-half of the total acid-binding capacity, this relation may be fortuitous and, therefore, did not warrant a detailed analysis of the composition of the precipitates in the region of protein excess.

2. *p*H Region of Precipitation.—The effect of *p*H on the precipitation of horse serum albumin by SDS was determined in the acetate buffer range (0.1 *N* sodium acetate) at a final protein concentration of 9.70 mg. per cc., at 31°. Two different concentrations of SDS were chosen; the one, 2.5 mg. per cc., was calculated as just sufficient to precipitate all the protein present, while the other, 1.5 mg. per cc., was estimated to yield about 50% precipitation (Fig. 3).

The lower curve, corresponding to partial precipitation, was established by Kjeldahl analysis. The upper curve was obtained by the observation that no precipitate was formed at *p*H 4.94 or higher, while at *p*H 4.73 and lower, no precipitate resulted on the addition of trichloroacetic acid to the clear supernatant solutions.[34]

When a solution of SDS or Duponol (adjusted to *p*H 4.85) is added to a salt-free, isoelectric solution of serum albumin (*p*H 4.85), no precipitation ensues, and the *p*H rises to a maximum value of about 6.4. On the addition of acid to the clear solution it becomes cloudy at the isoelectric point, and the protein is completely precipitated on further acidification. The *p*H increase undergone upon the titration of 1 g. of horse serum albumin in 100 cc. of water with 100 cc. of 0.25% Duponol is illustrated in Fig.

(33) A personal communication from Dr. T. L. McMeekin reveals that this point is in substantial agreement with his unpublished observations.

(34) We have verified the statement of Anson[5] that under specified conditions the presence of Duponol interferes with the precipitation of hemoglobin by trichloroacetic acid (see also (11)). Under similar conditions we have observed no interference with the trichloroacetic acid precipitation of serum albumin or serum globulin.

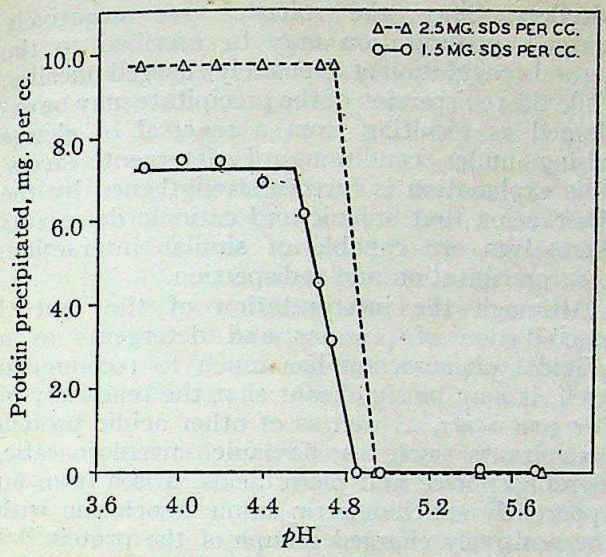

Fig. 3.—*p*H region of precipitation of crystalline horse serum albumin (9.70 mg. per cc.) by sodium dodecyl sulfate in 0.1 *N* sodium acetate. The upper curve (complete precipitation) refers to a detergent concentration of 2.5 mg. per cc., the lower curve (partial precipitation) to 1.5 mg. cc.

4. It is evident that in order to precipitate proteins with anionic detergents it is necessary to work in buffered solutions.

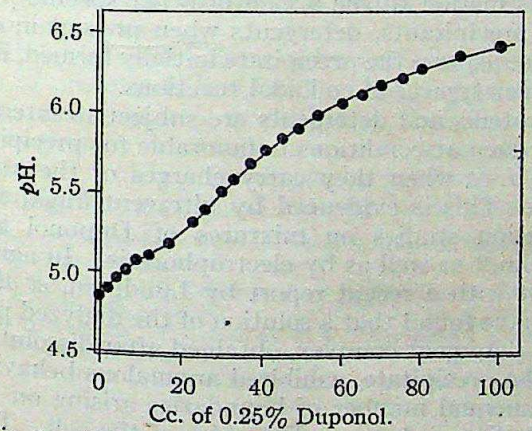

Fig. 4.—Change in *p*H of a salt-free 1% serum albumin solution (isoelectric point, *p*H 4.85) upon the addition of increments of Duponol (adjusted to *p*H 4.85).

3. Influence of Temperature and Salt Concentration.—The effect of temperature was first studied at a protein-detergent concentration ratio corresponding to the half-precipitation level. The reacting solutions were equilibrated at various temperatures, mixed, allowed to stand one-half hour, then centrifuged at the same temperature, and analyzed as already described. The protein concentration was 9.76 mg. per cc., the SDS concentration 1.5 mg. per cc., the solvent being 0.1 *N* sodium acetate, *p*H 4.5.

The large temperature effect observed under these conditions is shown in Fig. 5.

Although an albumin solution precipitated at 4° yields additional precipitate upon equilibration at 36°, to an extent corresponding to this point, the path going from 36 to 4° is only partially reversible.

Investigation of the influence of temperature on precipitation at various protein-detergent ratios revealed that this effect was confined to the protein or detergent

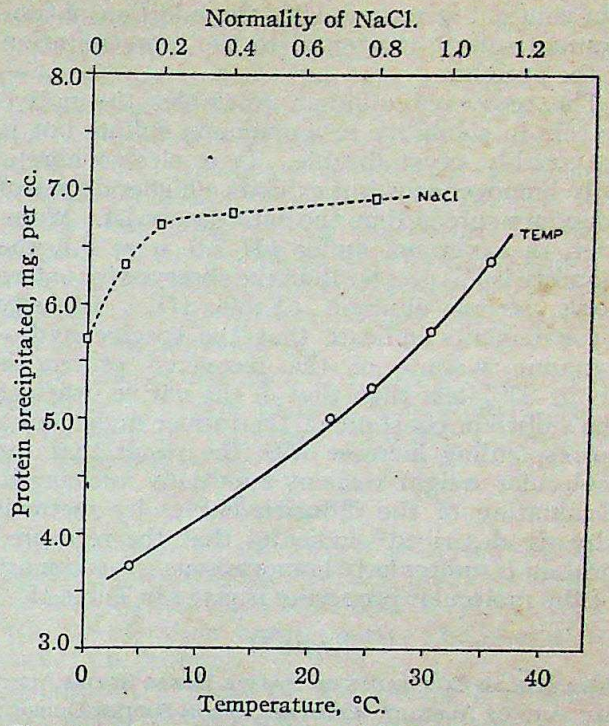

Fig. 5.—Influence of temperature and salt concentration on the partial precipitation of horse serum albumin (9.76 mg. per cc.) by sodium dodecyl sulfate (1.5 mg. per cc.). The bottom abscissa refers to temperature, the solvent being 0.1 *N* sodium acetate, *p*H 4.5. The top abscissa refers to sodium chloride concentration, the solvent likewise containing 0.1 *N* sodium acetate, *p*H 4.5 ($t = 31°$).

excess regions, the width of the equivalence zone being but little affected by changing temperature.

As shown in Fig. 5, increasing the salt concentration likewise enhances the precipitation of serum albumin at the half-precipitation level, the first increments of salt being most effective.

Properties of the Protein-Detergent Complex and of the Recovered Protein.—The complex precipitated in the equivalence zone is sparingly soluble in water, neutral salt solutions, or in weakly acidic buffers, but dissolves in alkaline solutions or on dialysis against water. Upon prolonged dialysis of an alkaline solution, some of the SDS passes through the membrane. However, complete separation of protein and detergent cannot be accomplished by this method, for the presence of undialyzable SDS may be demonstrated by the addition of barium chloride, or by the precipitation of the protein upon slight acidification of the solution. Moreover, considerably lower concentrations of ammonium sulfate are required for the precipitation of the protein under these conditions, than for the precipitation of native serum albumin.

Complete dissociation of the complex and removal of SDS may be accomplished by the addition of a small excess of barium chloride (1 mM. per 0.9 mM. of SDS). The highly insoluble barium dodecyl sulfate so formed is negative to qualitative protein tests after two washings. Excess barium remaining in the supernatant pro-

tein solution is removed by the addition of ammonium sulfate incidental to the reprecipitation of the protein.

The recovered albumin resembles the native protein in solubility in ammonium sulfate but is not readily crystallizable. It is electrophoretically homogeneous but exhibits a higher degree of boundary spread than the native material. Moreover, in a veronal buffer *p*H 7.6, $\mu = 0.1$, the mobility is 7% greater than the observed for native horse serum albumin (Table II). Viscosity measurements indicate that the specific hydrodynamic volume of the recovered protein is about 25% less than that of the native, whereas the diffusion constant of the former undergoes a corresponding increase with the result that the molecular weight remains essentially unchanged. Evaluation of the diffusion curves by methods already described[20] indicates that the recovered protein is molecularly homogeneous. A summary of the molecular properties is given in Table II.

Discussion

The precipitating action of detergents on proteins has already been observed in previous work. Following an observation by Bull and Neurath on the precipitating and dispersing effects of sodium dodecyl sulfate on egg albumin,[35] similar findings were reported by Miller and Andersson for insulin.[36] McMeekin[3] has investigated quantitatively the relative effectiveness of a number of homologous anionic detergents in precipitating crystalline egg albumin and β-lactoglobulin, while Schmidt[4] has reported analogous experiments involving cationic detergents.

Precipitation of proteins by synthetic detergents appears to be caused by electrostatic forces. This is suggested by the finding reported herein that with anionic detergents, precipitation is restricted to protein cations, while with cationic detergents it is limited to protein anions.[2,37] Ultracentrifugal and diffusion measurements indicate that the sodium alkyl sulfates exist in solution in micellar form, with a molecular weight of about 12,500.[36] Accordingly, it may be calculated that in the region of complete precipitation each protein molecule combines with 1 to 2 detergent micelles. Since the micelles are negatively charged, precipitation may be ascribed to the mutual coagulation of oppositely charged micelles, while the redispersion of the precipitate may be explained as resulting from a reversal of charge arising under conditions of detergent excess. This explanation is further strengthened by the observation that anionic and cationic detergents themselves are capable of similar interaction, *i. e.*, precipitation and redispersion.

Although the interpretation of the mutual precipitation of proteins and detergents as a colloidal phenomenon has much to recommend itself, it may be significant that the reactivity of *detergent acids*, as well as of other acidic protein precipitants such as flavianic, trichloroacetic, metaphosphoric and picric acids, arises from an apparently stoichiometric anion association with the positively charged groups of the protein.[38,39] The precipitating efficiency of these reagents, as well as their catalytic effectiveness in the hydrolysis of protein amide and peptide bonds, parallels their anion affinities, the affinities of dodecyl sulfate and dodecyl sulfonate being among the highest so far measured.[11] However, not all proteins are precipitated by detergents at a given acidity but each at a *p*H determined by the respective isoelectric point.[40] Moreover, in contradistinction to the action of other specific protein precipitants, detergents when present in excess redisperse the precipitate initially formed, in a manner typical of colloidal reactions.

Proteins and detergents are subject to interaction even at conditions unfavorable for precipitation, *i. e.*, when they carry charges of the same sign. This is evidenced by ultracentrifugal and diffusion studies on mixtures of Duponol and insulin,[36] as well as by electrophoresis. In agreement with a recent report by Lundgren, *et al.*,[15] we have found that a solution of the dialyzed protein-detergent complex, obtained after dissolution of the precipitate, exhibited anomalous behavior, an unequal number of boundaries arising on the ascending and descending sides of the cell. This phenomenon is similar in kind to that observed in the interaction between thymonucleic acid and serum albumin in *p*H regions alkaline to the isoelectric point of the protein.[42] In this case, too, precipitation ensues when the *p*H is adjusted to the acid side of the isoelectric point.

(40) Polymerized sodium metaphosphate offers an interesting analogy to the action of SDS. Briggs[41] has observed that on mixing sodium metaphosphate (*p*H 5.0) with isoelectric salt-free horse serum albumin, the solution remains clear and the *p*H rises abruptly in a manner somewhat similar to that observed herein for the addition of SDS (Fig. 4). On acidification, the metaphosphate protein solution becomes cloudy just above the isoelectric point and precipitates as the pH is decreased.

While the very structural features which render detergents protein precipitants may likewise be involved in their denaturing action, the two phenomena may be discerned under certain conditions. Thus, while for anionic detergents precipitation is confined to the acid side of the isoelectric point, denaturation, as revealed by viscosity measurements,[43] occurs to about the same extent in both acid and alkaline regions, with detergents of both the anionic and cationic types. Moreover, while relatively low concentrations of detergents exert a high denaturing action on proteins,[1,5] this effect increases with detergent concentration in the region of detergent excess.[43]

The properties of serum albumin recovered from the precipitated complex approximate more closely those of the protein regenerated from concentrated urea or guanidine hydrochloride solutions[13,44] than they do those of the native material. Since precipitation by SDS leads to changes in properties which may not be wholly reversed even upon subsequent dissociation of the protein-detergent complex, the recovered protein must be denatured according to the general definition proposed for denaturation.[45] However, it is the degree of denaturation that varies with detergent concentration, regardless of whether the combination between protein and detergent leads to precipitation.

While the application of detergents to the isolation of proteins is restricted by the degree of denaturation incurred, nevertheless, their use may be warranted in specific instances, even in the preparation of biologically *active* materials. For example, the serological activity of antibodies[46] or the hormonal activity of insulin[47] have been shown to be rather insensitive to even high degrees of denaturation. Also, under suitable conditions detergents may be employed in the preparation of protein-free filtrates or of regenerated proteins. Since precipitation of a given protein ceases at the isoelectric point, detergents may conceivably be adapted to the separation of protein mixtures under conditions at which the components carry opposite charges, *e. g.*, serum proteins. This aspect of the problem is now being investigated in this Laboratory.

Summary

Investigation of the effects of synthetic detergents on proteins has revealed that anionic detergents precipitate proteins only in the cationic form, precipitation ceasing above the isoelectric point of the protein.

Quantitative study of the system crystalline horse serum albumin-sodium dodecyl sulfate has shown that precipitation is governed by the following factors: protein-detergent weight concentration ratio, *p*H, temperature and ionic strength. At low detergent concentrations the protein may be completely precipitated while in regions of detergent excess redispersion of the precipitate occurs.

Dissociation of the protein-detergent complex by means of barium salts yields a protein which, as indicated by diffusion, viscosity and electrophoresis, is in a regenerated rather than in the native state.

The mechanism of precipitation and the potential application of detergents to the preparation and separation of proteins have been considered.

Polarographic Examination of Carbonyl Compounds

BY JOHN M. LUPTON AND CECIL C. LYNCH

Although the polarographic reduction of many carbonyl compounds has been reported,[1] it is not possible to obtain reduction waves with saturated, unsubstituted ketones. This fact led us to the study of methods by which carbonyl compounds may be examined polarographically.

In searching for an environment in which carbonyl reaction products would give polarographic waves, several reagents were tested. In acid hydrazine solution,[2] ketones give double waves as shown in Fig. 1. Aldehydes give similar waves. The half-wave potentials vary somewhat with concentration, but for ketones the first wave occurs near −1.1 v. (*vs.* S. C. E.); for aldehydes, near −0.9 v. For both aldehydes and ketones the half-wave potential of the second wave is in the

(2) The polarographic reduction of the hydrazonium and phenylhydrazonium ions has not been investigated. Since they do not appreciably alter the hydrogen discharge in hydrochloric and sulfuric acid solutions (0.1 *N*) their half-wave potentials must be more negative than −1.5 v.

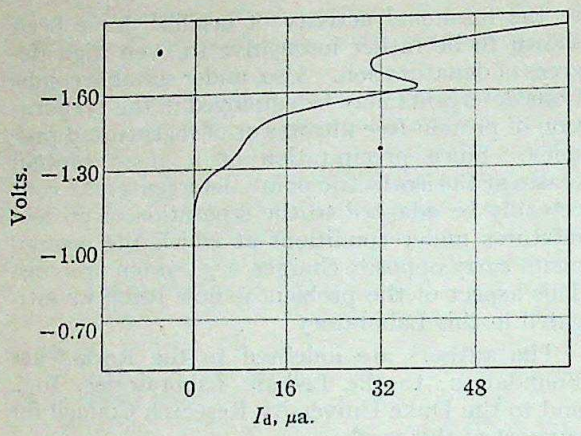

Fig. 1.—The reduction of methyl *n*-amyl ketone (0.006 *M*) in hydrazine solution.

range −1.3 to −1.4 v. The carbonyl compound reacts with the hydrazine solution, forming the hydrazone ($RR'CNNH_2$), the azine ($RR'CNNCRR'$), or a mixture of the two. The constants governing the relative quantities of the hydrazone and the azine produced under these conditions have not been determined here. The data indicate that a state of equilibrium exists in the system.

Acetone and *i*-butyraldehyde give reduction waves in acid phenylhydrazine[2] solution closely similar to those obtained in hydrazine solution, but the difficulty of obtaining and storing pure phenylhydrazine hydrochloride made the hydrazine reagent more satisfactory.

No carbonyl reduction waves were found with solutions of *i*-butyraldehyde and of methyl *i*-butyl ketone in ammonium chloride–hydrochloric acid solutions. Isobutyraldehyde gave no reduction wave in alkaline sodium sulfite solution. In slightly acid and neutral sodium sulfite solution only the bisulfite waves were observed.

Experimental

Work contained in this paper is limited to the investigation of the relationship between diffusion current and concentration in acid hydrazine solution for the following carbonyl compounds: isobutyraldehyde, acetone, methyl *i*-butyl ketone, methyl *n*-amyl ketone.

Apparatus.—The Leeds and Northrup Electrochemograph was used in obtaining all polarograms. Supplementary potential measurements were made with the Leeds and Northrup Universal *p*H Indicator.

The capillary tip was a piece of Pyrex capillary tubing about 0.05 mm. inner diameter, 6 mm. outer diameter, 8 cm. long. The mercury reservoir and regulating device was similar to that described by Furman, Bricker and Whitesell[3] except that connection to the capillary was made by a standard taper 10/30 ground joint. A typical value for the product $m^{2/3}t^{1/6}$ was 1.745 mg.$^{2/3}$ sec.$^{1/6}$, corresponding to a mean chloride diffusion current i'_d = 5.59 *Ma*, at 0.00100 *M*.

A mercury pool, never less than 3 sq. cm. in area, was used as the anode. The potential of this electrode in the standard hydrazine solution was 0.22 v. *vs.* the saturated calomel electrode. To convert potentials to the saturated calomel electrode base, 0.22 v. must be subtracted from observed values.

A large portion of the polarograms were run using the cell and transfer system shown in Fig. 2. A definite volume of supporting electrolyte solution, usually 25 ml., was added to a weighing buret. A stream of water-saturated nitrogen was passed through the liquid for twenty minutes to remove oxygen. After oxygen removal, the buret was opened briefly for the weighed addition of carbonyl compound, and shaken.

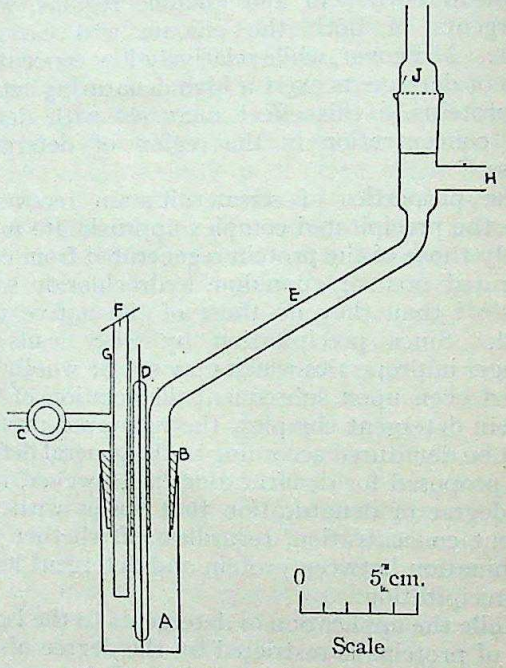

Fig. 2.—Cell and transfer system.

The cell (Fig. 2-A), the bottom covered with a layer of mercury, was fitted tightly over the #5 rubber stopper (B) through which were sealed auxiliary connections: a vent (C) equipped with a stopcock, a glass-covered connection to the mercury pool (D), and a filling tube (E). The dropping mercury electrode (F) entered the cell through the vent to which it must be sealed (G) by a rubber sleeve or by a sealing compound. Nitrogen under a pressure of 15 cm. of water was connected to the filling tube at the hose connection (H) and by the adapter (J).

After assembling the system the vent was opened and the system flushed with nitrogen for about five minutes. The vent was then closed, the ground glass joint opened, and the weighing buret, containing the sample, rapidly inserted between the adapter (J) and the filling tube. The cell and sample were protected from oxygen during this operation by the stream of nitrogen issuing from the filling tube and the adapter. When the buret stopcock was opened the sample solution could flow into the cell.

This system permitted mixing and transfer of solutions without serious absorption of oxygen and without serious loss of volatile carbonyl compounds.

Other runs were made using a large cell (capacity, 25 to 50 ml.) covered with a #10 rubber stopper. The dropping mercury electrode, the connection to the mercury pool, an aeration tube, a vent, and two standard taper 10/30 ground joints, outer members, were sealed into the stopper. A buret, 5 × 0.02 ml. capacity, fitted into one ground joint. The other served as the bearing for a paddle stirrer which could be turned manually through about 60° of angular rotation. In using this cell a definite volume of supporting electrolyte was added and the cell tightly closed except for the vent. Oxygen was removed by bubbling with water-saturated nitrogen. Aeration was then stopped leaving nitrogen at a pressure of about 2 inches of water connected to the vent. A blank was run, then carbonyl solution (in

Digitized by Arya Samaj Foundation Chennai and eGangotri

oxygen-free standard supporting electrolyte) was added from the buret, mixed by the stirring paddle with the liquid in the cell, and run. By this means a series of results could be obtained without changing the cell.

The actual cells used corresponded to the above descriptions except that some were provided with water jackets for temperature control. Cells without jackets were controlled by immersion in thermostat water. All polarograms were run at 25.0 ± 0.2°.

Purity and Purification of Materials.—The inorganic reagents were of reagent grade and were used without further purification. Polarographic tests indicated that no significant quantity of impurity was present. The hydrazine sulfate (Baker Analyzed) was assumed to be pure. Sulfuric and hydrochloric acids were analyzed before use. Mercury was of a grade suitable for polarographic work.

Merck Reagent acetone, b. p. 55.5–57.5°, was used without further purification. Other carbonyl compounds were of C. P. or technical grade and were carefully purified in a 3 foot by 0.5 inch rectifying column packed with Fenske rings. Fractions were considered to be pure when they condensed within 0.1° of the accepted boiling point at reflux ratios exceeding 20/1.

Results

Diffusion current values for the four carbonyl compounds were determined over the concentration range 0.0001 to 0.01 M and are summarized in Table I and in Figs. 3 and 4. In this table the data are represented through second degree equations of the type $R = AC + BC^2$. All results were obtained with a standard supporting electrolyte solution having the composition: hydrazine sulfate 0.100 M, sulfuric acid 0.0500 M, hydrochloric acid 0.00100 M. Higher concentrations of hydrazine sulfate were impractical, due to solubility considerations. In this solution the ratio, total electrolyte/carbonyl, falls below the conventional minimum, 50, when the carbonyl concentration exceeds 0.006 M. This would normally lead to coulomb effects. Since, however, diffusion current values are consistent over the concentration range 0.0001 to 0.010 M (i_d/C is a linear function of C) coulomb forces do not appear to be appreciable. Control experiments showed that thirty minutes must be allowed for reaction of the carbonyl compounds with this solution.

The method is useful at concentrations below 0.0001 M, but the configuration of the waves is such that a highly empirical method for determination of the diffusion current must be used. Because of the large maximum in the second carbonyl wave quantitative measurements of its diffusion current were not attempted. The diffusion current of the first carbonyl wave was determined by locating the inflection point between the two carbonyl waves and by measuring the difference in current between the inflection point and the point at which the extrapolated residual current reaches the potential of the inflection point. The same method was used in evaluating the chloride diffusion current.

Diffusion currents were calibrated by the pilot-ion technique.[1] The carbonyl diffusion current, i_d, was divided by the diffusion current of chloride ion, i'_d, at 0.00100 M, giving the ratio, R. All results were expressed in terms of R but may be converted to absolute values by the tip data above and the corresponding average value for i'_d at 0.00100 M, $i'_d = 5.59$ μa.

$$i'_d/m^{2/3}t^{1/6} = 5.59/1.745 = 3.20$$
$$i_d = i'_d R = 3.20 m^{2/3}t^{1/6} R$$

Use of the values for R below with other dropping electrodes and with other polarographs may be made by conversions to absolute values or by the pilot-ion technique.

Two attempts were made to predict total diffusion current for carbonyl mixtures (aldehydes and ketones do not give separate waves) from the

empirical equations for diffusion current. In each case the experimental diffusion current was much lower than the calculated value.

Discussion.—The chemical nature of the material undergoing reduction at the dropping electrode is not clear. The double wave could result from the presence of two reducible species, but probably represents the stepwise reduction of a single species. The similarity of waves obtained in the hydrazine and in the phenylhydrazine solution (where the azine cannot form) suggests but does not prove that the hydrazone is the major product. In any case, mathematical analysis of the first carbonyl-hydrazine wave shows that the electroreduction is irreversible, a value of 0.62 electron transferred being found.

The relatively low diffusion currents obtained at high concentrations and with carbonyl mixtures suggest that equilibrium exists in the system. At very low carbonyl concentrations the hydrazine–carbonyl concentration ratio will approach infinity and the equilibrium, if it exists, will be displaced toward complete reaction. Under these conditions the term in C^2 will become negligible and the current will be determined principally by A and C. Thus the constant A is related to the diffusion coefficient and the irreversibility factors, while B is related to the equilibrium constant of the reaction or reactions.

The mean deviation of all values for R is about 4% and is about three times the mean deviation of values for the chloride diffusion current. The increased deviation is due to the carbonyl wave, possibly because the system has not been adequately controlled. It is more probable, however, that the increased deviation is due to difficulties in locating precisely the inflection point between the carbonyl waves and to the possibility that the recorded wave, resulting from a dynamic instrument, does not accurately or consistently represent the rapidly changing electrode processes in the region of an inflection point.

Summary

It has been shown that aldehydes and ketones can be analyzed polarographically in acid hydrazine solution. The relationship between diffusion current and concentration has been determined for one aldehyde and three ketones over the range 0.0001 M to 0.01 M, and has been expressed by second degree equations. The precision of the method varies between 2 and 5%.

Oxidation Processes. XVII.[1] The Autoxidation of Ascorbic Acid in the Presence of Copper

BY A. WEISSBERGER AND J. E. LUVALLE

Introduction

In the preceding paper of this series we reported on the autoxidation of *l*-ascorbic acid at *p*H from 4.7 to 9.2, in the presence of sufficient cyanide and thiocyanate to suppress the catalytic action of metals. Under these conditions, both the monovalent and the divalent ion of the acid participate in the reaction. With oxygen of atmospheric pressure, the divalent ion reacts 10^5 times faster than the monovalent ion. If the partial pressure of the oxygen is reduced to 1/5, the reaction rate of the divalent ion sinks in proportion to the oxygen concentration, but not the reaction rate of the monovalent ion. The latter ion undergoes a slow process before it reacts with the oxygen, probably forming a reactive radical in the interaction with dehydroascorbic acid. In the absence of cyanide and thiocyanate and in the presence of copper, the reaction rate of the monovalent ion is proportional to the oxygen concentration.[1] This shows that the metal-catalyzed autoxidation of the monovalent ion is more rapid than the slow process just mentioned.

The question arises whether the effect of the metal on the reaction of the monovalent ion explains fully the metal catalysis in the autoxidation of ascorbic acid, or whether the autoxidations of unionized ascorbic acid and divalent ion are likewise catalyzed by copper. This problem is treated in the present paper.

Materials and Methods

l-Ascorbic Acid.—Eastman Kodak Co. *l*-ascorbic acid was used.

Water was redistilled in an all-Pyrex still.

Oxygen in cylinders (Linde) was used.

Sodium *p*-Phenolsulfonate.—Eastman Kodak Co. sodium *p*-phenolsulfonate dihydrate was recrystallized several times from distilled water, which for the last two recrystallizations had been redistilled as stated above.

All other chemicals were Baker Analytical or General Chemical Company Reagent Grades.

Apparatus and techniques were those described in the preceding papers of this series, using the two-chamber reaction vessel.[2] The temperature was 20.03 ± 0.02°. Each volume read was corrected to a barometric pressure of 760 mm. The reaction mixtures had a volume of 50 ml. The buffers, present in a concentration of 0.20 molar, were monopotassium phosphate, potassium hydrophthalate, sodium acetate, dipotassium phosphate and sodium *p*-phenolsulfonate. They were adjusted to the proper *p*H with nitric acid or potassium hydroxide.

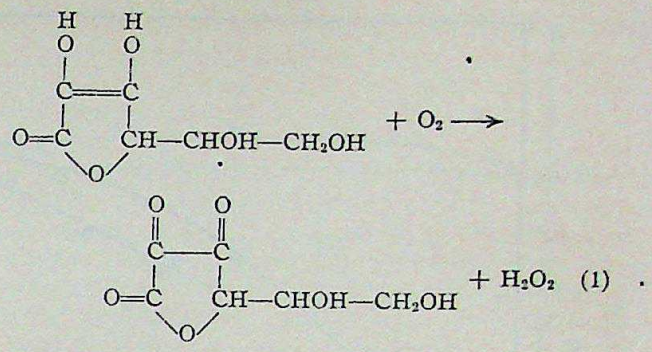
Before the start of the reaction, buffer and cupric nitrate in 45 ml. of water were placed in the lower chamber of the reaction vessel; the ascorbic acid in 5 ml. of water acidulated with 0.2 mmole of nitric acid was in the upper chamber.

Results and Discussion

The experimental results are collected in the table. The headings of the first five columns are the same as those in Table I of the preceding paper.[1] In the sixth column is listed the concentration of the solutions with respect to cupric nitrate as calculated from the amount of the salt added and the total volume of the reaction mixtures (50 ml.).

In column seven is listed the *total oxygen uptake*, a_{ob}, in mole O_2/mole ascorbic acid; a_{ob} is defined as the volume of oxygen absorbed after a time $t = 10\tau$ where τ is the time required for the absorption of 0.5 mole of oxygen per mole of ascorbic acid. If ascorbic acid reacts with oxygen forming dehydroascorbic acid and hydrogen peroxide according to equation 1



(1)

then theoretically one mole of oxygen will be absorbed per mole of ascorbic acid, provided the hydrogen peroxide neither reacts with ascorbic acid nor decomposes to oxygen and water. Either of the latter reactions might lower the total volume of oxygen absorbed to 0.5 mole, while a reaction of the peroxide with dehydroascorbic acid or its decomposition products would not affect this volume. The reaction of hydrogen peroxide with dehydroascorbic acid is very rapid in the

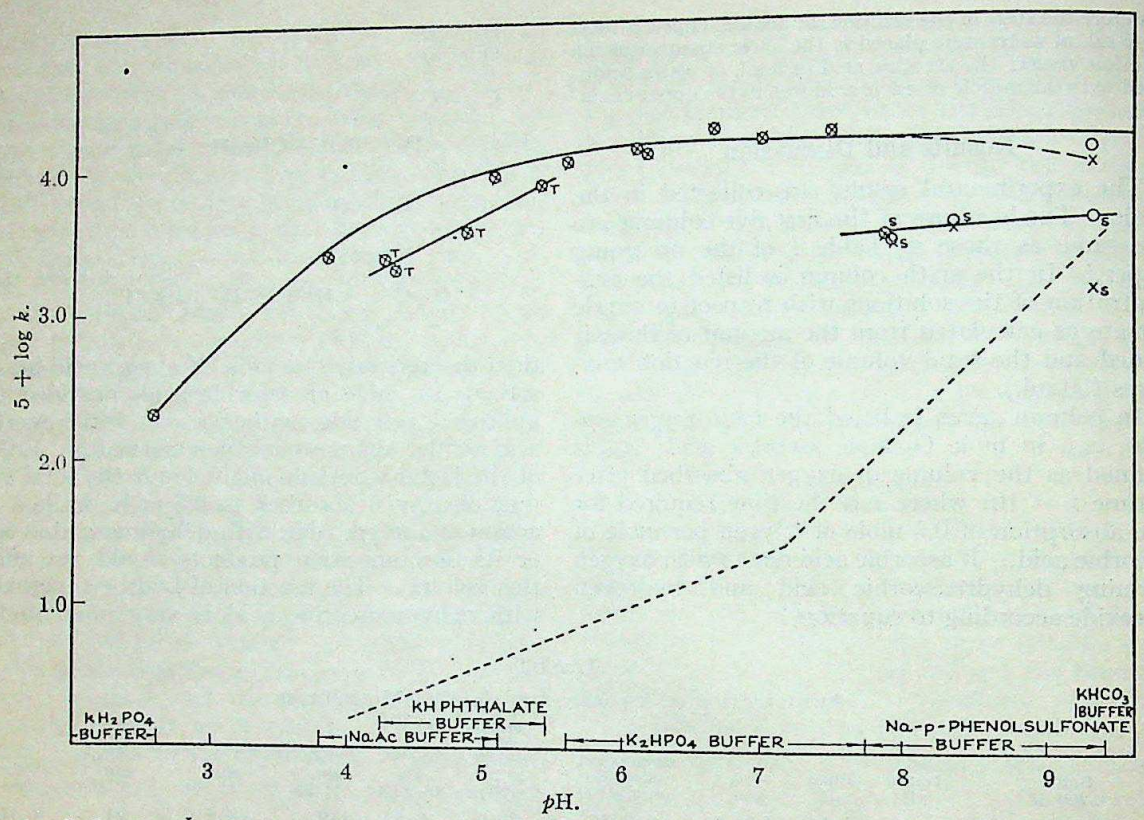

Fig. 1.—O, $5 + \log k^{I}$; ×, $5 + \log k_{Cu}$; . . . . . , $5 + \log k_1$; *T*, $C_6H_4(COO)_2HK$ buffer; *S*, $NaO_3SC_6H_4OH$ buffer.

alkaline range[3] in analogy to the common behavior of α-diketones.[2,4]

In the presence of copper the total uptake at *p*H 7.9 is close to the theoretical of eq. 1. At higher *p*H, a_{ob} is higher, 1.11 mole O_2 per mole of ascorbic acid at *p*H 9.3, presumably because decomposition products of dehydroascorbic acid absorb O_2.[1,5] At *p*H 7.8 to 6.2, the experiments were not observed sufficiently long to obtain a_{ob}. At *p*H 6.12 and down to *p*H 3.9, a_{ob} reaches only 80% of the theoretical value required by eq. 1, indicating that about 40% of the hydrogen peroxide decomposes to O_2 and H_2O, or 20% reacts with the ascorbic acid. Probably both reactions take place; the decomposition of hydrogen peroxide is catalyzed by cupric ion,[6] and the same catalysis has been suggested for the reaction of hydrogen peroxide with ascorbic acid.[7]

The plot of log $(a_{th}-x)$—where a_{th} is the theoretical volume of O_2 required by eq. 1 and x is the oxygen absorbed at the time t—against t is linear up to 80% of the theoretical uptake a_{th}, except for solutions of *p*H 5, which give straight lines for only 50% of the theoretical uptake.[8] This linearity justifies the calculation of a first-order reaction constant, k, by multiplication of the slope of the straight line with −2.303. The value of k corrected to an oxygen pressure of 760 mm. by multiplication with 760/(barometric pressure − P_{H_2O}) during the experiment is k^{I}. P_{H_2O}, the partial pressure of water at 20° is 17.5 mm.

The linearity of log $(a_{th} - x)$ *vs.* t shows in accordance with the literature,[9,1] that k is independent of the *concentration of ascorbic acid*. The dependence of the autoxidation rate on the *oxygen concentration* is reviewed in the introduction. The *dependence of log k^{I} on pH* of solutions to which is added 2×10^{-5} mole/liter of cupric nitrate, is shown in Fig. 1. The experimental points are marked by O. Those obtained in phosphate, acetate and carbonate buffer lie on a smooth curve. The rate in phthalate and *p*-phenolsulfonate buffer is lower than in phosphate, acetate and carbonate at the same *p*H.

The smooth log k^{I}/*p*H curve is discussed first. Barron, DeMeio and Klemperer[9a] as well as Schummer[9b] showed that ascorbic acid reacts

(8) One must wonder whether the experiments by Peterson and Walton, THIS JOURNAL, 65, 1212 (1943), justify the assumption of an autocatalytic reaction made by these authors. Their results might rather indicate a failure to keep the reaction mixture saturated with oxygen. This will depress the rate in the beginning of a reaction more than later on, because the volume of oxygen reacting per time unit is greatest at the start. For conditions of saturation with oxygen, see Weissberger, Mainz and Strasser, *Ber.*, 62, 1942 (1929); Weissberger and Thomas, THIS JOURNAL, 64, 1561 (1942).

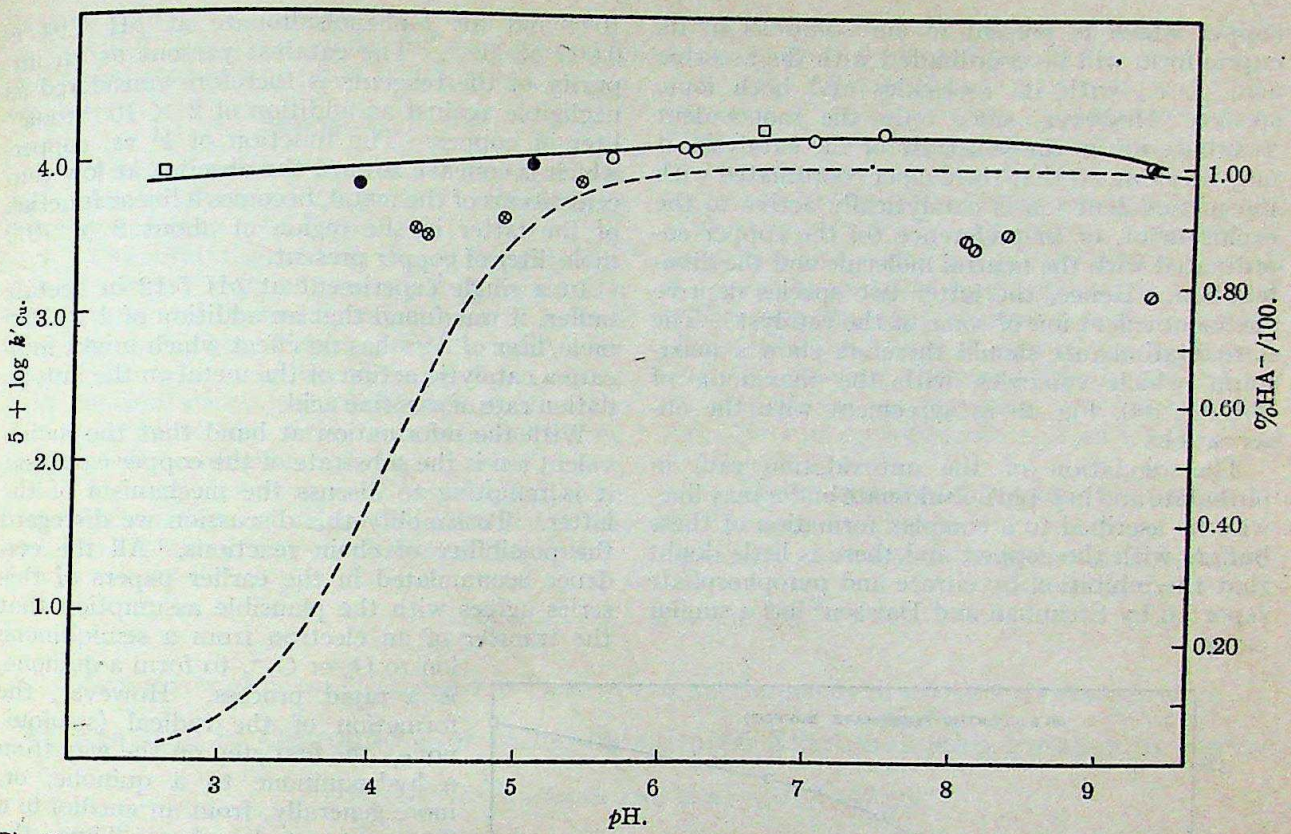

Fig. 2.— ———, $5 + \log k'_{Cu}$; — — — —, %HA⁻/100; ○, K_2HPO_4 buffer; □, KH_2PO_4 buffer; ●, $NaC_2H_3O_2$ buffer; ◑, $KHCO_3$ buffer; ⊕, $NaO_3SC_6H_4OH$ buffer; ⊗, $C_6H_4(COO)_2HK$ buffer.

with oxygen even under conditions which exclude the catalytic action of metals. The rate of this reaction as determined in the preceding paper of this series,[1] is given under k_1 in the table and log k_1 is represented by the dotted line in Fig. 1. If we assume that in the presence of copper the non metal-catalyzed reaction proceeds simultaneously with the copper-catalyzed, the rate of the copper-catalyzed reaction, $k_{Cu} = k^I - k_1$. At *p*H 2.59 to 7.73, k_1 is negligible in comparison with k^I, but at higher *p*H, log k_{Cu} differs appreciably from log k^I, as shown by Fig. 1, where x denotes log k_{Cu}.

In order to investigate whether copper catalyzes only the autoxidation of the monovalent ion or also that of the un-ionized acid and the divalent ion, we divide k_{Cu} by %HA⁻/100, *i. e.*, by the fraction of the monovalent ion,[1] at the respective *p*H, to obtain k'_{Cu}. The fraction %HA⁻/100 plotted against *p*H gives the dotted curve in Fig. 2, while log k'_{Cu} is represented by O and the solid line. The points corresponding to the smooth curve in Fig. 1 are approximately on a parallel to the abscissa. Such a parallelism should be expected if the *copper affects only the autoxidation of the monovalent ion of ascorbic acid and does not accelerate noticeably the autoxidation of the divalent ion or of the un-ionized acid.* According to these observations, the reactivity of the monovalent ion in the presence of 2×10^{-5} mole/liter of copper, k'_{Cu}, in the *p*H range 2.6 to 9.3 is 0.12 ± 0.03 min.$^{-1}$. It is 10^4 times greater than the reactivity of the monovalent ion in the absence of metal catalysis, k'.[1]

However, it must be noticed that the solid line in Fig. 2, which is drawn through the points corresponding to the smooth curve in Fig. 1, is not strictly straight and parallel to the abscissa, but provides for a flat maximum around *p*H 8. Although no measurements were made between *p*H 7.5 and 9.3 for lack of a suitable buffer, and although the rate at *p*H 9.3 is close to the limit of capacity of our apparatus,[8] this rate was ascertained by repeated measurements, and we believe that the maximum is real. It is readily explained as follows. The added copper, 2×10^{-5} molar, cannot be assumed to be present as atoms or free ions. No measurable solubility of copper atom could be found recorded in the literature. For cupric ion, according to Latimer's data,[10] the concentration of the saturated solution sinks below 2×10^{-5} at *p*H 6.5, and for cuprous ion the drop should occur around *p*H 4, caused in both cases by the precipitation of the respective hydroxides. Saturation phenomena were observed at neither of these *p*H values. On the other hand, cupric ion readily forms complexes with organic hydroxy compounds,[11] and

copper which is present in our solutions in its cupric form will be coördinated with the ascorbic acid, *i. e.*, with its molecules and both ionic species. However, since only the monovalent ascorbate ion is the substrate of the catalysis, it may be assumed that the copper coördinated with the monovalent ion is catalytically active to the exclusion of, or in preference to, the copper coördinated with the neutral molecule and the divalent ion. Hence, the latter two species deprive the monovalent ion of some of the catalyst. The autoxidation rate should therefore show a maximum which coincides with the maximum of $\%HA^-/100$, Fig. 2, in agreement with the observations.

The deviation of the autoxidation rate in phthalate and in *p*-phenolsulfonate buffer may likewise be ascribed to a complex formation of these buffers with the copper, and there is little doubt that the inhibition by citrate and pyrophosphate reported by Steinman and Dawson[3] has a similar cause.

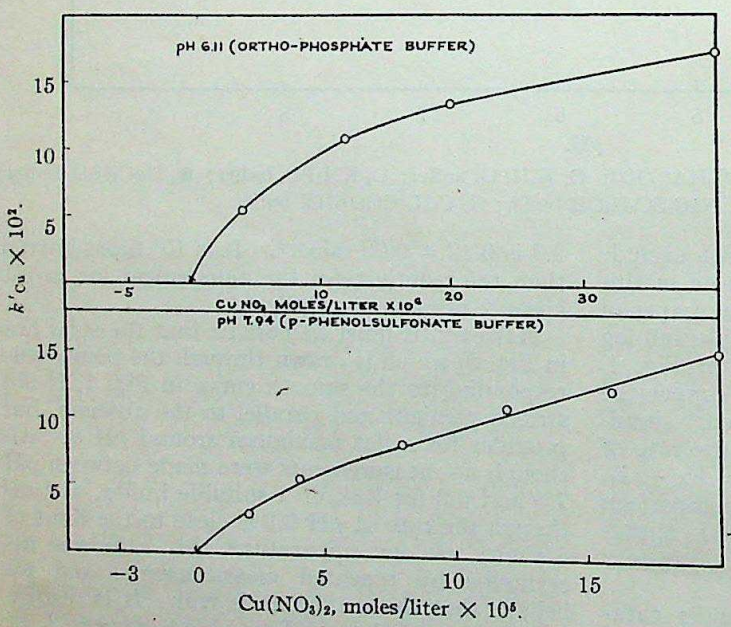

Fig. 3.

There remains to be discussed some scant experiments on the *dependence of k on the copper concentration*. In Fig. 3, k^I is plotted against the amount of copper added at *p*H 6.11 in phosphate and at *p*H 7.94 in *p*-phenolsulfonate buffer. The reaction rates at the same *p*H in the presence of cyanide and thiocyanate are used as the origin of the coördinates, and the reaction rates in the buffers, without addition of either cyanide and thiocyanate or copper, are marked by *X*. If one draws a smooth curve through all the points and the origin for a given *p*H, one can interpolate the amount of copper which would cause k^I to be raised from the origin to the value marked by *X*. This for phosphate at *p*H 6.11 is 0.03 × 10^{-5} and for *p*-phenolsulfonate at *p*H 7.94 is 0.005 × 10^{-5}. The catalyst present as an impurity of the reagents is therefore considered as negligible against an addition of 2 × 10^{-5} mole/liter of copper. The function of k^I *vs.* copper, which is concave toward the abscissa at low concentrations of the metal, becomes a linear function of the latter in the region of about 2 × 10^{-5} mole/liter of copper present.

In a single experiment at *p*H 5.12 in acetate buffer, it was found that an addition of 2 × 10^{-5} mole/liter of Ag^+ has no effect which might indicate a catalytic action of the metal on the autoxidation rate of ascorbic acid.

With the information at hand that the monovalent ion is the substrate of the copper catalysis, it is tempting to discuss the mechanism of the latter. To simplify this discussion we disregard the possibility of chain reactions. All the evidence accumulated in the earlier papers of this series agrees with the plausible assumption that the transfer of an electron from a semiquinone ion to O_2 or O_2^-, to form a quinone, is a rapid process. However, the formation of the radical (semiquinone), the first step on the way from a hydroquinone to a quinone, or, more generally, from an enediol to a diketone, can be slow. Thus, the dependence of k'_1 on O_2 indicated that in the autoxidation of the monovalent ascorbate ion in the absence of metals "the formation of an intermediate of semiquinone-like structure" is the rate-determining step.[1] Hence, it is a sufficient reason for the catalytic action of copper in the autoxidation of ascorbic acid, if the metal accelerates the reaction $HA^- \rightarrow A^- + H$.[12] This, as it is written, involving the elimination of hydrogen atom, is most improbable, while the sequence $HA^- \rightarrow HA + e$, $HA \rightleftharpoons H^+ + A^-$ presents a plausible process in which copper ion may act as electron acceptor. Correspondingly, the copper ion should undergo the change $Cu^{++} \rightarrow Cu^+$, or $Cu^+ \rightarrow Cu$. The second alternative is unlikely because it would lead to plating out of copper. On the other hand, Cu^{++}, as mentioned above, will be coördinated with the ascorbic acid. Hence, the monovalent ascorbate ion may change to the semiquinone-like radical by an electron transfer within the complex of Cu^{++} with the monovalent ion, $[Cu^{++}, HA^-] \rightarrow Cu^+$, HA. No indication was found in the literature[11b] for complex formation of Cu^+ with organic hydroxy compounds. Although radicals may

(12) Using the symbol H_2A for ascorbic acid, and, accordingly, A for dehydroascorbic acid, the semiquinone is written as HA and the semiquinone ion as A^-. The latter two species, related to each other by a simple acid ionization, *i. e.*, a fast process, are equivalent kinetically.

behave differently, the unbracketed "complex" is probably unstable, while the liberated Cu^{+} ion is likely to undergo rapid oxidation to Cu^{++}.

Summary

1. The autoxidation rate of *l*-ascorbic acid in the presence of copper (2×10^{-5} mole/liter) is investigated from *p*H 2.59 to 9.31.

2. The results agree with the assumption that in the primary reaction, one mole of dehydroascorbic acid and of hydrogen peroxide is formed from one mole of ascorbic acid and oxygen.

3. The rate is independent of the ascorbic acid concentration, and, as shown in the preceding paper of the series, proportional to the oxygen concentration.

4. At very low copper concentrations, the rate increases faster than the concentration of the metal. At higher concentrations of the latter, the rate increase becomes proportional to the increase in the copper concentration.

5. The dependence of the rate on *p*H in the presence of copper has the appearance of being complex. However, analysis shows that neither the neutral acid nor the divalent ion, but *only the monovalent ion of l-ascorbic acid is the substrate of the copper catalysis*, and that the apparent irregularity in the dependence of the rate on *p*H is caused by complex formation of some of the buffers with the copper catalyst. A concentration of 2×10^{-5} mole/liter of copper, about 4 mg. of $Cu(NO_3)_2$ per liter, increases the reaction rate of the monovalent ascorbate ion by a factor of 10^4.

6. No corresponding effect of silver was found at *p*H 5.12.

7. The mechanism of the catalysis is discussed briefly.

The Reaction of Dibromides of Mono-substituted Ethylenes with Potassium Iodide

BY DAVID PRESSMAN AND WILLIAM G. YOUNG

Iodide ion reacts with the dibromide of an olefinic compound to yield the original unsaturated compound, bromide ion and triiodide ion according to equation 1.[1]

$$RCHBrCH_2Br + 3I^- \longrightarrow 2Br^- + I_3^- + RHC{=}CH_2 \quad (1)$$

The reaction proceeds first order with respect to the dibromide concentration and also with respect to the iodide ion concentration in 99% methanol solution and is practically independent of the triiodide ion concentration.

We have shown that in the reactions of dibromides of *cis* and *trans* olefins with potassium iodide the reaction is slower for the dibromide from the *cis* olefin[2] and that the olefin produced is in its original stereoform in the case of the 2-butene dibromides.[3] The reaction takes place presumably through the attack by an iodide ion to remove a positive bromine atom as iodine bromide while, simultaneously, the electron pair which is left unshared by this removal attacks the carbon face opposite the remaining bromine atom forming a double bond and liberating a negative bromide ion.[3]

Our purpose in this research was to determine the reactivity of various mono-substituted ethylene dibromides with iodide ion. The reactions were studied in 99% methanol at two or more temperatures.

Experimental

Rates of Reaction.—The rate constants were obtained graphically by the use of equation 2

$$\mathrm{d}\log_{10}\frac{1-3b\varphi/a}{1-\varphi}\Big/\mathrm{d}t = \frac{a-3b}{2.303}k_{obs.} \quad (2)$$

where a and b are the initial iodide and dibromide concentrations respectively, φ is the fraction of dibromide reacted and t is the time in hours. The following corrections were made as discussed previously[2]: (a) correction to standard temperature of 45.00, 60.00, 75.00, 80.00 or 85.00°, (b) correction for activity of solvent (methanol preparations I, II, III are the same as those used previously[2]), (c) correction for salt effect, and (d) correction for solvent expansion.[4]

Preparation of Materials

1-Pentene dibromide was prepared by mixing slowly at 0° bromine with the 1-pentene obtained from ethylmagnesium bromide and allyl bromide. The product was fractionated through a Weston column and the fraction boiling at 84.5–85.5° at 15 mm. was used.

Acrylic Acid Dibromide.—The Eastman Kodak Co. product melting at 59–61° was used.

Styrene dibromide was prepared from styrene and bromine in carbon disulfide. The solvent was evaporated and the product recrystallized from alcohol; m. p. 74.0–74.5°.

Allylbenzene dibromide was prepared by brominating, in carbon tetrachloride, allylbenzene obtained from allyl bromide and phenylmagnesium bromide. The product was fractionated and the fraction boiling at 126° at 2 mm. was used.

Allyl Alcohol Dibromide.—The Eastman Kodak Co. product was refractionated and the fraction boiling 113–114° at 13 mm. was used.

(4) Corrections of 3.0, 4.8, 6.8, 7.6 and 8.1% were made at temperatures 45, 60, 75, 80 and 90°, respectively; (see ref. 2) Landolt–Börnstein, "Tabellen," Verlag von Julius Springer, Berlin, 1923, Vol. I, p. 278.

[a] These data were reported by Dillon using methanol which gave rate constants 7% lower than those obtained with the synthetic product (I) used as a standard in this work. [b] Synthetic methanol II, rates 2% lower than in methanol I. [c] Synthetic methanol III, rates same as in methanol I. [d] The constants have been corrected for reactivity of solvent, solvent expansion and to the temperatures 45.00, 60.00, 75.00, 80.00 or 85.00°. [e] These calculations were made from data reported by Dillon. Correction has not been made for the potassium iodide effect. [f] This value was obtained from slope of the curve in Fig. 2.

Bromoethylene Dibromide.—The Eastman Kodak Co. product was refractionated and the fraction boiling at 86.0–87.0° at 18 mm. was used.

Experimental Results

The pertinent date for the compounds studied are in Table I. There are also listed the values of the heats of activation calculated by the Arrhenius equation

$$\Delta H^{\ddagger} = RT^2 \mathrm{d} \ln k_{obs.}/\mathrm{d}t \qquad (3)$$

In Table II are given the observed relative values of the heats of activation $\Delta H^{\ddagger} - \Delta H_0^{\ddagger}$ and the entropies of activation $\Delta S^{\ddagger} - \Delta S_0^{\ddagger}$ (equation 4).[5]

$$\Delta S^{\ddagger} - \Delta S_0^{\ddagger} = \frac{\partial}{\partial T}\left(RT \ln \frac{k}{k_0}\right) \qquad (4)$$

$\Delta H_0^{\ddagger}$ and $\Delta S_0^{\ddagger}$ are, respectively, the heat and entropy of activation of the reference compound, ethylene dibromide.

Allyl alcohol	CH_2OH	.1079	0.4	2.0
Acrylic acid	COOH	1.825	−6.3	−2.3

The observed effect of various substituents, R, on the reaction of $RCHBrCH_2Br$ with iodide ion is to increase the heat of activation in the order $COOH < C_6H_5 < H < C_6H_5CH_2 < C_3H_7 < Br < CH_2OH$, $CH_3 < C_2H_5$ and to increase the entropy of activation in the order: $COOH < C_6H_5 < Br < C_6H_5CH_2 < C_3H_7 < CH_3 < H < CH_2OH < C_2H_5$.

Discussion

The functions $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ are in general relatively independent of temperature and are more reliable standards of comparison of reactivity than is the rate constant, since a sequence of order of reactivity as determined by the rate constant at any one temperature may be different at some other temperature. Empirically this occurs in the case of acrylic acid dibromide and styrene dibromide.[6] The rate constant of acrylic acid dibromide is larger than that of styrene dibromide at 45° but smaller at 85°.

However, in the reaction of potassium iodide with unsymmetrical dibromide such as styrene dibromide, even the observed heats of activation and the observed entropies of activation are not reliable bases of comparison of reactivity since they would be expected to be functions of temperature, aside from their general variation with temperature due to changes in the vibrational and rotational energy states with temperature. This arises from the fact that either bromine atom in an olefin dibromide molecule may be attacked by iodide ion and in the case of an unsymmetrical dibromide the two bromine atoms would be attacked at different rates. The rate of liberation of iodine is thus given by the equation

$$\begin{aligned} d(I_3^-)/dt &= (k_1 + k_2)(\text{Dibromide})(I^-) \\ &= k_{obs.}\ (\text{Dibromide})(I^-) \end{aligned} \quad (5)$$

where k_1 and k_2 are the rate constants for the attack of the individual bromine atoms by iodide ion and $k_{obs.}$ is the observed rate constant which is equal to the sum of k_1 and k_2.

The observed heat of activation $\Delta H^{\ddagger}$ is given then by equation 6.

$$d \ln (k_1 + k_2)/dT = \Delta H^{\ddagger}/RT^2 \quad (6)$$

(6) Similar cases have been pointed out by T. L. Davis and R. Heggie, *J. Org. Chem.*, **2**, 470 (1937).

Substituting for k_1 and k_2, their values as given in equations 7 and 8[7]

$$k_1 = \frac{kT}{h} e^{\Delta S_1^{\ddagger}/R} e^{-\Delta H_1^{\ddagger}/RT} \quad (7)$$

$$k_2 = \frac{kT}{h} e^{\Delta S_2^{\ddagger}/R} e^{-\Delta H_2^{\ddagger}/RT} \quad (8)$$

equation 9 is obtained.

$$d \ln \frac{kT}{h}\left(e^{\Delta S_1^{\ddagger}/R} e^{-\Delta H_1^{\ddagger}/RT} + e^{\Delta S_2^{\ddagger}/R} e^{-\Delta H_2^{\ddagger}/RT}\right) dT = \Delta H^{\ddagger}/RT^2 \quad (9)$$

Carrying out the indicated differentiation and neglecting the small term, $1/T$, gives equation 10.

$$\Delta H^{\ddagger} = \frac{\Delta H_1^{\ddagger} e^{(\Delta S_1^{\ddagger} - \Delta S_2^{\ddagger})/R} e^{(\Delta H_2^{\ddagger} - \Delta H_1^{\ddagger})/RT} + \Delta H_2^{\ddagger}}{e^{(\Delta S_1^{\ddagger} - \Delta S_2^{\ddagger})/R} e^{(\Delta H_2^{\ddagger} - \Delta H_1^{\ddagger})/RT} + 1} \quad (10)$$

As the temperature increases the apparent value $\Delta H^{\ddagger}$ approaches the value $(\Delta H_1^{\ddagger} e^{(\Delta S_1^{\ddagger} - \Delta S_2^{\ddagger})/R} + \Delta H_2^{\ddagger})/(e^{(\Delta S_1^{\ddagger} - \Delta S_2^{\ddagger})/R} + 1)$. This reduces to the average $(\Delta H_1^{\ddagger} + \Delta H_2^{\ddagger})/2$ if the entropy of activation is the same for the two reactions, *i. e.*, $\Delta S_1^{\ddagger} = \Delta S_2^{\ddagger}$. As the temperature decreases, the apparent value of $\Delta H^{\ddagger}$ approaches the smaller of the two values $\Delta H_1^{\ddagger}$ or $\Delta H_2^{\ddagger}$. We have adopted the convention that $\Delta H_1^{\ddagger}$ is the smaller.[8]

A more useful equation for discussion is obtained by subtracting $\Delta H_1^{\ddagger}$ from both sides of equation 10 to give equation 11.

$$\Delta H^{\ddagger} - \Delta H_1^{\ddagger} = \frac{\Delta H_2^{\ddagger} - \Delta H_1^{\ddagger}}{e^{(\Delta S_1^{\ddagger} - \Delta S_2^{\ddagger})/R} e^{(\Delta H_2^{\ddagger} - \Delta H_1^{\ddagger})/RT} + 1} \quad (11)$$

This equation shows that the difference between the observed value $\Delta H^{\ddagger}$ and the heat of activation for the reaction of either of the bromine atoms is a function of the relative values $(\Delta H_2^{\ddagger} - \Delta H_1^{\ddagger})$ and $(\Delta S_2^{\ddagger} - \Delta S_1^{\ddagger})$ and of T and is independent of the absolute magnitude of $\Delta H^{\ddagger}$.

In Table III are given for several different assumed values of $\Delta H_2^{\ddagger} - \Delta H_1^{\ddagger}$ and of $\Delta S_2^{\ddagger} - \Delta S_1^{\ddagger}$, the values at 75° of (a) $\Delta H^{\ddagger} - \Delta H_1^{\ddagger}$; (b) the rate of change of $\Delta H^{\ddagger}$ with temperature[9]; and (c) the fraction of the total reaction which is due to the bromine atom with the lower heat of activation,[10] $k_1/(k_1 + k_2)$. The assumed values of

(7) H. Eyring, *J. Chem. Phys.*, **3**, 107 (1935).

(8) Similar to $\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$ is a function of T, $\Delta S_1^{\ddagger}$, $\Delta S_2^{\ddagger}$, $\Delta H_1^{\ddagger}$ and $\Delta H_2^{\ddagger}$.

(9) The rate of change of the observed heat of activation with temperature is given by equation 12.

$$\frac{d\,\Delta H^{\ddagger}}{dT} = \frac{(\Delta H_2^{\ddagger} - \Delta H_1^{\ddagger})^2 e^{(\Delta S_1^{\ddagger} - \Delta S_2^{\ddagger})/R} e^{(\Delta H_2^{\ddagger} - \Delta H_1^{\ddagger})/RT}}{RT^2(e^{(\Delta S_1^{\ddagger} - \Delta S_2^{\ddagger})/R} e^{(\Delta H_2^{\ddagger} - \Delta H_1^{\ddagger})/RT} + 1)^2} \quad (12)$$

(10) This fraction is given by equation 13.

$$\frac{k_1}{k_1 + k_2} = \frac{e^{(\Delta S_1^{\ddagger} - \Delta S_2^{\ddagger})/R} e^{(\Delta H_2^{\ddagger} - \Delta H_1^{\ddagger})/RT}}{1 = e^{(\Delta S_1^{\ddagger} - \Delta S_2^{\ddagger})/R} e^{(\Delta H_2^{\ddagger} - \Delta H_1^{\ddagger})/RT}} \quad (13)$$

$\Delta H_2^{\ddagger} - \Delta H_1^{\ddagger}$ and $\Delta S_2^{\ddagger} - \Delta S_1^{\ddagger}$ used are of the same magnitude as was observed in changing substituents in symmetrically substituted ethylene dibromides.

Figure 1 shows plots of the apparent heat of activation relative to the lower of the individual values, $\Delta H_1^{\ddagger}$, as a function of temperature as calculated from equation 11 for several different assumed values of $\Delta H_2^{\ddagger} - \Delta H_1^{\ddagger}$ and of $\Delta S_2^{\ddagger} - \Delta S_1^{\ddagger}$. The temperature region in which our experiments were carried out is marked by dotted lines.

The calculated values in Table III and the plots of Fig. 1 show that the observed value, $\Delta H^{\ddagger}$, may be quite different from either of the values $\Delta H_1^{\ddagger}$ and $\Delta H_2^{\ddagger}$ which must be known before any quantitative theoretical consideration can be given to a discussion of the effect of structure on the reaction.

The calculated values of the rate of change of $\Delta H^{\ddagger}$ with temperature indicate that such a change would probably not be observed within the accuracy of our experiments. Experimentally, the heats of activation of the reactions of styrene dibromide and of acrylic acid dibromide appear to be constant over a range of 40°, as is shown by the straight line character of the plots of the logarithms of the reaction rate constants against the reciprocals of the absolute temperatures (Fig. 2).

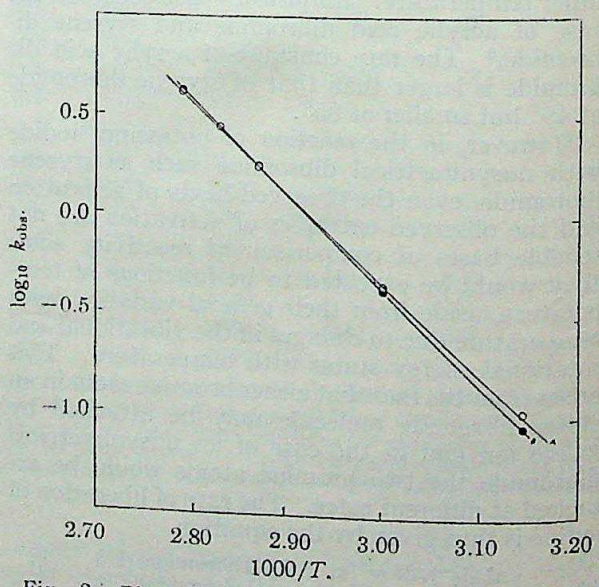

Fig. 2.—Plot of $\log_{10} k$ against reciprocal absolute temperature for acrylic acid dibromide ●, and for styrene dibromide ○.

The authors are indebted to Dr. C. D. Coryell for assistance in the calculation of the reaction rate constants.

Summary

The reaction rate constants and the heats and entropies of activation were determined for the

reaction in 99% methanol of potassium iodide with monosubstituted ethylene dibromides, $RCHBrCH_2Br$ where R was C_3H_7, C_6H_5, $C_6H_5CH_2$, CH_2OH, COOH and Br.

It is shown that, since each of the bromine atoms can react and at a different rate and with a different heat of activation, no theoretical significance can be given to the effect of various substituents, R, on the observed values of the heats of activation and entropies of activation of the reaction of $RCHBrCH_2Br$ with potassium iodide.

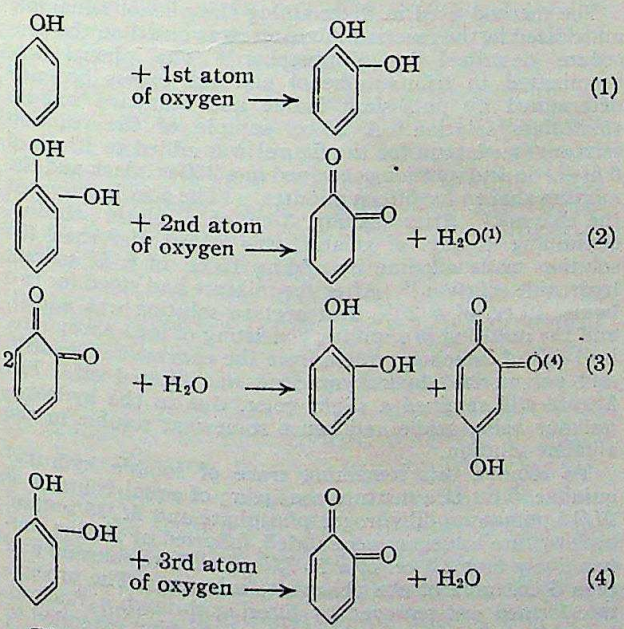
The Activity of Tyrosinase toward Phenol

BY RALPH C. BEHM AND J. M. NELSON

As shown by several investigators[1,2,3] the phenol oxidase, tyrosinase, possesses two essentially different enzymatic activities. It not only catalyzes the aerobic oxidation of many *o*-dihydric phenols to their corresponding *o*-quinones, but also catalyzes the introduction of a second hydroxyl group into several monohydric phenols, *ortho* to the hydroxyl group already present. These oxidation reactions are not simple, but involve several consecutive and concurrent reactions, especially when monohydric phenols constitute the substrate. Taking phenol and catechol as representing the two types of phenols, the final oxidation product in both instances is *p*-hydroxyquinone.[4] In the enzymatic oxidation of phenol at *p*H 6, 3 atoms of oxygen[5] are consumed per molecule of phenol oxidized.



The method usually used for estimating the activity of tyrosinase toward a monohydric phenol is based on determining the rate of oxygen uptake by means of a Warburg or Barcroft respirometer.[6] It is apparent, however, from what has been stated above, that only the first atom of oxygen is concerned with the enzyme's action on the monohydric phenol. The remaining two atoms of oxygen are consumed in the enzyme's action on the *o*-dihydric phenol. The question therefore arises: Can the rate of oxygen uptake serve as a true measure of the enzyme's activity toward a monohydric phenol?

To answer the latter question, it was decided to determine, instead of the rate of oxygen uptake, the rate of disappearance of the monohydric phenol from the reaction mixture. Such a method would be independent of all the accompanying reactions encountered in the oxygen uptake method. For the purpose a reaction mixture, consisting of the enzyme, phenol, buffer and water, was placed in a reaction vessel and air bubbled through the mixture. Samples were removed at regular time intervals and their phenol contents determined. The results obtained are shown as Curve I. Curve II represents the rate of oxygen uptake for a reaction mixture, identical in composition with the one used in following the rate of phenol disappearance. It will be observed that the two curves coincide within experimental error, showing that, at least when phenol is the monohydric phenol being oxidized by means of the enzyme, the concurrent reactions, equations (2), (3) and (4) must proceed at rates at least as great as the rate of the initial oxidation of the phenol (equation 1) and that, therefore, the rate of oxygen uptake can serve as a true measure of the enzyme's activity toward phenol.

Tyrosine preparations, depending on the method of preparation, often vary widely with respect to their relative activities toward monohydric and *o*-dihydric phenols. Therefore, it has become customary, in these Laboratories, to designate a preparation low in activity toward *p*-cresol compared to its activity toward catechol as a high catecholase preparation and a preparation high in *p*-cresolase activity as a high cresolase preparation.[7] Since in the present study phenol was used instead of *p*-cresol, it should be men-

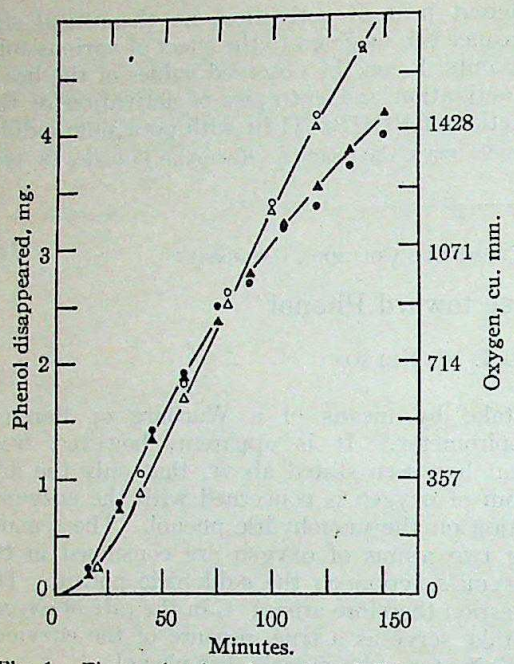

Fig. 1.—Figure showing the rates of disappearance of phenol and of oxygen uptake for the tyrosinase catalyzed aerobic oxidation of phenol at 25°. Warburg respirometer[8] was used in the oxygen uptake measurements. Curve II, triangles, shows the rate of oxygen uptake for a reaction mixture consisting of 2 cc. of $M/15$ phosphate buffer solution (*p*H 6.7), 1 cc. of phenol solution(20 mg.),[9] 1 cc. of gelatin solution (0.2 mg. of gelatin),[11] 1 cc. of a high catecholase preparation, containing 1.5 phenolase, 2.6 cresolase[6] and 32 catecholase units[12] (added at zero time from the side arm of the Warburg reaction flask) and sufficient water to make the final volume in the reaction vessel 8 cc. Curve I, circles, shows the rate of phenol disappearance from a reaction mixture similar to that for Curve II, except that 50 times the quantities of reactants were used. Curve IV, shaded triangles, shows the rate of oxygen uptake for a reaction mixture similar to that for Curve II, except 1 cc. of a high cresolase preparation, containing 1.5 phenolase, 1.3 cresolase, 17 catecholase units was used, and 1 cc. of water replaced the 1 cc. of gelatin solution. Curve III, shaded circles, shows the rate of disappearance of phenol from a reaction mixture similar to that used for the data represented by Curve IV, using, however, 50-fold quantities of the reactants. The reaction vessel used in determining the rate of disappearance of phenol consisted of a modified Reinder–Vles apparatus.[4] Briefly, the latter consisted of a 2-liter glass bottle provided with a rotating glass stirrer, so constructed that air was sucked into the reaction mixture. At suitable intervals 25-cc. samples were withdrawn and the phenol determined. Since both theoretically and experimentally, 1 mg. of phenol requires 357 c. mm. of oxygen for complete oxidation to the 3 atom stage, the data were plotted for purpose of comparison of the rates of phenol disappearance with the rate of oxygen uptake so that 357 c. mm. of oxygen uptake and 1 mg. loss of phenol had the same ordinate value in the graph. The tyrosinase preparations were obtained from the common mushroom, *Psalliota campestris*.

(8) Dixon, "Manometric Methods," Cambridge University Press, 1934.

(9) To obtain the maximum activity tyrosinase preparations, especially high cresolase, require optimum substrate concentrations.[10] The high catecholase preparation used for Curves I and II had an optimum phenol concentration of 2 mg. of phenol per 8 cc. of reaction mixture, while the high cresolase preparation (Curves III and IV) required about 20 mg. of phenol per 8 cc. Since the use of 20 mg. of phenol per 8 cc. of reaction mixture did not alter to any extent the activity of the high catecholase preparation, this concentration of substrate was used in all experiments.

(10) Gregg and Nelson, THIS JOURNAL, **62**, 2506 (1940).

(11) Gelatin was used to stabilize the tyrosinase preparation.[6]

tioned that in the case of tyrosinase preparations, in which most of the concomitant protein has been removed, the phenolase activity is not very different from the *p*-cresol activity. (For units of activity of the preparations used in the investigation, see the legend for the accompanying figure.) The preparation used in obtaining the results represented by Curves I and II was a high catecholase.

The monohydric phenol activity being dependent on the reaction represented by equation (1) and the *o*-dihydric phenol activity depending on the reactions corresponding to equations (2), (3), and (4), it was decided to compare also the method, based on the rate of phenol disappearance, with that based on the rate of oxygen uptake, when a high cresolase was used instead of a high catecholase preparation. The results obtained are represented by Curves III and IV. It will be observed that again the linear portions of Curves III and IV—the portions of the curves used for determining the units of activity—practically superimpose. Therefore, the method based on the rate of oxygen uptake also is applicable (for high cresolase as well as for high catecholase preparations) for determining the activity toward phenol.

Experimental

The method used in determining the phenol remaining unoxidized in the reaction mixtures, was based on the procedure described by Koppeschar.[13] The phenol was brominated to tribromophenol and the excess bromine determined by potassium iodide and standard sodium thiosulfate solution. A 25-cc. sample of the reaction mixture (see legend for the figure) was added to 10 cc. of 6 M acetic acid solution contained in a 250-cc. flask and the mixture shaken for fifteen minutes. (The acid inactivated the enzyme.) After shaking, 3 cc. of a gelatin solution, containing 15 mg. of gelatin, was added and then the solution made alkaline by adding 15 cc. of 6 M sodium hydroxide solution.[14] After the mixture had stood for two hours, 10 cc. of a 20% lead acetate solution was added, and the resulting precipitate, consisting of lead phosphate, lead salt of catechol, protein from the enzyme and gelatin, and polymerized hydroxyquinone was filtered off. The filtrate still retained a slight color, due to the hydroxyquinone being acidic and hence somewhat soluble in the alkaline solution.

To remove this remaining trace of soluble hydroxyquinone, 5 cc. of a mixture consisting of equal volumes of $M/15$ potassium dihydrogen phosphate and $M/15$ sodium biphosphate solutions were added, followed by adding consecutively first 2.5 cc. of a 20% lead acetate solution and then 5 cc. more of the phosphate mixture. The precipitate formed was removed by filtering through a Büchner funnel in such a way that the stem of the filter extended to the bottom of the suction flask, to which 20 cc. of 6 M sodium hydroxide solution had been previously added. The purpose of this mode of filtering was to prevent any

(13) Koppeschar, *Z. anal. Chem.*, **15**, 233 (1876).

(14) In the alkaline solution, any incomplete oxidation of partly oxidized phenol, such as catechol or *o*-quinone, was converted by autoxidation into the final difficultly soluble polymerized hydroxyquinone. The presence of the gelatin seemed to aid the coagulation, probably by precipitation, of this final oxidation product.

Digitized by Arya Samaj Foundation Chennai and eGangotri

possible loss of phenol vapor, which is appreciable under the reduced pressure. To minimize, in the subsequent bromination of the phenol, the loss of bromine and to prevent[15] the bromination of any catechol still present, the last-mentioned mixture was cooled to −3° by the addition of 500 g. of chopped ice (prepared from distilled water). To the cold mixture 12.2 cc. of 0.1 *M* potassium bromate solution and 10 cc. of 15% potassium bromide solution were added and the mixture allowed to stand for twenty minutes. After the bromination had taken place, 10 cc. of a 25% solution of potassium iodide was added and the mixture allowed to stand in a dark place for fifteen minutes, after which the liberated iodine was determined by means of 0.1 *M* sodium thiosulfate solution.

In determinations involving small amounts of phenol (30 to 35 mg.) in the presence of large amounts of the final oxidation product the procedure was modified by using 5 cc. instead of 3 of the gelatin solution and twice as much lead acetate solution.

(15) Francis and Hill, THIS JOURNAL, 46. 2498 (1924).

The results of analyses made on prepared mixtures of phenol and catechol oxidation products had an average deviation of ±0.7%. The quantities of phenol found to be present at any time in the experiments corresponding to Curves I and II in the figure were therefore reliable to ±0.7%.

Summary

1. A method has been devised for determining the activity of tyrosinase toward phenol by determining the rate of disappearance of phenol from the reaction mixture.

2. A comparison of the direct phenol method with the oxygen uptake method, which is usually used, shows that the latter method is reliable for estimating the monohydric phenol activity of tyrosinase toward phenol.

The Aerobic Oxidation of Phenol by Means of Tyrosinase

BY RALPH C. BEHM AND J. M. NELSON

When monohydric phenols, such as *p*-cresol,[1] phenol or *l*-tyrosine[2] are aerobically oxidized by means of tyrosinase, the reactions usually start with an initial lag. This induction period is overcome by the addition of a small amount of an *o*-dihydric phenol, such as catechol, to the reaction mixture.[1,2,3] Several explanations have been suggested as to how the *o*-dihydric phenol serves to decrease the induction period.[2,3,4] Since the enzyme also catalyzes the oxidation of *o*-dihydric phenols to their corresponding *o*-quinones, most of these explanations have been based on the view that the monohydric phenols are oxidized by the quinones. Bordner and Nelson,[1] however, have shown that the oxidation of the monohydric phenols to the *o*-dihydric state cannot be attributed to the quinones.

A theory for the oxidation of monohydric phenols by means of tyrosinase, which has several experimental facts in its favor, has been gradually taking shape in these laboratories. It is based on the idea that for tyrosinase to catalyze the oxidation of monohydric phenols, it must first be activated toward monohydric phenols, by simultaneously oxidizing an *o*-dihydric phenol.[1,5] This theory can be expressed briefly by reactions represented as shown beyond.

Some experimentally established facts, supporting the theory, are listed below and in the case of some of these a brief explanation has been added: (1) The fact that when phenol is enzymatically oxidized three atoms of oxygen are consumed per molecule of phenol oxidized is taken care of. (2) The addition of catechol decreasing the induction period and enabling the enzyme to catalyze the oxidation of phenol is accounted for by reactions (1) and (2). (3) Adding oxidizing agents, such as potassium ferricyanide, or the phenol oxidase, laccase, at the beginning of the reaction when phenol is oxidized by the enzyme lengthens the induction period.[1] These oxidizing agents would tend to deprive the enzyme of oxidizing catechol (reaction 2) and hence decrease the activation of the enzyme toward phenol. Less activation at the beginning of the reaction would slow down reaction (1) and lengthen the induction period. (4) Benzenesulfinic acid added initially to the reaction mixture when *p*-cresol or phenol is oxidized by the enzyme greatly lengthens the induction period.[1,6] Benzenesulfinic acid combines with *o*-quinone[1,6] and consequently would eliminate reaction (3). Elimination of reaction (3) would mean less catechol being formed and oxidized and hence less activation. Less activation, as pointed out in 3, would lengthen the induction period. (5) The length of the induction period has been found to decrease with increase in *p*H.[1] The *o*-quinone disappears faster as its aqueous solution becomes more alkaline.[7] The latter means the rate of reaction (3) increases with increase in *p*H and hence catechol is returned to the solution and oxidized faster. As a result the enzyme is activated faster, the rate of reaction (1) increased and the induction period shortened. (6) In the present study it has been found that the addition of a reducing agent such as ascorbic acid shortens the induction period. Since the

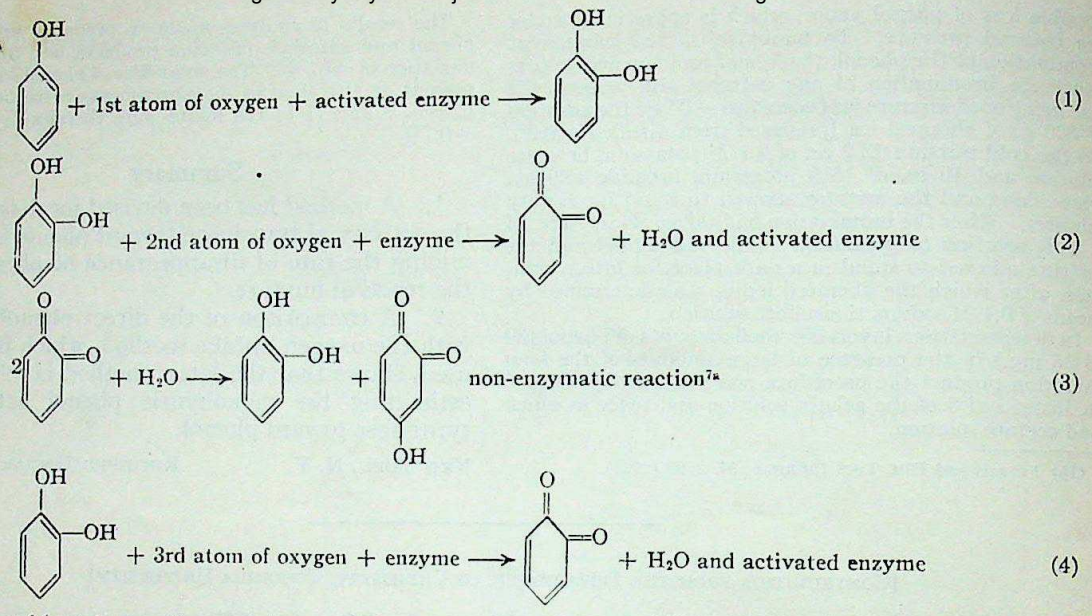
Digitized by Arya Samaj Foundation Chennai and eGangotri



ascorbic acid reduces the *o*-quinone formed in reaction (2), more catechol would be formed and oxidized. As a result the enzyme would be activated faster and increase the rate of reaction (1). In other words, the induction period would be shortened. (7) When 4,5-dimethylphenol (xylenol) is oxidized by means of tyrosinase the induction period is long.[8] Due to positions 4 and 5 being occupied, the 4,5-dimethylquinone cannot undergo reaction (3) and less of the catechol compound is returned to the reaction mixture than when phenol constituted the substrate. The oxidation of less *o*-dihydric phenol amounts to less activation, slower rate for reaction (1) and consequently a longer induction period. (8) The fact that no preparation of tyrosinase, free of *o*-dihydric phenol activity, has ever been prepared also can be taken as evidence supporting the above theory.

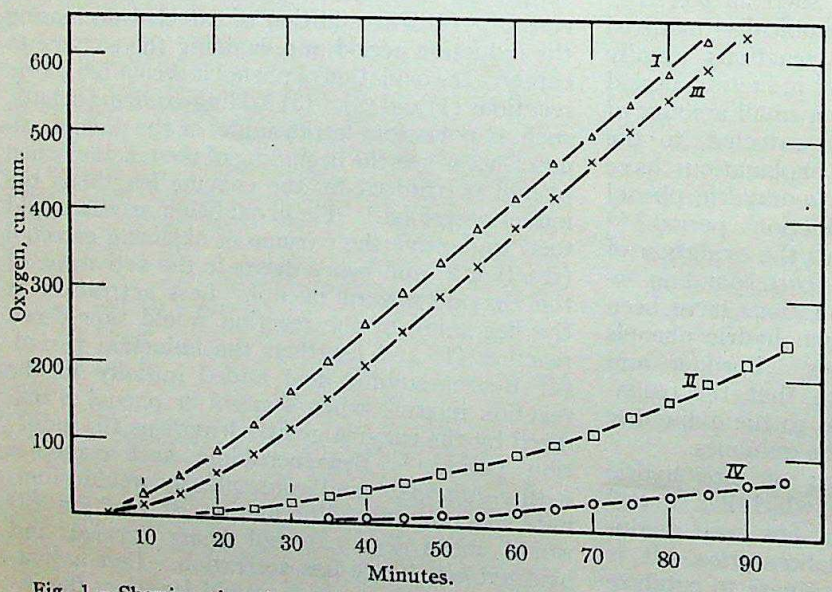


Fig. 1.—Showing that the oxidation of phenol by means of tyrosinase is more dependent on the oxidation of *o*-dihydric phenol than is the oxidation of *p*-cresol: Warburg respirometer; temperature 25°; *p*H 7.0. Reaction mixture for Curve I: 4 cc. of *M*/15 phosphate buffer, 1 cc. of gelatin solution (5 mg. of gelatin), 2 cc. of *p*-cresol (8 mg. *p*-cresol), and 1 cc. of mushroom tyrosinase containing 0.85 *p*-cresolase unit.[12] Reaction mixture Curve II: same as for Curve I, except 4 cc. of *M*/15 sodium borate buffer used in place of the phosphate buffer (final *p*H 7). Reaction mixtures for Curves III and IV, similar to those for Curves I and II, respectively, except 2 cc. of a phenol solution (8 mg. of phenol) was used in place of the *p*-cresol.

That the activation of tyrosinase toward monohydric phenols is transitory and requires the simultaneous oxidation of an *o*-dihydric phenol, *i. e.*, reaction (1) can only occur if at the same time reaction (2) is taking place, is indicated by the following experiment. A hundred times the amount of catechol necessary to prevent the induction period was first oxidized completely by the enzyme (catechol is oxidized very rapidly by tyrosinase[9]). Immediately afterward phenol was added. The enzymatic oxidation of the phenol, however, started

with a lag period showing that the activation caused by the previous oxidation of the catechol had disappeared.

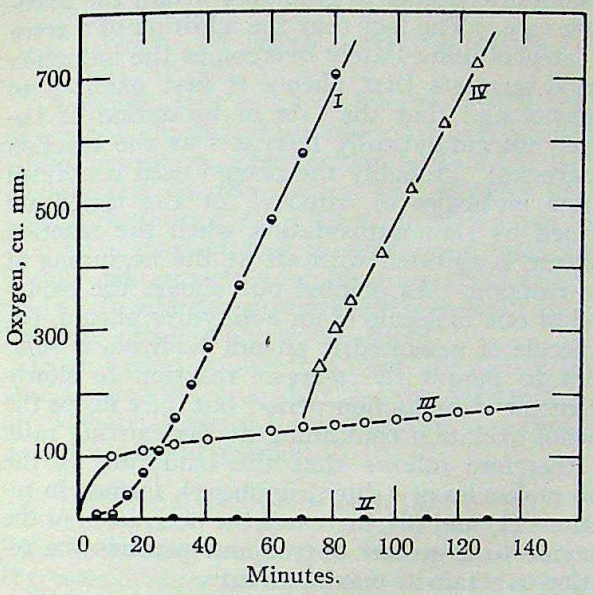

Fig. 2.—Showing that the oxidation of one molecule of catechol per molecule of phenol oxidized does not activate tyrosinase sufficiently to enable the reaction to overcome the induction period, nor to increase the existing rate of oxidation when an excess of phenol–enzyme complex is present in the reaction mixture. Warburg respirometer was used[10]; temp. 25°. Curve I represents the rate of oxygen uptake (rate of phenol disappearance from the reaction mixture[11]) when phenol was oxidized by means of tyrosinase. Reaction mixture for Curve I: 1 cc. of phenol solution (5 mg. of phenol), 2 cc. of *M*/15 phosphate buffer (*p*H 6.7), 1 cc. of gelatin solution (0.2 mg.),[11a] 1 cc. of a high catecholase preparation of mushroom tyrosinase containing 1.1 phenolase[12] and 22.8 catecholase[13] units[13a] and sufficient water to make the final reaction volume equal to 8 cc. Curve II shows that benzene sulfinic acid, initially present, prevents the enzymatic oxidation of the phenol. Reaction mixture for Curve II: same as for Curve I, except it also contained 3 mg. of sodium benzene sulfinate. Curve III shows that the addition of a small amount of catechol overcomes the inhibiting action of the benzenesulfinic acid. Reaction mixture for Curve III: same as for Curve II, except 0.2 mg. of catechol was added at zero time.[14a] The addition of 20 mg. of phenol to the reaction mixture corresponding to Curve III, after the reaction had been in progress for seventy minutes, failed to increase the rate of oxygen uptake. Although the concentration of the phenol–enzyme complex must have been increased considerably when the 20 mg. of phenol was added, the presence of the sulfinic acid, preventing reaction (3) from taking place, left only the one molecule of catechol, formed in reaction (1), to be oxidized per molecule of phenol oxidized. The oxidation of this one molecule of catechol was only able to activate the enzyme to such an extent that the existing rate of oxygen uptake could continue. As soon, however, as 0.2 mg. of catechol was added with the 20 mg. of phenol, after the reaction had been in progress for seventy minutes, enough catechol was oxidized, per molecule of phenol oxidized, to raise the rate of oxygen uptake to the maximum rate, Curve IV, determined by the enzyme operating at a phenol concentration equivalent to the optimum phenol concentration.

As already mentioned, the influence of benzenesulfinic acid, initially present, on the oxidation of phenol prevents the reaction from starting, but only lengthens the induction period when *p*-cresol is the substrate. This difference shown by the two monohydric phenols suggests that the enzyme requires more activation, *i. e.*, a greater rate of *o*-dihydric phenol oxidation (reaction (2)) in the case of the enzymatic oxidation of phenol than when *p*-cresol is being oxidized. That such is actually the case is indicated by the results shown in Fig. 1. The two monohydric phenols were oxidized by means of the enzyme in the presence and absence of boric acid. It will be noticed that the oxidation of the phenol was retarded more by the boric acid than that of the *p*-cresol. It is well known that boric acid tends to combine with *o*-dihydric phenols and therefore would tend to reduce the amount of *o*-dihydric phenol oxidized in reaction (2). If the phenol oxidation requires more activation of the enzyme than does the *p*-cresol oxidation, then it follows that the presence of the boric acid would affect the phenol oxidation the most.

The data in Fig. 2 show that the oxidation of one molecule of catechol (reaction (2)) per molecule of phenol oxidized only permits the enzymatic oxidation of phenol to proceed at the existing rate. When benzenesulfinic acid is present at the beginning of the reaction and the rate of the phenol oxidation is zero, the rate remains zero (Curve II). On the other hand, if the reaction is progressing in the presence of the sulfinic acid and the rate is not zero (Curve III) then the rate will continue at this rate, even though the concentration of the phenol–enzyme complex is increased by the addition of a large amount of phenol to the reaction mixture. The latter rate of oxygen uptake can only be increased by also adding a small amount of catechol (Curve IV). This constant rate of phenol oxidation, in the presence of benzene sulfinic acid, irrespective of the concentration of the phenol–enzyme complex, indicates that the one molecule of catechol formed in reaction (1) (reaction (2) being prevented from taking place by the sulfinic acid) does not give rise to sufficient activation to increase the existing rate of oxidation of the phenol. On the other hand (see Fig. 4, Bordner and Nelson[1]),

(13a) The enzyme preparation had an optimum phenol concentration of less than 5 mg. of phenol per 8 cc. reaction mixture.[14] The phenolase units were determined by the same method as used for cresolase units.

(14) Gregg and Nelson, THIS JOURNAL, **62**, 2506 (1940).

(14a) Besides removing the *o*-benzoquinone, as it is formed in reaction (2), the sulfinic acid also competes with the phenol for the enzyme, *i. e.*, it is a competitive inhibitor as shown in Fig. 3. Therefore, the rate of oxygen uptake shown by Curve III, after the induction period (zero rate) was overcome by the addition of the 0.2 mg. of catechol, is the maximum rate. The reason the maximum rate (Curve III) was much less than the maximum rate shown by Curve I was due to the sulfinic acid, as a competitive inhibitor, lowering the concentration of the phenol–enzyme complex.

when *p*-cresol is oxidized in the presence of sulfinic acid the oxidation of one molecule of homocatechol per molecule of *p*-cresol oxidized (Reaction (2)) causes enough activation of the enzyme to permit the rate of oxidation to gradually increase and overcome the induction period, although more slowly than when no sulfinic acid is present.

The question may arise: How can tyrosinase initiate the oxidation of a monohydric phenol, if it first has to be activated by catalyzing the oxidation of an *o*-dihydric phenol? The induction period shows that some product is formed autocatalytically which enables the oxidation of the monohydric phenol to gradually attain the maximum rate. The fact that the addition of a trace of catechol immediately overcomes the induction period suggests that phenol is first oxidized to catechol and that the rate of formation of the latter autocatalytically increases as the reaction progresses. Probably the phenol used contained a few molecules of catechol, or the latter are formed by slow autoxidation when the reaction mixture is agitated with air at the beginning of the reaction. As pointed out above, the oxidation of one molecule of an *o*-dihydric phenol, per molecule of monohydric phenol oxidized, is sufficient to permit the *p*-cresol reaction to slowly overcome its induction period but only keeps the phenol oxidation continuing at the existing rate. It therefore follows that the oxidation of the two molecules of *o*-dihydric phenol, formed in reactions (1) and (3), increases the activation of the enzyme to a greater degree and permits the reaction to attain its maximum rate.

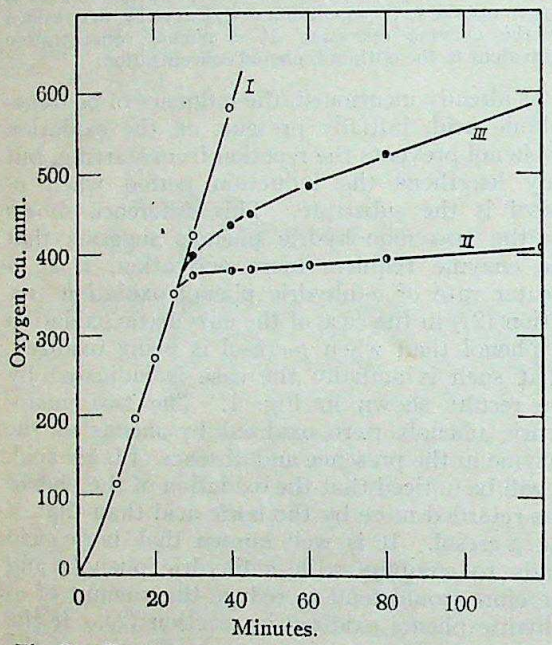

Fig. 3.—Showing that benzenesulfinic acid behaves as a competitive inhibitor toward phenol in the aerobic oxidation of phenol by means of tyrosinase. Curve I shows the rate of oxygen uptake for a reaction mixture consisting of 2 cc. of *M*/15 phosphate buffer *p*H 6.7, 1 cc. of phenol solution (20 mg.), 1 cc. of gelatin solution (0.2 mg.), 1 cc. of a high catecholase preparation containing 1.3 phenolase[12] units and 28.3 catecholase units,[13] and sufficient water to make the total volume in the reaction vessel 8 cc. The same curve was obtained if 1 cc. of phenol solution contained only 5 mg. of phenol. In each case the reaction had been in progress for ten minutes before the manometers of the Warburg respirometer were closed at "zero" time. Curve II shows the effect of addition of 35 mg. of sodium benzenesulfinate at time = 25 minutes to a reaction mixture similar to that for Curve I, using 5 mg. of phenol. Curve III shows the effect of addition of 35 mg. of sodium benzenesulfinate at time = 25 minutes to a reaction mixture similar to that for Curve I, using 20 mg. of phenol. The slope of the constant rate achieved after the addition of sulfinate in the experiment represented by Curve II (using 5 mg. of phenol) is 0.38 cu. mm. of oxygen uptake per minute; that of the experiment represented by Curve III (using 20 mg. of phenol) is 1.67 cu. mm. of oxygen uptake per minute. The change in slope, caused by the four-fold variation in phenol concentration in the presence of a constant amount of sodium benzenesulfinate, is 4.4. In view of the fact that experience in these laboratories has shown that benzenesulfinate has practically no effect on the rate of the enzymatic oxidation of catechol (the primary agent in this system) the retarding effect of the sulfinate on the phenol oxidation seems best explained on the basis that it displaces phenol from the enzyme; or in other words, benzenesulfinic acid behaves as a competitive inhibitor for phenol in the aerobic oxidation of phenol by means of tyrosinase.

Concerning the nature of the activation of tyrosinase toward monohydric phenols caused by the enzymatic oxidation of an *o*-dihydric phenol little is known. As shown by Bordner and Nelson, the oxidation of the monohydric phenols cannot be attributed to quinones or hydrogen peroxide formed in the oxidation of the *o*-dihydric phenols. That any other oxidation product of the *o*-dihydric phenols is responsible for the monohydric phenol also seems to be excluded as is indicated by the following experiment. Phenol was oxidized by means of the enzyme in the absence and presence of a relatively large amount of catechol and the rate of phenol disappearance from the reaction mixture followed in both instances by the method of Behm and Nelson.[11] The results indicated that the oxidation of the added catechol exerted practically no influence on the rate of disappearance of the phenol, except to eliminate the induction period.

Summary

Additional evidence is presented supporting the view that for tyrosinase to catalyze the oxidation of a monohydric phenol, the enzyme must catalyze simultaneously the oxidation of an *o*-dihydric phenol.

To overcome the induction period, when phenol is acted on by tyrosinase, it is necessary for the enzyme to catalyze simultaneously the oxidation of more than one molecule of catechol per molecule of phenol oxidized.

To increase the existing rate in the oxidation of phenol, when the latter is lower than the maximum, it is necessary to oxidize simultaneously more than one molecule of an *o*-dihydric phenol per molecule of phenol oxidized.

Analytical Procedures Employing Karl Fischer Reagent. X. The Determination of Aliphatic Hydroxy Amines (Amino Alcohols)[1]

BY DONALD MILTON SMITH, J. MITCHELL, JR., AND WALTER HAWKINS

The acidimetric methods for the determination of alcoholic hydroxyl usually are based on acetylation involving acetyl chloride[2,3] or on some modification of the Verley and Bölsing acetic anhydride procedure.[4] These methods are subject to a marked loss in sensitivity where the sample contains considerable amounts of water or acids. In addition primary and secondary amines interfere, often to a variable extent.

In an earlier publication from this Laboratory[5] an esterification procedure for the determination of alcoholic hydroxyl was described, depending upon the general reaction

$$ROH + CH_3COOH = CH_3COOR + H_2O$$

This technique, employing boron trifluoride as the esterification catalyst, has been extended to include hydroxyamines. As in the previous case the water liberated in the above reaction, which is equivalent to the hydroxyl esterified, is determined by direct titration with Karl Fischer reagent. Since the reaction of the amine group with the acid or boron trifluoride does not involve water, no interference is encountered.

The new procedure is applicable to aliphatic mono- and polyhydric hydroxyamines in general, including branched chain types and such aromatic hydroxyamines as have the hydroxyl group attached to an aliphatic side chain. The method is applicable also to the determination of hydroxyl in the presence of ammonia or amines. Aminophenols, however, do not react completely.

Experimental

Reagents.—The esterification reagent is prepared by dissolving about 200 g. of boron trifluoride gas[6] in sufficient Merck C. P. glacial acetic acid to make one liter of solution. Dry Baker C. P. or Eastman Kodak No. 214-H pyridine may be used without further purification. Karl Fischer reagent is prepared as indicated in an earlier publication.[7]

Analytical Procedure.—The sample, containing up to 0.1 equivalent of hydroxyl, is weighed into a 50-ml. glass-stoppered volumetric flask about one-third filled with glacial acetic acid. (It is usually safer to chill the flask containing the acetic acid before addition of the sample.) The solution is made up to volume with more acetic acid. Five ml. (using calibrated pipet) of the sample solution is transferred to a 250-ml. glass-stoppered volumetric flask[8] and 20 ml. of the esterification reagent added. The flask is stoppered tightly and together with a control containing 20 ml. of reagent and 5 ml. of acetic acid, is placed in a water-bath or oven at 70 ± 2° for two hours. At the end of this time the flasks are removed and allowed to cool to room temperature spontaneously. Ten ml. of dry pyridine is added to each and the mixture titrated with Karl Fischer reagent.

After correction for the water in acetic acid, esterification reagent and pyridine, the millimoles of water present after reaction less the water originally present, are equal to the milliequivalents of free hydroxyl in the sample.

The water originally present may be obtained by titrating 5 ml. of the original acetic acid solution with Fischer reagent. A correction for the water present in the acetic acid is obtained by titrating a 5-ml. portion and correcting to the volume of acid actually present in the sample solution.

Analytical Results

The experimental results obtained with twelve hydroxyamines are given in Table I. With the exception of the mono- and diethanolamines the trade products were used without further purification.

Aminophenols do not esterify completely under the conditions of the general procedure; *m*-aminophenol reacted only about 40%.

The precision and accuracy average about ±0.3%, comparing favorably with the earlier hydroxyl procedure.[5]

TABLE I

ANALYTICAL DATA FOR HYDROXYAMINES

Substance	Found, wt. % Hydroxyamine	H_2O	Total
Monoethanolamine (6)[a]	99.8 ± 0.1	0.1	99.9
Diethanolamine (4)	99.9 ± 0.1	.0	99.9
Triethanolamine[b] (4)	99.9 ± 0.1	.0	99.9
Diisopropanolamine (2)	100.1 ± 0.1	.7	100.8
Triisopropanolamine (2)	95.0 ± 0.4	.2	95.2
2-Amino-2-methyl-1-propanol[c] (4)	99.6 ± 0.2	.3	99.9
Hydroxyethyl ethylenediamine (2)	97.8 ± 0.3	.6	98.4
2-Amino-2-methyl-1,3-propanediol[c] (4)	99.5 ± 0.4	.0	99.5
2-Amino-2-ethyl-1,3-propanediol[c] (4)	89.9 ± 0.5	.4	90.3
2-Amino-1-butanol[c] (4)	96.5 ± 0.3	1.6	98.1
Tris-(hydroxymethyl)-aminomethane[c] (4)	99.2 ± 0.2	.0	99.2
Ethylphenylethanolamine (2)	96.7 ± 0.2	.4	97.1

mono- and diethanolamines, using various concentrations of boron trifluoride in acetic acid with ten milliequivalents of hydroxyl. Results obtained are shown in Table II.

TABLE II

EFFECT OF CONCENTRATION OF BF_3 ON ESTERIFICATION OF ETHANOLAMINE

	—% Reaction of —OH group—		
	50 g. BF_3/l.	100 g. BF_3/l.	200 g./l.
Monoethanolamine	38	96	99.8
Diethanolamine	79	96	99.9

It is interesting to note that in the experiment using 50 g. of boron trifluoride per liter the reaction of diethanolamine was considerably greater than the monoethanolamine.

Interfering Substances.—The new hydroxyl procedure is unfavorably affected by aldehydes and ketones, acetals and ketals as indicated in an earlier publication.[5]

Orthoesters react quantitatively. The reaction apparently is general, probably following the equation

$$RC(OR')(OR')(OR') + 2CH_3COOH \longrightarrow RCOOR' + 2CH_3COOR' + H_2O$$

Five Eastman Kodak Co. orthoesters were mixed with the 100 g. of catalyst and heated for two hours at 60° and at 67°. Analytical results are summarized in Table III.

TABLE III

ANALYTICAL DATA ON ORTHOESTERS

Substance	Found, wt. %
Ethyl orthoformate	97.6 ± 0.4
Methyl orthoacetate	99.4 ± 0.3
Methyl orthopropionate	97.4 ± 0.0
Methyl ortho-*n*-butyrate	97.1 ± 0.0
Methyl ortho-*n*-valerate	92.2 ± 0.3

Summary

1. A specific quantitative method for the determination of hydroxyamines has been described. The method is based on quantitative esterification and subsequent titration of the water liberated with Karl Fischer reagent.

2. The method is applicable to the determination of hydroxyl in the presence of ammonia or amines.

3. Analytical results are reported for twelve amino alcohols.

4. The method is quantitative for samples containing a large excess of water.

5. Orthoesters react quantitatively with the acetic acid in the esterification reagent.

The Reaction between Cyclic β-Diketones and Grignard Reagents. II. 8,8-Dimethylperinaphthindandione-7,9[1]

BY T. A. GEISSMAN AND LESTER MORRIS

The reaction between cyclic β-diketones and Grignard reagents has been studied in a few cases only, and in none of these cases has the cleavage of the diketone been observed, normal addition of the reagent to the carbonyl groups having occurred.[2] This behavior is in marked contrast to that of many open-chain diketones, which are cleaved by the action of Grignard reagents according to the partial equation

$$-CO-C(R)(R)-CO- + R'MgX \longrightarrow -COR' + \left(-COC(R)(R)\right)MgX$$

When the ketone represented by —COR′ is capable of further reaction with the reagent a tertiary alcohol is the final product.

In the present work the study has been extended to include a diketone in which the diketonic function is a part of a six-membered ring: 8,8-dimethylperinaphthindandione-7,9 (I). The reaction of this compound with phenylmagnesium bromide has been carried out under a variety of conditions and three products have been isolated and characterized. None of these is the expected cleavage product.

8,8-Dimethylperinaphthindandione-7,9 was prepared by the methylation (in two steps) of perinaphthindandione-7,9.[3] It has been described by Freund and Fleischer,[4] who prepared it by the condensation of naphthalene with dimethylmalonyl chloride under the influence of aluminum chloride, followed by manual separation of the crystals of the three possible isomers, all of which were produced. An unsuccessful attempt was made in the present work to prepare the monomethyl derivative by the condensation of ethyl propionate with methyl 1,8-naphthalate; although the expected product was formed the yield was very low.

By a suitable control of the experimental con-

ditions the reaction between the diketone (I) and phenylmagnesium bromide can be made to yield as the predominant product any of three substances. These are the normal monoaddition compound (II), the normal diaddition compound (III) and a compound which is formed by normal addition to one of the carbonyl groups followed by 1,4-addition (into the naphthalene ring) to the other (IV).

The monoaddition product (II) was formed when one mole of phenylmagnesium bromide was added at 0° to the diketone. The compound was converted into a methyl ether (V) and a monochloro compound (VI) when it was treated with hydrogen chloride in methanol and benzene, respectively.

The action of excess phenylmagnesium bromide upon the diketone at 25° led to the formation of the normal diaddition product (III). An attempt to convert this compound into the dimethyl ether by treating it with hydrogen chloride in methanol resulted in the formation of a substance to which has been assigned the structure of the endoxo compound VII, formed by transannular dehydration of the diol. The oxide (VII) liberated no gas and consumed no reagent when treated with methylmagnesium iodide in the "Grignard machine."

When an excess of phenylmagnesium bromide was added to the diketone at the temperature of boiling benzene, the principal product was a substance (IV) different from I and II. It formed a monomethyl ether (VIII) in acidic methanol, showed one active hydrogen and one carbonyl group in the "Grignard machine" and formed a monochloro compound (IX) when treated with anhydrous hydrogen chloride in benzene. These observations definitely exclude the possibility that it is the isomeric diaddition product corresponding to III, of which a *cis* and a *trans* form can exist. It was at first assumed, on the basis of carbon–hydrogen analyses, that IV was isomeric with III. Since IV is not the cleavage product (which has been synthesized independently[5]) and is not a glycol, the only reasonable assumption was that it was the product of 1,2- and 1,4-addition to the carbonyl groups. The product formed in such a way, however, would be a dihydronaphthalene derivative and would be expected to show considerable reactivity toward oxidizing agents and bromine. The compound (IV) is quite resistant to attack by such reagents and thus it appears that it has lost the two hydrogen atoms which would be present in the direct product of a 1,4-addition into the naphthalene nucleus. Such an aromatization, occurring either during the course of the initial reaction or in the isolation process, has been observed in analogous cases.[6]

The compound which would be expected if cleavage of the diketone had occurred (X) has been synthesized by an independent method.[5] It is not identical with any of the products obtained by the action of phenylmagnesium bromide on I.

8,8-Dimethylperinaphthindandione-7,9 is one more example of a cyclic β-diketone which does not undergo cleavage upon reaction with a Grignard reagent. Except for the reaction leading to the product IV its behavior parallels that of 2,2-dimethyl-1,3-diketohydrindene.[2] No observation made in the present work offers a basis for modifying or extending the discussion of the reaction of cyclic β-diketones and Grignard reagents, presented in the previous paper of this series.[2] The present results serve to emphasize the influence of the spatial disposition of the β-diketone function upon the course of its reaction with a Grignard reagent.

Experimental

Dimethyl 1,8-Naphthalate.[7]—A solution of 116 g. of naphthalic anhydride (recrystallized from concentrated nitric acid) in 670 ml. of a solution of 224 g. of potassium hydroxide in two liters of absolute methanol was placed in a 3-necked flask fitted with two dropping funnels. Into one of the dropping funnels was placed the remainder of the alcoholic potassium hydroxide solution and into the other was placed 373 ml. of dimethyl sulfate. The two reagents were run in simultaneously in a 4:1 ratio, with stirring and cooling of the flask contents. After all of the reagents had been added the potassium methyl sulfate was removed by filtration and the filtrate cooled in ice–salt. The product was collected and the filtrate diluted with water to precipitate the remainder. The second crop was recrystallized from methanol and combined with the first crop. The yield was 143 g. (89%), m. p. 102° (reported,[7] 25% yield, m. p. 102–103°).

The condensation of ethyl propionate with methyl 1,8-naphthalate in the presence of sodium resulted in the formation of a very small amount of 8-methylperinaphthindandione-7,9.

Perinaphthindandione-7,9.[3]—A mixture of 100 g. each of pulverized naphthalic anhydride, 100 g. of freshly fused zinc chloride and 200 g. of ethyl malonate was heated at 170–175° for four hours, with occasional stirring to break up a hard crust which formed around the edges of the mass. The mixture became yellow, then brown, and largely liquefied as the reaction progressed. The mixture was cooled and stirred with 500 ml. of 0.1 *N* hydrochloric acid, ground in a mortar with a fresh portion of acid and then shaken with two further portions. The resulting brown, granular material was stirred with 600 ml. of 4 *N* sodium hydroxide and the mixture filtered. The deep red filtrate was acidified, the bright yellow precipitate collected, redissolved in alkali and reprecipitated. Crystallization of the product from glacial acetic acid yielded 65 g. of brownish-yellow granular crystals, m. p. 247°, dec. Reported,[3] turns brown at 250°, melts toward 265°.

8-Methylperinaphthindandione-7,9.—To a solution of 2.5 g. of sodium in 150 ml. of absolute alcohol was added 14 g. of perinaphthindandione-7,9 and 14 ml. of methyl iodide. A heavy-walled bottle equipped with a pressure-tight closure was used. The bottle was heated before sealing and sealed when vapors of the contents began to escape. It was then heated at 100° for four hours. After cooling, the contents of the bottle were filtered. The filtrate was concentrated on the water-bath, cooled, and to the resulting solution eight volumes of 4 *N* sodium hydroxide were added. The undissolved solid (a mixture of O-methyl ether and dimethylated products) was removed and the filtrate acidified. The yellow precipitate was redissolved in alkali, reprecipitated, and recrystallized from ethanol. The yield of orange-yellow product, m. p. 183–185°, was 60%.

Anal. Calcd. for $C_{14}H_{10}O_2$: C, 80.0; H, 4.8. Found: C, 79.8; H, 4.8.

8,8-Dimethylperinaphthindandione-7,9 (I).—In a 500-ml., three-necked flask fitted with a reflux condenser, stirrer and dropping funnel were placed 30 ml. of anhydrous acetone, 8 ml. of methyl iodide and 12 g. of the monomethyl compound. A solution of 1.3 g. of sodium in the minimum quantity of absolute methanol was added over a period of three hours under reflux and with constant stirring. The final mixture was concentrated on the water-bath until most of the solvents had been removed and to the residue was added dilute sodium hydroxide solution. A crystalline material separated. This was removed and recrystallized from ligroin (b. p. 95–100°), affording long, light yellow needles of the dimethyl compound mixed with a small amount of tiny rosets of the O-methyl ether. The latter could be separated easily by shaking the dried crystals on a piece of wire gauze, the coarse needles of the desired product being retained and the fine needles of the impurity passing through. The yield of final material, m. p. 99–101°, was 30–40% (m. p. reported[4] 100–101°).

(7) Graebe, *Ann.*, **340**, 247 (1905).

2,4-Dinitrophenylhydrazone of I.—A solution of the diketone and 2,4-dinitrophenylhydrazine in alcohol, containing a few drops of hydrochloric acid, was boiled for twenty minutes. On cooling a dark purple material separated. Recrystallization of this crude product from ethyl acetate–petroleum ether afforded brown-red crystals, m. p. 208–210°.

Anal. Calcd. for $C_{21}H_{16}O_5N_2$: C, 62.4; H, 4.0. Found: C, 62.3; H, 4.0.

The Reaction of the Diketone (I) with Phenylmagnesium Bromide. One Mole of C_6H_5MgBr at 0°: 7-Phenyl-7-hydroxy-8,8-dimethylperinaphthindanone-9 (II).—To a solution of 3.3 g. of the diketone (I) in a mixture of 50 ml. of benzene and 10 ml. of ether, cooled in an ice-bath, was slowly added exactly one equivalent of an ether solution of phenylmagnesium bromide. A deep purple complex separated. After two hours the mixture was hydrolyzed with iced ammonium chloride solution and subjected to steam distillation. The involatile residue was recrystallized from alcohol, yielding 1.3 g. of II and, from the mother liquors, 1.5 g. of unchanged I. In later runs it was found that extending the time of the reaction to six to eight hours gave better yields of II. The product formed colorless prisms, m. p. 190°.

Anal. Calcd. for $C_{21}H_{18}O_2$: C, 83.4; H, 6.0. Found: C, 83.2; H, 5.8.

The compound gave a cherry-red solution in concentrated sulfuric acid. Attempts to prepare a dinitrophenylhydrazone were not successful.

7-Phenyl-7-methoxy-8,8-dimethylperinaphthindanone-9 (V).—The conversion of II into its methyl ether was readily brought about by adding a drop of concd. hydrochloric acid to its solution in boiling methanol and allowing the solution to cool. The ether separated in iridescent needles, m. p. 214–216°.

Anal. Calcd. for $C_{22}H_{20}O_2$: OCH_3, 9.8. Found: OCH_3, 9.8.

7-Phenyl-7-chloro-8,8-dimethylperinaphthindanone-9 (VI).—Anhydrous hydrogen chloride was passed through a solution of 0.1 g. of II in 6 ml. of dry benzene for three hours. Evaporation of the solvent left a clear glass. This was dissolved in a little benzene and the solution allowed to evaporate slowly; large, cubical crystals were deposited. The compound melted at 156°, dec.

Anal. Calcd. for $C_{21}H_{17}OCl$: Cl, 11.1. Found: Cl, 10.9.

Excess C_6H_5MgBr at Room Temperature: 7,9-Diphenyl-7,9-dihydroxy-8,8-dimethylperinaphthindane (III).—To a solution of 3.2 g. of the diketone (I) in 100 ml. of benzene, cooled in an ice-bath, was added an ether solution of three equivalents of phenylmagnesium bromide. The purple complex which formed persisted after three hours, so the mixture was allowed to come to room temperature. The purple color disappeared and a clear red-violet solution resulted. After four hours the solution was decomposed with iced ammonium chloride and the mixture steam distilled. The residue was recrystallized from ligroin, forming colorless prisms, m. p. 168°.

Anal. Calcd. for $C_{27}H_{24}O_2$: C, 85.2; H, 6.4; active H, 2. Found: C, 85.2; H, 6.2; active H (Grignard machine), 2.0.

The glycol gives a deep blue-violet color in concd. sulfuric acid, forming a dark, resinous mass.

7,9-Diphenyl-7,9-endoxo-8,8-dimethylperinaphthindane (VII).—A solution of the glycol (III) in methanol containing a trace of hydrochloric acid was boiled for a short time and cooled. Colorless crystals separated, m. p. 134°.

Anal. Calcd. for $C_{27}H_{22}O$: C, 89.5; H, 6.1. Found: C, 89.4; H, 5.9.

The compound liberated no gas in the Grignard machine.

Excess C_6H_5MgBr at 80°: 1,7-Diphenyl-7-hydroxyperinaphthindanone-9 (IV).—To a solution of 3.0 g. of the diketone (I) in 100 ml. of boiling benzene was slowly (two hours) added a solution of three equivalents of phenylmagnesium bromide in ether. A purple complex separated

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

at first but later disappeared with the formation of a clear, light red solution. The solution was cooled, decomposed with iced ammonium chloride and steam distilled. Recrystallization of the residue from alcohol yielded colorless needles, m. p. 238–239°. From the mother liquors was isolated a small amount of the glycol (III), identified by m. p. and conversion into VII.

Anal. Calcd. for $C_{27}H_{22}O_2$: C, 85.7; H, 5.9; active H, 1; carbonyl, 1. Found: C, 85.5; H, 6.1; active H, 0.96; carbonyl (addition), 1.05.

The compound gives a red-violet color in concd. sulfuric acid. It does not react with bromine in acetic acid or carbon tetrachloride nor with cold potassium permanganate solution in acetone. It is reduced by hydriodic acid (in boiling acetic acid) with the formation of a compound, m. p. 157°, which was obtained in small amounts only and was not further characterized.

1,7-Diphenyl-7-methoxy-8,8-dimethylperinaphthindanone-9 (VIII).—The ether was formed when a solution of IV in boiling methanol was treated with a trace of hydrochloric acid and allowed to cool. It formed colorless crystals, m. p. 224°.

Anal. Calcd. for $C_{28}H_{24}O_2$: C, 85.7; H, 6.2; OCH_3, 7.8. Found: C, 85.4; H, 6.3; OCH_3, 7.9.

1,7-Diphenyl-7-chloro-8,8-dimethylperinaphthindanone-9 (IX).—Anhydrous hydrogen chloride was passed into a solution of 0.2 g. of IV in warm, anhydrous benzene, containing a few granules of calcium chloride. Evaporation of the benzene left a colorless oil which crystallized slowly when dissolved in benzene–petroleum ether and allowed to stand. The chloro compound melted at 158–162°, dec.

Anal. Calcd. for $C_{27}H_{23}OCl$: C, 81.3; H, 5.8; Cl, 8.9. Found: C, 81.1; H, 5.7; Cl, 9.4.

Summary

A study has been made of the reaction between phenylmagnesium bromide and 8,8-dimethylperinaphthindandione-7,9. The diketonic function was not cleaved under any of the conditions used. Three products were obtained, two of which were the result of normal addition to either one or both of the carbonyl groups, the other being the result of 1,2-addition to one of the carbonyl groups and 1,4-addition to the other.

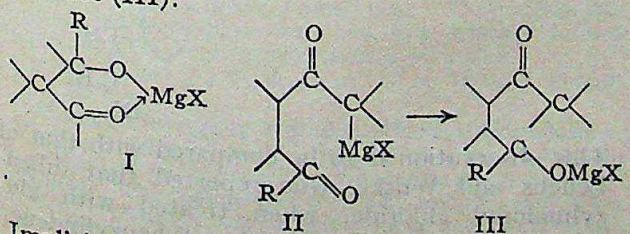
The Reaction between Cyclic β-Diketones and Grignard Reagents. III. 2-Methyl-2-benzoylhydrindone

BY T. A. GEISSMAN AND VSEVOLOD TULAGIN

It has been shown in a number of instances that β-diketones in which the two carbonyl groups are members of a four-,[1] five-,[2] or six-membered[3] ring undergo normal addition when treated with Grignard reagents. This behavior is in contrast to that of many open-chain β-diketones, which are readily cleaved by alkyl- and arylmagnesium halides.[4] Among the possible explanations for this difference in behavior are[2] (1) that for cleavage to occur it must be necessary for a coördination complex such as I to form after the first mole of reagent adds, and (2) that the cleavage product (II) which would be expected in the case of a cyclic β-diketone is incapable of existence because of its readiness, for steric reasons, to reform the monoaddition product (III).

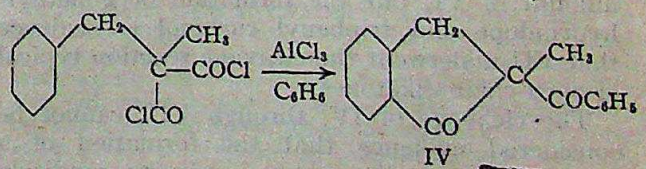


I II III

Implicit in the second explanation is the assumption that there is no bar to the initiation of cleavage, but only that it cannot proceed to such an extent as to allow a second mole of reagent to add to the resulting carbonyl group to yield an enolate–carbinolate. It is to be remarked that the conditions under which a β-diketone is allowed to react with a Grignard reagent will have an effect upon the nature of the reaction, and that a discussion of the presence or absence of cleavage in any case must take into account whether or not the reaction was carried out under conditions which would be expected to favor cleavage.

In the present paper are described the results of a study of the reaction between phenylmagnesium bromide and a β-diketone in which the carbonyl groups are disposed in such a way that chelation in the monoaddition product can occur, but in which the spatial arrangement of the groups is such that the sequence indicated by II→III could also occur.

2-Methyl-2-benzoylhydrindone (IV) was prepared by the treatment of methylbenzylmalonyl chloride with aluminum chloride in benzene solution. Simultaneous ring closure and condensation occurred smoothly to form IV in good yield.



IV

The structure of IV was proved by its cleavage with alkali to benzoic acid and 2-methylhydrindone, and by the nature of the products formed when it reacted with phenylmagnesium bromide.

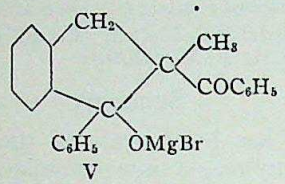
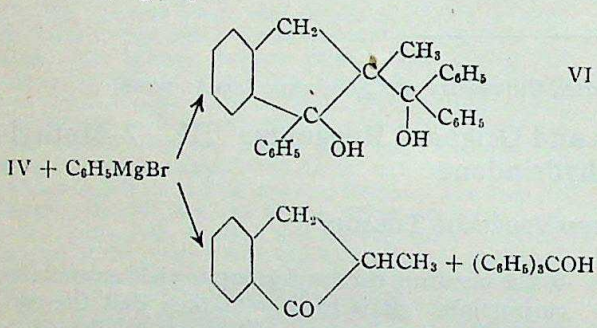
It was anticipated that the cyclic carbonyl group of IV would be the more reactive, and that the monoaddition compound V would arise as the first product of the reaction of IV with phenylmagnesium bromide.



V

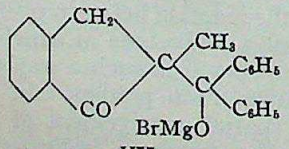
This compound (V) fulfils the conditions which should lead to cleavage if a chelated intermediate is a sufficient condition for cleavage. The reaction actually went in two ways, resulting in diaddition to form the glycol (VI), and cleavage into products which could only have arisen as the result of an initial attack of the reagent at the *benzoyl* group.



VI

The relative amounts of the products isolated indicated that about one-fifth of the total amount of reaction followed the route leading to cleavage, the remainder leading to VI.

The initial products formed by the attack of phenylmagnesium bromide on IV would be the monoaddition compounds V and VII



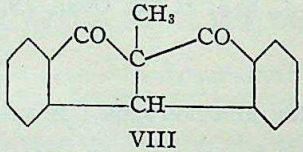
VII

It is clear from the products isolated that the subsequent reaction of V involved the addition of a second mole of the reagent to yield VI (after hydrolysis). The further reaction of VII may have led in part to the formation of an additional amount of VI, but the formation of 2-methylhydrindone and triphenyl carbinol is evidence that VII underwent the cleavage reaction typical of open-chain diketones.

The cleavage of IV, through VII, cannot be considered evidence that the formation of a chelated intermediate is a necessary condition for cleavage, since this case parallels that of a simple open-chain β-diketone. The lack of cleavage through the intermediate V does prove, however, that the formation, or possibility of formation, of a chelated intermediate is not a sufficient condition for cleavage. The question of the necessity for such an intermediate in the cleavage reaction must be examined in a different way, but it can be said that in no case so far examined in which such an intermediate cannot form has cleavage been observed.

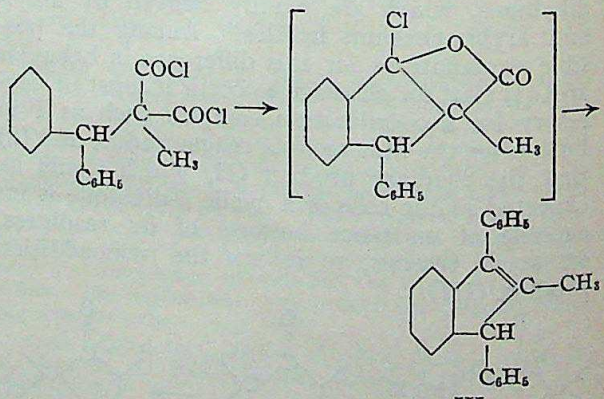
Preliminary to the preparation and study of IV attempts were made to prepare two other diketones in which the carbonyl groups are disposed in such a way that it appeared (from models) that a coördinated complex such as I could form, but in which the conditions for the reaction II→III were also present. These experiments were unsuccessful, but will be described briefly because of certain features of interest in the synthetic work done.

The preparation of the diketone VIII was attempted by the sequence: diethyl benzalmalo-



VIII

nate + phenylmagnesium bromide→diethyl benzhydrylmalonate[5]→diethyl methylbenzhydrylmalonate→methylbenzhydryl malonic acid→chloride, and ring-closure of this to yield VIII. The only product isolated in attempts to bring about this ring closure resulted when the reaction was carried out in benzene solution. It was a crystalline substance the analysis of which corresponded to the formula $C_{22}H_{18}$. This compound is assumed to have arisen as follows, and to have the structure IX



IX

This observation is to be compared with that of Leuchs and Wutke, who reported that dibenzylmalonyl chloride, when treated with aluminum chloride, yielded 1-chloro-2-benzylindene.[6] Thomas[7] has reported other, analogous cases.

The preparation of the diketone X was attempted in the following way: dibenzylacetic

X

acid→β,β-dibenzylpropionic acid (by the Arndt–Eistert reaction)→3-benzyltetralone→ethyl 3-benzyltetralone - 2 - glyoxylate → ethyl 3 - benzyltetralone - 2 - methyl - 2 - glyoxylate → ethyl 3 - benzyltetralone - 2 - methyl - 2 - carboxylate → acid, followed by ring closure to yield XI. Difficulties were encountered in attempts to hydrolyze ethyl 3-benzyltetralone-2-methyl-2-carboxylate to the corresponding acid, and the synthesis was finally abandoned in favor of studies on the diketone IV.

Experimental

Methylbenzylmalonic Acid.—Absolute alcohol was added in small portions to a suspension of 8 g. of powdered sodium in 50 ml. of boiling, dry benzene, until a clear solution was obtained. The solvents were removed at 100° and 22 mm., and to the dry sodium ethoxide was added a solution of 90 g. of ethylbenzylmalonate in 150 ml. of dry benzene. The mixture was treated with 70 g. of methyl iodide and allowed to stand overnight. After the addition of water, the benzene layer was separated and the benzene removed under reduced pressure. The residue was dissolved in a solution of 40 g. of sodium hydroxide in 60 ml. of water and 300 ml. of alcohol and the solution refluxed for twenty-four hours. The resulting suspension was dissolved in 1 liter of water, the alcohol removed by distillation, the aqueous solution decolorized and acidified. The oily acid was taken up in ether and after the removal of the ether, crystallized from benzene. The product weighed 60 g. (80%); m. p. 139.5–140° (literature[8] 135°).

2-Methyl-2-benzoylhydrindone (IV).—A suspension of 20 g. of methylbenzylmalonic acid in a mixture of 50 ml. of dry benzene, 50 g. of thionyl chloride and 3 drops of pyridine was allowed to stand, with occasional agitation, until all of the solid had dissolved. The solution was evaporated and to the residual oil was added 12 g. of phosphorus pentachloride and a few ml. of benzene. After thirty minutes the volatile material was removed at 22 mm. and 100°, the residue taken up in 50 ml. of dry benzene, and 40 g. of aluminum chloride added in small portions. Hydrogen chloride was evolved and the solution changed through red to a deep violet. After standing overnight, the mixture was decomposed with ice and hydrochloric acid, the benzene layer separated and evaporated and the residue distilled at 3 mm. Most of the material distilled at 195–197° as a light yellow oil which crystallized when rubbed with a few drops of acetic acid. The material was crystallized from dilute methanol, from which it formed large clumps of colorless needles, m. p. 62.5–63.5°.

Anal. Calcd. for $C_{17}H_{14}O_2$: C, 81.6; H, 5.6. Found: C, 81.3; H, 5.7.

Alkaline Cleavage of 2-Methyl-2-benzoylhydrindone.—A mixture of 5 g. of the diketone, 5 g. of sodium hydroxide and 10 ml. of water was refluxed overnight and then steam-distilled. The residue was acidified; upon cooling it deposited crystals of benzoic acid: m. p. and mixed m. p., 120–121°; neutral equivalent found, 123; calculated, 122. The steam distillate contained 2-methylhydrindone as a light yellow, mobile oil from which were prepared an oxime, m. p. 103–104.5 (literature[9] 104–106°), a *p*-nitrophenylhydrazone, m. p. 171–172° (literature[9] 167–168°), and a 2,4-dinitrophenylhydrazone, m. p. 213–215°.

The Reaction of 2-Methyl-2-benzoylhydrindone with Phenylmagnesium Bromide.—A solution of phenylmagnesium bromide in equal parts of ether and benzene was added dropwise to a refluxing solution of 4 g. of the diketone in 50 ml. of dry benzene. The first mole of the reagent caused the formation of a gummy, orange-yellow precipitate which dissolved as a second mole was slowly added, a clear yellow solution resulting. The addition of the first two moles of reagent took an hour; a third mole was then added all at once to insure the completion of the reaction. The resulting solution was refluxed for two hours, cooled and decomposed with ice and hydrochloric acid. The solvents were removed by steam distillation. The semi-crystalline residue remaining was crystallized from toluene, yielding 3.9 g. of colorless crystals, m. p. 214–215°. This material (VI) is readily soluble in hot acetone, acetic acid, benzene and toluene, but only slightly soluble in these solvents in the cold.

Anal. Calcd. for $C_{29}H_{26}O_2$: C, 85.9; H, 5.9. Found: C, 85.8; H, 6.2.

The mother liquor from which VI had crystallized was evaporated and the residue taken up in hot acetone. An additional amount of VI separated; this was removed and the solution cooled to 0°. On standing, the solution deposited 1.3 g. of triphenylcarbinol, m. p. (after recrystallization) and mixed m. p. 159–162°. In order to isolate 2-methylhydrindone, another sample of 8 g. of the diketone was treated as above; the benzene layer, separated after decomposition with ice and ammonium chloride, was cooled to remove VI and then distilled through a small helix-packed column. The last traces of benzene were removed at 100° and 22 mm. and the residue steam-distilled. The light yellow oil present in the steam distillate was converted into a 2,4-dinitrophenylhydrazone, m. p. and mixed m. p. 214–215°.

Oxidation of the Diol (VI).—A suspension of 2 g. of VI in a solution of 20 ml. of concentrated nitric acid in 60 ml. of water was refluxed for one hour. The resulting dark red oil was taken up in ether, the ether solution washed with water and with sodium bicarbonate solution, dried and evaporated. The residue was distilled at 3 mm., yielding an oily distillate which crystallized when seeded with benzophenone. The material melted, alone or mixed with benzophenone, at 48–49°. It formed a 2,4-dinitrophenylhydrazone, m. p. and mixed m. p. with an authentic sample of benzophenone 2,4-dinitrophenylhydrazone, 235–237°. The yield was 48%, based upon unrecovered diol.

The sodium bicarbonate extract of the original ether solution was acidified and extracted with ether. From the ether solution was isolated 210 mg. of *o*-benzoylbenzoic acid: neutral equivalent found, 227; calculated, 228. It melted at 126–128° and did not depress the m. p. of an authentic sample of *o*-benzoylbenzoic acid. It formed a hydrate, m. p. 93–94°, identical with an authentic sample.

There was no neutral fraction other than that represented by benzophenone and no ether-soluble acid other than *o*-benzoylbenzoic acid.

Methylbenzhydrylmalonic Acid.—A solution of 58 g. of ethyl benzhydrylmalonate in 600 ml. of dry ether was stirred with 4 g. of sodium wire until all of the metal had disappeared. A solution of 55 g. of methyl iodide in 50 ml. of ether was then added dropwise during thirty minutes and the mixture allowed to stand overnight. Water was added and the layers separated. The crude ester weighed 60 g.; it was not purified before saponification.

A solution of 53 g. of the ester, 100 g. of sodium hydroxide, 200 ml. of water and 300 ml. of alcohol was heated on the steam-bath for one hour. The thick crystalline magma was dissolved by the addition of 150 ml. of water and the resulting solution refluxed for twenty hours. After dilution with water the solution was acidified; the dark brown oil which separated crystallized on standing at 0°. The crude acid was recrystallized from dilute acetic acid. It formed nearly colorless prisms, m. p. 143–145° with gas evolution. The yield was 26.5 g.

Anal. Calcd. for $C_{17}H_{16}O_4$: C, 71.8; H, 5.7; neut. eq., 142. Found: C, 71.9; H, 6.0; neut. eq., 140.

Attempted Ring Closure of Methylbenzhydrylmalonyl Chloride.—(A) In benzene solution: to a solution of 5 g.

of the acid in benzene was added 5 g. of phosphorus pentachloride. After thirty minutes the benzene and phosphorus compounds were removed on the water-bath at 20 mm. and to the residue, dissolved in 50 ml. of benzene, was added 6 g. of aluminum chloride in small portions. The initial yellow color slowly changed to red in the course of several hours. After twenty-four hours the mixture was decomposed with ice and hydrochloric acid, the benzene layer separated, dried and evaporated. The residue was distilled at 2 mm., yielding a light yellow distillate which crystallized from dilute acetic acid. There was obtained 0.81 g. of colorless crystals, m. p. 91–92°. The compound was not soluble in cold, concentrated sulfuric acid, very soluble in ligroin and slightly soluble in acetone.

Anal. Calcd. for $C_{22}H_{18}$: C, 93.6; H, 6.4. Found: C, 93.2; H, 6.6.

When stannic chloride was used in place of aluminum chloride the same compound was formed.

(B) In carbon bisulfide: No crystalline material could be isolated when carbon bisulfide was used as the solvent in place of benzene.

β,β-Dibenzylpropionic Acid.—A solution of 15 g. of dibenzylacetic acid, 18 g. of thionyl chloride, 3 drops of pyridine and 60 ml. of dry benzene was allowed to stand for an hour at room temperature. The solution was evaporated at 22 mm. and 100°, the residue taken up in 50 ml. of dry benzene and treated with a dried solution of diazomethane, prepared from 30 g. of nitrosomethylurea, in ether. After an hour the solution was filtered and the solvents removed under reduced pressure. The residue crystallized as orange needles. Recrystallized from 90% methanol, the diazoketone formed pale yellow needles, m. p. 72–74°; yield, 15 g. (90%).

Anal. Calcd. for $C_{17}H_{16}ON_2$: C, 77.3; H, 6.1. Found: C, 76.9; H, 6.2.

The recrystallized diazoketone was dissolved in 100 ml. of anhydrous ethanol and treated with 3 g. of dry silver oxide. On warming to 50° a vigorous evolution of nitrogen occurred and the solution was cooled. The solution was then warmed at 60° for an hour and filtered. Five grams of potassium hydroxide was added and after three hours at room temperature the silver oxide which had precipitated was removed and the solution refluxed for thirty minutes. Water was added, the alcohol removed by distillation and the solution acidified. The precipitated acid was extracted with ether and, after removal of the ether, crystallized from dilute acetic acid. The product melted at 85–86°; the yield was 13.1 g. (91%, based on the diazoketone).

Anal. Calcd. for $C_{17}H_{18}O_2$: C, 80.3; H, 7.1; neut. eq., 254. Found: C, 80.0; H, 7.1; neut. eq., 255.

The acid was also prepared through the Reformatsky reaction starting with ethyl bromoacetate and dibenzyl ketone, the hydroxy ester being dehydrated to the unsaturated ester, the latter saponified and the acid reduced with Raney nickel at 150° and 1700 lb. The over-all yield was 15% of a product identical with that prepared as described above.

3-Benzyltetralone.—Five grams of β,β-dibenzylpropionic acid was converted into its chloride with thionyl chloride and cyclized by treating it with 8 g. of stannic chloride in benzene solution. The crude product, isolated in the usual way, was distilled at 2 mm., then crystallized from ligroin (b. p. 90–100°) and petroleum ether (b. p. 30–60°). The yield was 4 g. of material melting at 54–56°.

Anal. Calcd. for $C_{17}H_{16}O$: C, 86.4; H, 6.8. Found: C, 86.6; H, 7.1.

Methyl 3-Benzyltetralone-2-glyoxalate.—Dry sodium methoxide was prepared from 1.5 g. of sodium and absolute methanol, and to it was added 15 g. of dimethyl oxalate and 50 ml. of dry benzene. A solution of 15.5 g. of 3-benzyltetralone in 15 ml. of benzene was added dropwise, and the mixture allowed to stand overnight. Water was added, the benzene layer separated and evaporated, and the residue crystallized from methanol. There was obtained 14 g. of colorless needles, m. p. 85–87°.

Anal. Calcd. for $C_{20}H_{18}O_4$: C, 74.6; H, 5.6. Found: C, 74.4; H, 5.7.

Methyl 3-Benzyltetralone-2-carboxylate.—The glyoxylic ester was mixed with 20 g. of powdered soft glass (previously treated with aqua regia, water, alkali and then thoroughly washed) and the mixture heated for twenty minutes at 175°. The product was extracted with acetone, the acetone removed, and the residue recrystallized from methanol. Large colorless needles, m. p. 77–78°, were obtained. The yield was quantitative.

Anal. Calcd. for $C_{19}H_{18}O_3$: C, 77.6; H, 6.1. Found: C, 77.3; H, 6.3.

Methyl 2-Methyl-3-benzyltetralone-2-carboxylate.—To the dry sodium methoxide prepared from 0.46 g. of sodium was added a solution of 5.9 g. of methyl 3-benzyltetralone-2-carboxylate in 25 ml. of dry benzene. When the solid had dissolved, 6 g. of methyl iodide was added and the solution allowed to stand overnight. After the addition of water and ether, the ether layer was separated, dried and evaporated. The residue crystallized from methanol, yielding a first crop of 4.4 g. of material, m. p. 114–115°, and a second crop of 0.7 g. of slightly less pure material. The total yield was 5.1 g. (84%).

Anal. Calcd. for $C_{20}H_{20}O_3$: C, 77.9; H, 6.5. Found: C, 77.5; H, 6.7.

Summary

The reaction between phenylmagnesium bromide and 2-methyl-2-benzoylhydrindone follows two courses, leading to products derived from (a) diaddition to the carbonyl groups and (b) cleavage. Cleavage occurs only when the initial attack by the reagent is on the extracyclic carbonyl group.

It is postulated that the ability of the monoaddition product to form an intramolecular coordination complex is not a sufficient condition for cleavage.

The Preparation of 24-Keto and 24-Hydroxycholesterol and Certain Derivatives[1]

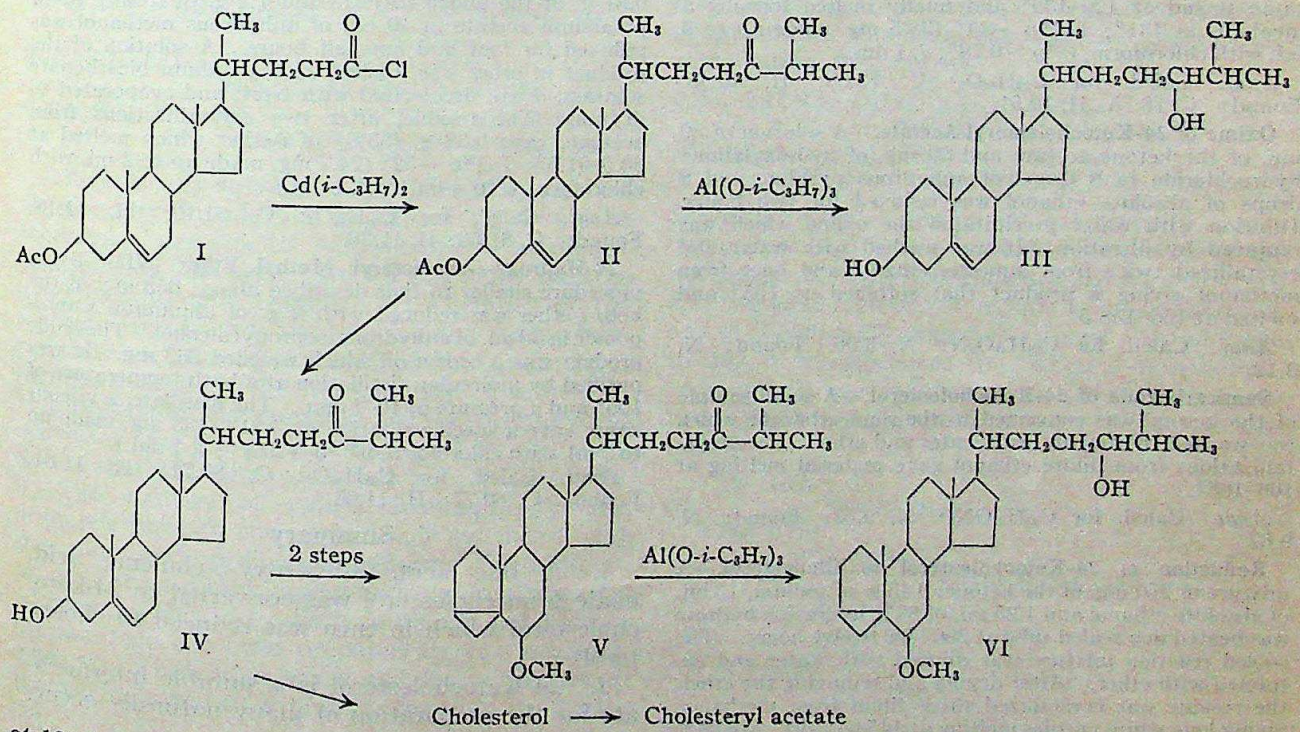
BY BYRON RIEGEL AND IRVING ALLAN KAYE

The structures of the side chains of sterols have been elucidated chiefly by degradative studies. Surprisingly little has been done to establish more definitely these structures by resyntheses from degraded products containing the 3-hydroxyl group and the 5,6-double bond.[2]

The carbon skeletons of naturally occurring sterols differ only in the substituents at the 24-position. Thus, a suitable intermediate for the preparation of sterols having various side chains would be 24-ketocholesterol (IV). This intermediate will also permit further study of the stereochemical contribution of the side chain to the optical rotation. An excellent method for the preparation of this compound involves the reaction of diisopropylcadmium with 3-acetoxy-5-cholenyl chloride[2d] (I). 24-Ketocholesterol melts at 137–138.5° and has a specific rotation of −37°. Its semicarbazone, acetate and the acetate oxime were prepared.

Cholesterol was obtained directly from 24-ketocholesterol by a modified Wolff–Kishner reduction of the carbonyl group. The Clemmensen and the ordinary Wolff–Kishner reductions gave tarry products. Reduction of the ketone (II) by means of aluminum isopropoxide gave 24-hydroxycholesterol (III). Intermediates from which the 24-hydroxyl group might be removed by dehydration were sought. Attempts to make the 3-monoacetate by partial acetylation gave only the diacetate or starting material.

Use was then made of the so-called *i*-ether configuration as a method for the specific protection of the 3-hydroxyl group. The tosylate of 24-ketocholesterol, when heated in a-buffered methanol solution, gave 24-keto-*i*-cholesteryl methyl ether (V) which melted at 90.5–91.5° and gave a specific rotation of +52°. This ketone (V) in the presence of aluminum isopropoxide was reduced to 24-hydroxy-*i*-cholesteryl methyl ether. The conversion of some of these compounds to other naturally occurring sterols is now being studied.



The authors wish to thank the Rockefeller Foundation for financially supporting this work.

Experimental[3]

24-Ketocholesterol (IV).—The 3-acetoxy-5-cholenyl chloride[2d] prepared from 25 g. of 3-acetoxy-5-cholenic acid[4] (m. p. 183–185°) was not isolated but was dissolved in dry benzene and then added to a diisopropylcadmium solution. The latter solution was made from 14.65 g. of magnesium, 125 g. of isopropyl bromide, anhydrous ether and 88 g. of

anhydrous cadmium bromide. The reaction mixture, after standing overnight, was worked up in the usual way and the product was saponified with methanolic potassium hydroxide. The ether soluble material from the saponification was crystallized three times from petroleum ether (Skellysolve C, b. p. 85–100°). A yield of 11.19 g. (46%) of large clumps of hard needles, melting at 134.5–135.5°, was obtained. More material was recovered from the mother liquors by forming the semicarbazone of the crude ketone. The semicarbazone was washed well with water, dried and decolorized by extraction with ether in a Soxhlet extractor. The white powdery product was hydrolyzed, dissolved in ether, and decolorized with Norit. Removal of the ether and crystallization from Skellysolve C gave 1.57 g. (7%) of material melting at 134–135.5°. After three more crystallizations of the ketone from aqueous methanol, it melted at 137–138.5°; $[\alpha]^{26}D$ −37° (19.6 mg. made up to 2 ml. with chloroform, $\alpha^{26}D$ −0.36°; *l*, 1 dm.).

Anal. Calcd. for $C_{27}H_{44}O_2$: C, 80.94; H, 11.07. Found: C, 80.87; H, 11.02.

24-Ketocholesteryl Acetate (II).—The interaction of the acid chloride with the cadmium Grignard reagent gave considerable esterification which is difficult to understand. However, from the reaction mixture the 24-ketocholesteryl acetate could be isolated by means of Girard's reagent-T. Even after two crystallizations from methanol and two more from 95% ethanol it gave a peculiar melting point. It melted at 127.5–128° but did not become fluid, then became turbid at 129–130° and finally melted forming a meniscus at 131°; $[\alpha]^{26}D$ −41° (38.5 mg. made up to 2 ml. with chloroform, $\alpha^{26}D$ −0.78°; *l*, 1 dm.).

Anal. Calcd. for $C_{29}H_{46}O_3$: C, 78.68; H, 10.48. Found: C, 78.75; H, 10.51.

Oxime of 24-Ketocholesteryl Acetate.—A solution of 50 mg. of the ketone acetate and 50 mg. of hydroxylamine hydrochloride in 8 drops of anhydrous pyridine and 8 drops of absolute ethanol was refluxed for two hours. Dilution with water precipitated the oxime which was removed by filtration. It was washed with water and crystallized twice from aqueous ethanol and once from methanol giving a product that softened at 155° and melted at 156–158.5°.

Anal. Calcd. for $C_{29}H_{47}O_3N$: N, 3.06. Found: N, 3.12.

Semicarbazone of 24-Ketocholesterol.—A small sample of the ketone was converted to the semicarbazone which was washed thoroughly with water and ether. Two crystallizations from dilute ethanol gave material melting at 166–168°.

Anal. Calcd. for $C_{28}H_{47}ON_3$: N, 9.52. Found: N, 9.67.

Reduction of 24-Ketocholesterol to Cholesterol.—A mixture of 250 mg. of the ketone, 0.45 g. of sodium, 15 ml. of absolute ethanol and 1.25 ml. of 85% hydrazine hydrate was heated in a sealed tube at 200° for twelve hours. The cooled reaction mixture was diluted with water and extracted with ether. After drying and removing the ether, the residue was crystallized three times from methanol, giving long white needles melting at 145.6–146.1°; $[\alpha]^{28.5}D$ −36° (27.5 mg. made up to 2 ml. with chloroform, $\alpha^{28.5}D$ −0.50°; *l*, 1 dm.). It gave a mixed m. p. of 144–145.8° when mixed with an authentic sample of cholesterol (m. p. 150–151°).

The acetate was prepared by heating 90 mg. of the above product with 3 ml. of acetic anhydride. After removing the acetic anhydride, the residue was crystallized once from methanol and twice from dilute ethanol. It melted at 113–114°, gave no depression in m. p. when mixed with an authentic sample of cholesteryl acetate and gave a specific rotation of −46° (6.8 mg. made up to 2 ml. with chloroform, $\alpha^{28}D$ −0.15°; *l*, 1 dm.).

24-Hydroxycholesterol (III).—A solution of 0.5 g. of 24-ketocholesteryl acetate and 5 g. of aluminum isopropoxide in 75 ml. of anhydrous isopropyl alcohol was refluxed for three hours. About one-half of the solvent was removed by slow distillation, 75 ml. more of anhydrous isopropyl alcohol was added and again distilled slowly until removed. The reaction mixture was cooled and decomposed by adding 50 ml. of dilute hydrochloric acid. The product was removed by filtration and crystallized from dilute methanol giving 470 mg. (94%) of material melting at 166–169°.

Anal. Calcd. for $C_{27}H_{46}O_2$: C, 80.54; H, 11.52. Found: C, 80.55; H, 11.97.

Diacetate.—When the above diol was treated with acetic anhydride the diacetate was obtained readily. After two crystallizations from aqueous ethanol and two from methanol, it softened at 93° and melted at 95–96°.

Anal. Calcd. for $C_{31}H_{50}O_4$: C, 76.50; H, 10.36. Found: C, 76.75; H, 10.44.

24-Ketocholesteryl *p*-Toluenesulfonate.—Following the method of Freudenberg and Hess,[5] 1 g. of 24-ketocholesterol gave 1.1 g. (82%) of tosylate. From low boiling petroleum ether, it formed small, hard crystals which softened at 115° and melted at 119–120° (dec.); $[\alpha]^{26}D$ −35° (23.5 mg. made up to 2 ml. with chloroform, $\alpha^{26}D$ −0.42°; *l*, 1 dm.).

Anal. Calcd. for $C_{34}H_{50}O_4S$: C, 73.60; H, 9.08. Found: C, 74.28; H, 9.34.

24-Keto-*i*-cholesteryl Methyl Ether (V).—A solution of 0.81 g. of the above tosylate and 1.2 g. of freshly fused potassium acetate in 40 ml. of anhydrous methanol was refluxed for four and one-half hours. A solution of the product in ether was washed with a sodium bicarbonate solution, dried, decolorized with Norit and evaporated to dryness. The residue, after two crystallizations from acetone, gave 0.32 g. (53%) of *i*-ether which melted at 90.5–91.5°; $[\alpha]^{26}D$ +52° (24.7 mg. made up to 2 ml. with chloroform, $\alpha^{26}D$ +0.64°; *l*, 1 dm.).

Anal. Calcd. for $C_{28}H_{46}O_2$: C, 81.10; H, 11.18. Found: C, 81.50; H, 11.28.

24-Hydroxy-*i*-cholesteryl Methyl Ether (VI).—By a procedure similar to that described above, 658 mg. of the keto *i*-ether was reduced with 2 g. of aluminum isopropoxide in 60 ml. of anhydrous isopropyl alcohol. The crude product was a brown oil which weighed 563 mg. It was purified by molecular distillation at a bath temperature of 106° and a pressure of 10^{-4} mm. The distillate, a viscous sirup, gave a specific rotation of +31° (133 mg. made up to 2 ml. with chloroform, $\alpha^{27.5}D$ +2.07°; *l*, 1 dm.).

Anal. Calcd. for $C_{28}H_{48}O_2$: C, 80.71; H, 11.61. Found: C, 80.77; H, 11.66.

Summary

1. A bile acid, 3-hydroxy-5-cholenic acid, made from cholesterol was converted to 24-ketocholesterol which in turn was reduced to cholesterol.

2. 24-Ketocholesterol is a suitable intermediate for the preparation of many naturally occurring sterols.

3. Reduction of the 24-keto group, by the Meerwein–Ponndorff method, gave 24-hydroxycholesterol.

4. The 3-hydroxyl group of these compounds can be protected for some reactions by the excellent method of conversion to their *i*-ethers.

5. Several other derivatives of these steroids are reported.

Basically Substituted Aliphatic Nitriles and their Catalytic Reduction to Amines[1]

BY FRANK C. WHITMORE, HARRY S. MOSHER,[2] ROBERT R. ADAMS,[3] ROBERT B. TAYLOR, EARL C. CHAPIN,[3] CHARLES WEISEL AND WILLIAM YANKO[3,4]

In the course of our work on basically substituted heterocyclic compounds it became necessary to prepare a group of aliphatic substituted diamines. This paper is a report on the more successful of these experiments. Since it was necessary to produce rather large amounts of these compounds, the phthalimide synthesis which has been used most often for this purpose was judged unsuitable and it was finally decided to use the reduction of basically substituted nitriles to obtain these amines. The general procedures used are represented by the following equations, where R may be hydrogen, alkyl or bound in a heterocyclic ring system.

$$R_2NH + CH_2{=}CHCN \longrightarrow R_2NCH_2CH_2CN \quad (I)$$

$$2R_2NH + ClCH_2CH_2CH_2CN \longrightarrow R_2NCH_2CH_2CH_2CN + R_2NH{\cdot}HCl \quad (II)$$

$$Et_2N(CH_2)_nOH + CH_2{=}CHCN \xrightarrow{NaOMe} Et_2N(CH_2)_n{-}O{-}CH_2CH_2CN \quad (III)$$

$$R_2N(CH_2)_nCN + 2H_2 \longrightarrow R_2N(CH_2)_{n+1}NH_2 \text{ and } [R_2N(CH_2)_{n+1}]_2NH + NH_3 \quad (IV)$$

The basically substituted propionitriles are best obtained by the addition of ammonia, primary, or secondary amines to acrylonitrile.[5] Although this method has been used for the same purpose by Holcomb and Hamilton,[6] no studies of the reaction itself and the mechanism have been published. Structural proof of the products is furnished first by the non-identity of α-diethylaminopropionitrile prepared by the cyanohydrin synthesis and the product obtained by the addition of diethylamine to acrylonitrile, and secondly by the identity of γ-diethylaminopropylamine prepared through the phthalimide synthesis[7] and the compound obtained by reducing the addition product from diethylamine and acrylonitrile. In addition to this, β-(γ-diethylaminopropylamino)-propionitrile has been prepared by two separate methods as indicated below and the properties of the products and their picrates found to be identical.

$$\left.\begin{array}{l} Br{-}CH_2CH_2CN + H_2N(CH_2)_3NEt_2 \\ CH_2{=}CHCN + H_2N(CH_2)_3NEt_2 \end{array}\right\} \rightarrow NCCH_2CH_2NH(CH_2)_3NEt_2 \quad (V)$$

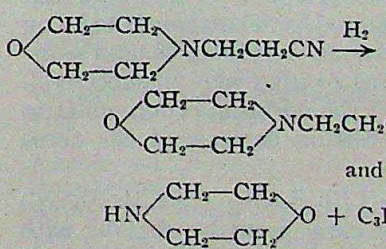
Thus the mechanism by which the addition takes place probably involves a typical 1,4-addition.

From the following experimental evidence it is apparent that the reaction is reversible. When the higher β-dialkylaminopropionitriles are heated near their boiling points for any length of time, they slowly decompose to give some of the dialkylamine. This is especially true in the case of diethanolamine, addition of which to acrylonitrile gives a viscous liquid from which is readily obtained the crystalline picrate of β-diethanolaminopropionitrile. Attempted distillation of this reaction product, however, gives back all of the diethanolamine used as starting material and leaves only a non-distillable polymer. If, however, the addition compound is reduced without distillation, a fair yield of γ-diethanolaminopropylamine, which can be distilled without decomposition, is obtained.

$$CH_2{=}CHCN + (HOCH_2CH_2)_2NH \rightleftharpoons (HOCH_2CH_2)_2NCH_2CH_2CN \quad (VI)$$

$$(HOCH_2CH_2)_2NCH_2CH_2CN + 2H_2 \longrightarrow (HOCH_2CH_2)_2NCH_2CH_2CH_2NH_2$$

Secondly, when equal molar amounts of a secondary amine and acrylonitrile react, some of the unreacted starting materials are always recovered and the yield is never as high as when an excess of one of the starting materials is used. In addition to this, it was observed that when β-morpholinopropionitrile was reduced at an elevated temperature (190°) a 35% yield of morpholine was obtained.



$$\xrightarrow{H_2} \text{(45\%)} \quad \text{and} \quad \text{(55\%)} \quad (VII)$$

Although this may be explained by hydrogenolysis, it can equally well be explained on the basis of a reversal of the morpholine–acrylonitrile–β-morpholinopropionitrile equilibrium at the elevated temperature. Finally the spontaneous polymerization of β-aminopropionitrile on standing to give a polymer and ammonia can best be explained by assuming its disproportionation into acrylonitrile and ammonia followed by the polymerization of the acrylonitrile.

$$H_2NCH_2CH_2CN \rightleftharpoons NH_3 + CH_2{=}CHCN \longrightarrow \text{Polymer} + NH_3 \quad (VIII)$$

The ease with which the various amines react

with acrylonitrile is interesting. Piperidine is the most reactive and the solution should be cooled during the addition; morpholine is next in activity, being only slightly less reactive than piperidine; diethylamine is the most reactive of the dialkylamines employed but its rate of addition is very much slower than that for either of the two above cyclic bases and no noticeable heat is evolved on mixing with acrylonitrile. The rate of addition of the remaining dialkylamines decreases progressively with the length and size of the alkyl groups and the formation of β-[di-(2-ethylhexylamino]-propionitrile was only 77% complete after heating di-(2-ethylhexyl)-amine and acrylonitrile together for 360 hours at 100°. That the rate of addition is not a function of the basic strength of the addenda is shown by the relative reactivities of diethylamine, piperidine and morpholine (whose ionization constants are, respectively, 1.2×10^{-3}, 1.6×10^{-3} and 2.4×10^{-6})[8] but apparently is more dependent upon the size and shape of the entering molecule.

In the case of certain heterocyclic and aromatic amines a catalyst was necessary. Thus methylaniline did not react with acrylonitrile in a sealed tube at 200° in the absence of a catalyst nor did any reaction take place between the two when refluxed in dioxane in the presence of benzyltrimethylammonium hydroxide. But in the presence of hydrated copper sulfate at 180° the desired β-(methylphenylamino)-propionitrile was produced. Likewise carbazole would not react without a catalyst but in the presence of benzyltrimethylammonium hydroxide, the reaction proceeded vigorously. Neither copper bronze, copper sulfate, small amounts of sulfuric acid, nor benzyltrimethylammonium hydroxide would catalyze the addition of tetrahydroquinoline to acrylonitrile but in acetic acid solution a good yield of the addition product was obtained.[9] All attempts to bring about a reaction between acrylonitrile and anisidine, 2-aminopyridine or urea were unsuccessful.

The special case of the addition of ammonia to acrylonitrile[5] is interesting because of the three possible products.

$H_2NCH_2CH_2CN$ $HN(CH_2CH_2CN)_2$ $N(CH_2CH_2CN)_3$

When the reaction is carried out by shaking with aqueous ammonia, the secondary and tertiary amines predominate but when the reaction takes place in a seven molar excess of liquid ammonia at about 40°, a 22% yield of the primary amine and a 64% yield of the secondary amine result with very little of the completely substituted product. The data indicate that the addition of β-aminopropionitrile to acrylonitrile takes place approximately 20 times faster than the corresponding addition of ammonia. The reduction of a similar reaction mixture resulted in a 20% yield of trimethylenediamine.

(8) Ingram and Luder, THIS JOURNAL, 64, 3043 (1942).

(9) The use of acetic acid as solvent for this reaction was made at the suggestion of Dr. J. B. Dickey of Eastman Kodak Company.

The group of amines which contain an ether linkage were obtained by the method of Bruson and Riener[10] by the action of acrylonitrile on a basically substituted alcohol such as diethylaminoethanol in the presence of sodium methoxide (Equation III). The yields with diethylaminoethanol and γ-diethylaminopropanol were 79.5 and 75.4%, respectively, while that for the secondary alcohol, 1-diethylamino-4-pentanol,[11] was 66%.

The γ-aminobutyronitriles were all obtained in excellent yields by the reaction of secondary amines with γ-chloro- or γ-bromo-butyronitriles according to the method employed by Utermohlen and Hamilton,[12] and Strukov.[13] Their yields were greatly improved by the use of a solvent.

The reduction of the nitriles to amines was usually accomplished with Raney nickel catalyst at temperatures of 90–130° and hydrogen pressures of 67 to 270 atmospheres. This was found to be superior to platinum at lower pressures or to reduction at higher temperatures. A typical example is the hydrogenation of β-morpholinopropionitrile, 4.8 moles of which was reduced without solvent in twenty minutes at 120° and 1400 lb. per sq. in. pressure to give a 60% yield of γ-morpholinopropylamine. The reduction of nitriles has been studied extensively[14] and is known to produce as a by-product the secondary amine as well as the primary amine (Equation IV) in which it seems quite certain that the mechanism envolves the reaction of a part of the primary amine which has been produced, with the intermediate imine.[15] The formation of similar triamines has been reported by Mannich and Margotte,[16] in a patent by Münch and Schlichting,[17] by Winans and Adkins,[15] and Magidson[13] has also used such an amine in the synthesis of an acridine derivative.

These secondary amines were normally observed in each of our reductions when sufficiently large runs were made and constituted 5 to 32% yields. The γ-aminobutyronitriles gave uniformly higher yields of the secondary amines than the corresponding propionitriles; thus γ-piperidinobutyronitrile gave a 54% yield of the primary amine and a 31% yield of the secondary amine.

$$C_5H_{10}NCH_2CH_2CH_2CN \nearrow C_5H_{10}NCH_2CH_2CH_2CH_2NH_2 \quad 54\%$$
$$\searrow [C_5H_{10}NCH_2CH_2CH_2CH_2]_2NH \quad 31\%$$

while β-piperidinopropionitrile gave a 45% yield of primary amine and a 17% yield of the secondary amine under the same conditions. The reduction can be controlled and the yield of primary amine increased by carrying out the hydrogenation in the presence of ammonia,[18] thus reversing the reaction which produces the secondary amine. By this method the 45% yield of γ-piperidinopropylamine reported above was raised to 68.5%, the 54% yield of γ-diethylamiopropylamine raised to 72% and the 60% yield of γ-morpholinopropylamine raised to 70.6%. It was likewise found possible to increase the yield of secondary amine by performing the reduction of the nitrile in the presence of an excess of the primary amine. Thus when an equal molar mixture of γ-diethylaminopropylamine and β-diethylaminopropionitrile was reduced, a 28% yield of the di-(γ-diethylaminopropyl)-amine was obtained in contrast to the 13% yield found when the hydrogenation was carried out in the normal manner or the 5% yield obtained when carried out in the presence of ammonia. It is apparent that this reduction may be controlled within limits to produce either a larger or smaller yield of primary or secondary amine depending upon which product is most desired. It is believed that the yields of the primary products can be increased in almost every case if hydrogen pressures of 250 to 300 atmospheres are employed and larger amounts of ammonia introduced. Tables I and II give the nitriles and amines which were prepared along with boiling points, indices, yields, melting points of the picrate derivatives and the observed and calculated neutralization equivalents. All of the propionitriles with the one exception noted were made from acrylonitrile, while all of the butyronitriles were prepared from γ-chlorobutyronitrile. The reductions were all carried out catalytically with approximately 10 g. of Raney nickel per mole of nitrile. All boiling points are within a one degree range and all melting points within a one-half degree range unless otherwise noted.

A representative group of seven sulfanilamide derivatives was prepared from these aliphatic amines by shaking in acetone solution over a saturated potassium carbonate solution with acetylsulfanilyl chloride. Because of the strongly basic character of the aliphatic amines, it was impossible to obtain the products by using pyridine or pyridine-acetone as solvents and only red, unworkable solutions resulted in these cases. These sulfanilamide derivatives are given in Table III along with melting points, yields, and the melting points of the acetyl derivatives. Compounds similar to these have been reported by Drozdov[19] and Walker.[20]

Experimental

Preparation of β-Aminopropionitriles.—The addition of secondary amines to acrylonitrile has already been described in patents[5] and by Holcomb and Hamilton.[6] The general procedure used here is illustrated by the preparation of β-diethylaminopropionitrile. Fractionated acrylonitrile, b. p. 77.2° (732.4 mm.), $n^{20}D$ 1.3911, 424 g. (8.0 moles) and diethylamine, 1000 g. (13.7 moles) were mixed and warmed at 50° for twenty-four hours and after standing at room temperature for two days, the excess diethylamine was removed at atmospheric pressure and the residue distilled through a modified Claisen flask to give 970 g. of material boiling from 119 to 120° at 70 mm. pressure; $n^{20}D$ 1.4351 to 1.4353, yield 97%. Another run in which the reactants were mixed in mole to mole ratio, heated on the steam-bath for eight hours, and immediately distilled at atmospheric pressure (b. p. 196–198° at 737 mm.), resulted in a 74% yield. A third experiment in which 355 g. of diethylamine (5 moles) was added to 500 g. of commercial acrylonitrile (9.5 moles) with some cooling over a period of ten minutes and the reaction mixture refluxed for one-half hour, set in the refrigerator overnight and distilled, resulted in a 93% yield of β-diethylaminopropionitrile boiling between 104 and 106° at 35 mm. pressure. This product can be titrated to a sharp end-point with hydrochloric acid using methyl orange as the indicator; equivalent weight calculated, 126.2; found 126.1. It forms a picrate which is readily recrystallized from methanol–acetone mixture and melts sharply at 85°. In general it seems that a better yield results if the reaction is allowed to reach equilibrium at room temperature before the final distillation. For the same reason the product should be distilled more or less rapidly at a low temperature if possible. A slow, careful fractionation through an efficient fractionating column is a distinct disadvantage in the case of the higher dialkylamino derivatives since dissociation into the original reactants results.

β-[Di-(γ-diethylaminopropyl)-amino]-propionitrile.—In a 500-ml. flint glass bottle was mixed 26 g. (0.107 mole) of di-(γ-diethylaminopropyl)-amine and 32 g. (0.6 mole) of acrylonitrile along with 0.1 g. of copper bronze. The flask was stoppered and heated at 100° for twenty-four hours, allowed to stand at room temperature for a like period, and distilled to give 24.6 g. (78% yield) of product, b. p. 145° (5 mm.), $n^{20}D$ 1.3640.

β-(γ-Diethylaminopropylamino)-propionitrile.—This compound was made by two different methods; *i. e.*, by the addition of γ-diethylaminopropylamine to acrylonitrile in 79.4% yield and by the reaction of β-bromopropionitrile[21] with γ-diethylaminopropylamine in 76.4% yield by the same method as described for the preparation of γ-piperidinobutyronitrile.

β-(β′-Diethylaminoethoxy)-propionitrile.—To a mixture of 220 g. (1.88 moles) of diethylaminoethanol and 2.3 g. of sodium methoxide in a 1-liter flask equipped with a thermometer, stirrer and dropping funnel was added 100 g. (189 moles) of acrylonitrile over a one-half hour period while the temperature was kept at 25°. The reaction mixture was stirred for a short while longer, allowed to stand overnight, 4.2 ml. of concd. sulfuric acid cautiously added, the solution filtered, and the filtrate distilled to give 260 g. (80% yield); b. p. 140–145° (25 mm.), $n^{20}D$ 1.4430. With the secondary alcohol, 1-diethylamino-4-pentanol,[11] the reaction did not proceed as rapidly and a yield of only 66% was obtained.

The Reaction of Ethylamine with Acrylonitrile.—Acrylonitrile, 106 g. (2 moles), was added to a 70% aqueous solution of ethylamine, 200 g. (3 moles), over a period of two hours while the temperature was kept below 30°. The reaction mixture was stirred at room temperature for five hours and finally heated on the steam-bath for one hour. After the reaction mixture had stood overnight, the water was removed by adding 50 g. of anhydrous potassium carbonate and separating the aqueous layer. The product was purified by distillation to give 176.9 g., b. p. 92–95° (30 mm.), $n^{20}D$ 1.4318–1.4322; yield 90.4% of β-ethyl-

[a] Approximately 10 g. of Raney nickel catalyst used per mole of nitrile reduced. [b] See ref. 5a. [c] This yield represents only one of two products isolated in the reaction. [d] Mentioned in a paper presented by Dr. M. T. Leffler at the Medicinal Section of the American Chemical Society in Detroit, April 14, 1943. [e] See ref. 6. [f] This compound was only slightly water soluble and a satisfactory end-point could not be obtained by titration. [g] See Burckhalter, Jones, Holcomb and Sweet, THIS JOURNAL, 65, 2012 (1943). [h] Calcd. for $C_{13}H_{26}N_2$: N, 14.0. Found: N, 13.7. [i] Calcd. for $C_{15}H_{34}N_2$: N, 11.7. Found: N, 11.6. [j] See ref. 12. [k] This compound decomposes on distillation at 1 mm. press. into the starting amine and polymerized acrylonitrile. [l] See ref. 10. [m] Synthesized from acrylonitrile and γ-diethylaminopropylamine. [n] Synthesized from β-bromopropionitrile and γ-diethylaminopropylamine. [o] See the experimental for the conditions used in this reaction. [p] See ref. 5b. [q] Does not form a picrate derivative.

aminopropionitrile. Equivalent weight calculated: 98.15, found 98.15. When a 70% ethylamine solution, 130 g. (2 moles), was added to an excess of acrylonitrile, 250 g. (4.7 moles), and the warm mixture heated on the steam-bath for two hours and worked up as indicated above, a 60% yield (180.5 g.) of di-(β-cyanoethyl)-ethylamine, b. p. 202–205° (30 mm.), $n^{20}D$ 1.4585–1.4591 was obtained.

The Reaction of Diethanolamine and Acrylonitrile.—Freshly distilled diethanolamine (52.6 g., 0.5 mole) was mixed with acrylonitrile (160 g., 3 moles) and the heterogeneous mixture shaken until homogeneous. After this reaction mixture had stood at room temperature for eight hours, the excess acrylonitrile was removed under vacuum. The residue (77.5 g.) corresponded to an increase in weight of 0.47 mole of acrylonitrile. A sample of the reaction product formed a picrate in alcohol which on recrystallization melted at 108–109°. The picrate of diethanolamine is completely soluble in alcohol but when crystallized from ether–alcohol mixture, melts at 108.8–109.0°. A mixture of these two picrates melted, however, at 94–97°. The addition product from the diethanolamine and acrylonitrile was reduced in 100 ml. of ethanol using Raney nickel catalyst and hydrogen at an average pressure of 133 atmospheres and a temperature of 105–110°. Separation by distillation was somewhat difficult because of the viscous nature of the product. Constant-index constant-boiling material 31.4 g., was obtained at 158° (2 mm.) and $n^{20}D$ 1.4975 which had an equivalent weight of 84.1 as compared

A, No solvent. B, Liquid ammonia, 69 moles, used as solvent. C, The nitrile was saturated with ammonia at room temperature and approx. 15 atm. press. prior to hydrogenation. D, One mole equivalent of γ-diethylaminopropylamine used as solvent in the reduction. E, Approximately 150 ml. of sat. alc. ammonia solution used as solvent. The reduction was carried out in approx. 100 ml. of abs. alc. G, Reduced in 600 ml. of dioxane. H, Reduced in a solution of 40 ml. of liquid ammonia and 150 ml. of abs. alc. [a] This yield represents only one of two products isolated in the reduction. [b] See Fischer and Kock, *Ber.*, **17**, 1799 (1881). [c] This yield was obtained upon the reaction of a large excess of liquid ammonia with acrylonitrile and the reduction of the reaction mixture in liquid ammonia solvent. [d] See ref. 7. [e] See ref. 6. [f] This compound was only slightly soluble in water and a satisfactory end-point could not be obtained by titration. [g] See Burkhalter, Jones, Holcomb and Sweet, THIS JOURNAL, **65**, 2012 (1943). [h] See ref. 24. [i] Combined yield on the addition and reduction. [j] See ref. 12. [k] Calcd. for the hydrobromide salt, $C_{10}H_{17}N_2Br$, m. p. 120°: Br, 32.7. Found: Br, 32.8. [l] Calcd. for the hydrochloride salt, $C_{15}H_{17}N_2Cl$, m. p. 273°: Cl, 13.6. Found: Cl, 13.6.

to the theoretical value of 81.1. It forms a picrate in alcohol which melts at 156.5–157.5° after recrystallization from acetone–ethyl acetate. When an attempt was made to distill the acrylonitrile diethanolamine addition product, a 67% recovery of material which was identified by its boiling point, picrate derivative, and equivalent weight as diethanolamine was obtained. The major portion of the remaining material was non-distillable residue.

9-(γ-Aminopropyl)-carbazole.—An intimate mixture of 167 g. of carbazole[22] and 250 ml. of acrylonitrile was cooled in an ice-bath and then made to react by the addition of 2 cc. of 40% solution of benzyltrimethylammonium hydroxide to the well stirred mixture. Upon the addition of the catalyst a vigorous reaction ensued; the mixture warmed up and the pasty mass partially solidified. The mixture was heated on the steam-bath for one hour and upon cooling a mass of crystals separated from the solution. These were removed by filtration and added to a second crop of crystals obtained by concentrating the mother liquors. The yield was 188 g. (85.4%); m. p. 155.5°. Recrystallization from acetone did not raise the melting point. 9-(β-Cyanoethyl)-carbazole, 150 g., was reduced catalyti-

(22) Carbazole "95%" was furnished through the courtesy of Reilly Tar and Chemical Company.

cally by dissolving in 600 ml. of warm dioxane, adding 20 g. of Raney nickel and shaking at 118° in the presence of 67 atmospheres pressure of hydrogen for one and one-half hours. The dioxane was removed from the reduction mixture by distillation at atmospheric pressure and the residue distilled to give 107 g. of 9-(γ-aminopropylamino)-carbazole, b. p. 228–30° (3 mm.). The first fraction of this material melted at 47° and the last at 48°. The product forms a picrate, m. p. 206–207° after two crystallizations from alcohol, and a hydrochloride, m. p. 273° after recrystallization from 95% ethanol. *Anal.* Calcd. for $C_{15}H_{17}N_2Cl$: Cl, 13.59. Found: Cl, 13.62.

The Reaction of Methylaniline and Acrylonitrile.—When a mixture of 27 g. of acrylonitrile and 53 g. of methylaniline was sealed in a tube and heated at 180° for four hours and the reaction mixture distilled, all of the methylaniline was recovered unchanged. But when the identical reaction was performed in the presence of 1 g. of hydrated copper sulfate, only 18 g. of the methylaniline was recovered and 20 g. of β-(methylphenyl)-propionitrile, b. p. 175–7° (20 mm.), was obtained. This product is too water insoluble to titrate to a satisfactory end-point. It forms a well-defined picrate melting at 118°. When a mixture of 50 g. of methylaniline, 1 ml. of a 40% solution of benzyltrimethylammonium hydroxide and 100 ml. of dioxane was heated to 90–100° and 25 g. of acrylonitrile added dropwise over a period of one and one-half hours and the solution refluxed for an additional eight hours, no reaction took place and 47 g. of the methylaniline and 22 g. of the acrylonitrile were recovered unchanged.

The Reaction of Tetrahydroquinoline with Acrylonitrile.—The heating of a mixture of tetrahydroquinoline and acrylonitrile in the presence of a small amount of copper–bronze, copper sulfate, and sulfuric acid at 160° for four hours gave no appreciable reaction; 81% of the tetrahydroquinoline and 60% of the acrylonitrile were recovered. The remaining material was either very high boiling or a non-distillable residue. A basic catalyst was also found to be inadequate for bringing about the reaction. A mixture of 133 g. of tetrahydroquinoline, 100 ml. of acrylonitrile and 2 ml. of a 40% solution of benzyltrimethylammonium hydroxide was refluxed for ten hours, during which time the temperature of the boiling mixture rose from 88 to 120°. On cooling a polymer separated. The methanol extracts of this reaction mixture gave an 82% recovery of tetrahydroquinoline upon distillation. At the suggestion of Dr. J. B. Dickey, the reaction was carried out in acetic acid. A solution of 133 g. of tetrahydroquinoline and 100 g. of acetic acid was heated to 125° and 100 g. of acrylonitrile dropped in over a period of three hours. After the addition of the first mole, the temperature dropped to 108°. The mixture was heated at reflux for six hours. Neutralization of the reaction mixture with a saturated solution of potassium carbonate in the cold, extraction with 3, 100-ml. portions of chloroform, and distillation of the dried extracts gave 140.4 g. (75.5% yield) of N-β-cyanoethyltetrahydroquinoline, b. p. 192° (10 mm.), $n^{20}D$ 1.5780.[23]

γ-Aminobutyronitriles.—γ-Diethylaminobutyronitrile and γ-morpholinobutyronitrile have been prepared by Utermohlen and Hamilton[12] but in only fair yields. The following is an example of the general procedure used in the preparation of these compounds. In a 5-liter flask equipped with stirrer, condenser, and dropping funnel was placed a solution of 600 g. (7 moles) of piperidine in a mixture of 500 ml. of dry benzene and 100 ml. of chloroform. To the refluxing solution was added a total of 310 g. (3 moles) of γ-chlorobutyronitrile[24] over a one-half hour period. The reaction mixture, after refluxing five hours was then allowed to stand overnight and the crystals of piperidine hydrochloride removed by filtration. These were washed with ether and the ether washings and the benzene–chloroform filtrate containing most of the γ-piperidinobutyronitrile were combined and distilled from a short Vigreux column until the temperature reached 108°. The residue was cooled and a second crop of piperidine hydrochloride collected and washed with ether. The total amount of piperidine hydrochloride was 350 g. or 96% of the theoretical amount. The filtrate and ether washings were combined, the ether removed by distillation and the residue vacuum distilled to obtain 393 g. (86.2% yield) of product, b. p. 129–131° (25 mm.), $n^{20}D$ 1.4653. In the preparation of γ-diethylaminobutyronitrile, γ-bromobutyronitrile was substituted for the γ-chlorobutyronitrile; yield 86%.

Reduction of the Nitriles.—The reduction of basically substituted nitriles has been carried out using sodium and alcohol–toluene by Strukov[13] and Utermohlen and Hamilton,[12] and catalytically by Münch and Schlichting[17] using nickel on Kieselguhr and by Schwoegler and Adkins[14] using Raney nickel. After trying platinum oxide at low pressures and platinum oxide in the presence of acetic anhydride and discarding these methods, the method of Adkins was followed. The general procedure employed is illustrated by the preparation of δ-piperidinobutylamine which follows.

δ-Piperidinobutylamine.—In a 1300-ml. capacity Adkins hydrogenation bomb was placed 390 g. of γ-piperidinobutyronitrile and 10 g. of Raney nickel catalyst under 109 atmospheres pressure of hydrogen. The bomb was heated to 100° and shaken for one and one-half hours after which time the absorption of hydrogen had ceased and was approximately 90% of the theoretical. A large amount of ammonia was evolved when the bomb was opened. The reduction mixture was transferred to a modified Claisen flask and distilled to give 215 g. (53.8% yield) of δ-piperidinobutylamine; b. p. 120–122° (25 mm.), $n^{20}D$ 1.4756 and 118.4 g. (31.2% yield) of di-(δ-piperidinobutyl)-amine; b. p. 195–200° (5 mm.), $n^{20}D$ 1.4898. The total combined yield was 85%.

γ-Piperidinopropylamine and Di-(γ-piperidinopropyl)-amine.—β-Piperidinopropionitrile was prepared by mixing 10 moles each of acrylonitrile and piperidine with cooling and allowing the mixture to stand overnight. This was used in the two subsequent experiments without purification. γ-Piperidinopropionitrile, 1180 g. (8.55 moles), was reduced at 120° and 109 atmospheres pressure in the presence of 60 g. of Raney nickel catalyst. The theoretical amount of hydrogen had been absorbed in thirty-five minutes; the product was fractionated through a 12-plate column to give 543 g. (45% over-all yield) of constant-boiling (203–204°), constant-index ($n^{20}D$ 1.4750) γ-piperidinopropylamine[25] and 135.5 g. (19% over-all yield) of di-(γ-piperidinopropyl)-amine; b. p. 205–207° (17 mm.), $n^{20}D$ 1.4911–1.4917, picrate m. p. 190–192°. A 200-g. portion of the same crude β-piperidinopropionitrile as used above was reduced in the presence of 20 g. of Raney nickel catalyst after first saturating the nitrile with ammonia (at 8 atmospheres pressure). Hydrogen absorption had ceased after three hours at 1500 lb. per sq. in. pressure and 100° and was approximately 90% of the theoretical. The product was fractionated through a 12-plate column to give 137 g. (66.8% over-all yield) of γ-piperidinopropylamine.

γ-Morpholinopropylamine.—A mixture of 150 ml. of absolute ethanol, 371 g. of β-morpholinopropionitrile, 50 cc. of liquid ammonia and 25 g. of Raney nickel was reduced by shaking in the presence of 200 to 280 atmospheres pressure of hydrogen at a temperature of 105°. The theoretical amount of hydrogen was absorbed in one and one-half hours. Distillation of the reduction mixture gave 270 g. (70.6% yield) of γ-morpholinopropylamine; b. p.

(23) Dr. J. B. Dickey, private communication, has described a similar experiment using sulfuric acid as solvent and heating on the steam-bath for 65 hours which resulted in a 73% yield of N-β-cyanoethyl-7-methyltetrahydroquinoline.

(24) This material was the crude γ-chlorobutyronitrile made in 70.4% yield according to a slight modification of the directions of Charles F. H. Allen, "Organic Syntheses," Collected Vol. I, second edition, 1941, p. 156. This product as obtained here is approximately 15% γ-bromobutyronitrile and 85% γ-chlorobutyronitrile. The yield is raised from the reported 40–47% to 68–70% by extracting the reaction mixture with four portions of chloroform instead of one as recommended. The crude material is quite satisfactory for this reaction but may readily be separated into its components by fractionation through a 12-plate laboratory column.

129–132° (40 mm.), $n^{20}D$ 1.4763–1.4769. A higher boiling product, b. p. 185° (5 mm.), $n^{20}D$ 1.4923–1.4924, proved to be di-(γ-morpholinopropyl)-amine; yield 36 g. (10%).

γ-Diethylaminopropylamine.—In a similar manner 4 moles of β-diethylaminopropionitrile which had been saturated with ammonia at 7 atmospheres pressure (by attaching an ammonia tank to one of the leads of the bomb and shaking it for one-half hour) was reduced to give a 72% yield of γ-diethylaminopropylamine; b. p. 167.5–167.7° (735 mm.), $n^{20}D$ 1.4419, d^{20} 0.8254, picrate m. p. 193.5–194.0°, phenylurea derivative m. p. 66–67°, and phenylthiourea derivative m. p. 116.5–117.0°. The mixed melting point of this last substance with the phenylthiourea derivative obtained from γ-diethylaminopropylamine made by the phthalimide synthesis according to Shriner and Hickey[7] was 116.0–116.5°. Molecular refraction calculated, 41.89; observed, 41.71. The higher boiling fraction, 150–155° (15 mm.), 25 g. (5% yield), is di-(γ-diethylaminopropyl)-amine, $n^{20}D$ 1.4541; equivalent weight calculated, 81.3; found, 81.0; picrate m. p. 153.4°.

N¹-(γ-Morpholinopropyl)-sulfanilamide.—To a solution of 28.2 g. (0.2 mole) of γ-morpholinopropylamine in 150 cc. of acetone which was contained in a separatory funnel over a solution of 33 g. of potassium carbonate dissolved in 30 cc. of water was added a total of 50 g. (0.21 mole) of *p*-acetylaminobenzenesulfonyl chloride with intermittent shaking over a period of one and one-half hours. Upon completion of the addition, a white crystalline solid separated which was filtered and washed three times with 50-cc. portions of water to remove potassium carbonate and potassium chloride. The filtrate was concentrated to 100 ml. and on cooling a second crop was collected. These crystals were dried and recrystallized from acetone–water mixture to give 62.5 g. of product which melted sharply at 97°; yield 91.5%. The acetyl derivative was hydrolyzed by heating on the steam-bath with 20% hydrochloric acid for three and one-half hours. The cold hydrolysis mixture was carefully neutralized to the equivalence point with sodium hydroxide and cooled in the refrigerator overnight. The crystallized cake was recrystallized from an acetone–water mixture to give a total of 39.8 g. of N¹-(γ-morpholinopropyl)-sulfanilamide, m. p. 47–50°. On recrystallizing from acetone–ether an anhydrous crystalline product, 33.4 g., was obtained which melted at 94.5–95°; yield 70%.

TABLE III

SULFANILAMIDE DERIVATIVES

-N¹-Sulfanilamide	M. p., °C.	Yield, %	Acetyl derivative, m. p., °C.
γ-Diethylaminopropyl-	109–110	20	[a]
γ-Dipropylaminopropyl-	98–98.5	57	[a]
γ-Dibutylaminopropyl- (as hydrochloride)	110–115	53.5	[a]
γ-Piperidinopropyl-	105.5–106	63.5	109–111
γ-Morpholinopropyl-	94.5–95	79	97–98
Di-(γ-diethylaminopropyl)- (as hydrochloride)	195–197	66.5	83–85
Di-(γ-piperidinopropyl)-	74–76	71	[a]

[a] The acetyl derivatives were obtained only as thick viscous sirups which would not crystallize and were so hydrolyzed without purification.

Summary

The reaction of acrylonitrile with ammonia, primary amines, secondary amines, and amino alcohols and the reduction of the resultant beta-substituted propionitriles to the very useful γ-aminopropylamines has been studied. Twenty of these compounds are described.

γ-Aminobutyronitriles have been prepared from γ-chlorobutyronitrile and reduced to the corresponding δ-aminobutylamines.

The reduction of these basically substituted nitriles not only gives the primary amines but also basically substituted secondary amines in yields of 5 to 30%. Eleven new compounds of this type were isolated.

The procedures described offer a convenient and general method for the synthesis of γ- and δ-basically substituted alkylamines in good yields.

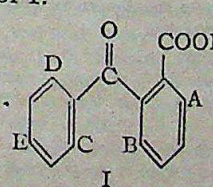
Normal and Pseudo Esters of 2-Benzoylbenzoic Acid Types. II

BY MELVIN S. NEWMAN AND BRADLEY T. LORD[1]

A study of the acid catalyzed esterification of substituted 2-benzoylbenzoic acids was undertaken in order to find out more about the structural features which determine whether normal or pseudo esters will form. In a previous publication[2] we outlined a program for the preparation of all of the substituted 2-benzoylbenzoic acids having one or more methyl groups at positions A, B, C, and D of I.



I

We have modified our program to include methyl groups at E because the compounds containing groups at C and/or D are easier to make if they also have a group at E. The presence of a group at E would not be expected to affect any results greatly.

Furthermore, by having groups at E, the preparation of the required compounds becomes more instructive because it is possible to compare the behavior of substituted phthalic anhydrides in the Friedel–Crafts and Grignard condensations. For example, it is possible to compare the behavior of 3-methylphthalic anhydride with benzene in the Friedel–Crafts reaction and with phenylmagnesium bromide since a mixture of the same keto-acids is obtained in each case.[3] It is not possible to compare these reactions using toluene and *o*-tolylmagnesium bromide because toluene

TABLE I

PROPERTIES AND YIELDS OF METHYL ESTERS

Compound	II	III	IV	V
Formula				M. p., °C. (cor.)	182.6–183.2	165.2–165.8	174.8–175.8	141.8–142.2
A (Fischer) % yield	85	34	78	90
A (Fischer) m. p., °C.	112.0–113.8	61.0–63.0	110.0–111.0	64.0–65.5
B (Normal) % yield	87	83	92	95
B (Normal) m. p., °C.	50.4–51.6	62.6–63.6	110.8–111.8	64.6–65.6
C (Pseudo) % yield	79	75	60	71
C (Pseudo) m. p., °C.	113.6–114.4	86.8–87.2	110.0–111.0	62.2–63.2

In all cases the per cent. yield means the yield of crystalline product with the indicated melting point. The total yield of ester in each case was well over 90%. Compound IV: all esters identical. Compound V: ester C different from ester A and B, the mixed melting point being 41–52°.

orients para. With *m*-xylene and 2,4-dimethylphenylmagnesium bromide, however, the same products are formed and comparison is possible. The same is true with mesitylene and 2,4-6-trimethylphenylmagnesium bromide.

In this paper we report on the esterification of 3,6-dimethyl-2-benzoylbenzoic acid, II, 3,6-dimethyl-2-(2,4-dimethylbenzoyl)-benzoic acid, III, 3,6 - dimethyl - 2 - (2,4,6 - trimethylbenzoyl) - benzoic acid, IV, and 2-(2,4-dimethylbenzoyl)-benzoic acid, V. Of these acids, II, III, and V could be converted into two different methyl esters. As in the previous cases[2] the esters formed with diazomethane were assumed to be normal esters whereas those formed by treatment of the acid chlorides with methanol and pyridine were assigned the cyclic structure. We have confirmed this assignement of structure by ultraviolet absorption spectra studies.[4] Acid IV gave only the normal ester under all conditions of esterification tried, as was the case previously with 2 - (2,4,6 - trimethylbenzoyl) - benzoic acid.[2] The behavior of the acids II, III, IV, and V on Fischer–Speier esterification and the properties of the various esters are indicated in Table I.

The preparation of acids II, III, and IV is described in the following publication.[5]

Experimental

2-(2,4-Dimethylbenzoyl)-benzoic Acid, V.—This acid was prepared by the condensation of phthalic anhydride with *m*-xylene[6] in sulfur-free benzene. The yield of crude acid, m. p. 139–141°, was 95%. On recrystallization from benzene, the pure acid V, m. p. 141.8–142.2° cor., was obtained.

Preparation of Methyl Esters.—The esters in columns A, B, and C of Table I were made by (A) refluxing the acid in absolute methanol containing dry hydrogen chloride, (B) treatment of the acid with ethereal diazomethane, and (C) treatment of the acid chloride with methanol and pyridine. The esters were isolated as described in detail in previous work.[2] The analyses of the new esters formed are given in Table II.

The Behavior of 3,6-Dimethylphthalic Anhydride in Friedel–Crafts and Grignard Condensations

BY MELVIN S. NEWMAN AND BRADLEY T. LORD[1]

While preparing certain compounds required in another investigation[2] we obtained some results which were not at all what we expected. Because of their bearing on the mechanisms of the Grignard and Friedel–Crafts reactions, we are reporting these results separately.

The Grignard Reaction.—Many believe that the first step in the reaction of Grignard reagents with esters or acid halides consists in addition to the carbonyl group.[3] An alternate mechanism supposes a metathetical reaction involving the carbon–oxygen single bond in esters and the carbon–halogen bond in acid halides.[4]

As an outgrowth of many studies of the reactions of Grignard reagents with substituted phthalic anhydride types, we have become interested in this same choice of mechanisms as applied to anhydrides. In previous work it was found that when Grignard reagents reacted with unsymmetrical phthalic anhydride types, substituents ortho to one of the carboxyl functions cut down reaction at this group.[5] A more careful study of the reaction of phenylmagnesium bromide on 3-methylphthalic anhydride[6] showed that the ratio of products of reaction at the carboxyl in the unhindered position (position 1) to products of reaction at the hindered carboxyl (position 2) was about 3. This ratio is lower than one would expect on the assumption that condensation takes place exclusively by addition to the carbonyl groups.

Because of the hindrance to both carbonyl groups in 3,6-dimethylphthalic anhydride it was expected that reaction with the Grignard reagent would take place with difficulty if at all. However, this anhydride reacted smoothly with phenylmagnesium bromide to give the expected 3,6-dimethyl-2-benzoylbenzoic acid in 81% yield. Successful condensations also took place with 2,4-dimethyl- and 2,4,6-trimethylphenylmagnesium bromides (see Table I). These condensations provide evidence that Grignard reagents may react with anhydrides by a metathetical mechanism involving the carbon–oxygen single bond. The successful competition of the metathetical reaction with the addition reaction is probably responsible for the above-mentioned low ratio in the case of 3-methylphthalic anhydride and similar anhydrides.

The Friedel–Crafts Reaction.—Little or nothing is known about the effect of steric hindrance on the ease of reaction of acylating agents in the Friedel–Crafts reaction. Several 3-substituted phthalic anhydrides have been condensed with aromatic derivatives but in most cases the separation and identification of the isomeric keto-acids were not carried out carefully enough for valid conclusions to be drawn.[7] Frequently a preference for condensation at the 2-position was noted.

In previous work with benzene and 3-methylphthalic anhydride, we determined that condensation at the 1- and 2-positions took place to almost the same extent.[6] Consequently we expected that 3,6-dimethylphthalic anhydride would condense readily with benzene. However, after refluxing for five hours, 78% of the anhydride was recovered with the production of only 12% of keto acid. Heating in *sym*-tetrachloroethane solution at 100° for eight hours was required for complete disappearance of anhydride yet only 57% of keto-acid was obtained. No obvious explanation of the contrasting behaviors of 3-methyl- and 3,6-dimethylphthalic anhydrides is apparent. However, with the more reactive *m*-xylene 3,6-dimethylphthalic anhydride condensed readily. The condensations of 3,6-dimethylphthalic anhydride with benzene, *m*-xylene, and mesitylene are summarized in Table I.

The keto-acids resulting from condensations with benzene and *m*-xylene were reasonably pure as first isolated. The acid fractions from reaction with mesitylene, however, had wide melting ranges. Although this suggested that rearrangement of the methyl groups might have taken place, the mesitylene recovered was pure. In order to establish the structure of 3,6-dimethyl-2-(2,4,6-trimethylbenzoyl)-benzoic acid, it was decarboxylated to 2,4,6,2′,5′-pentamethylbenzophenone. This new ketone, synthesized by condensing 2,5-dimethylbenzoyl chloride with mesitylene, proved identical with the decarboxylation product.

The 3,6-dimethylphthalic anhydride used was prepared by the dehydration in 90% sulfuric acid of the adduct of dimethylfuran and maleic anhydride.[8]

Experimental[9]

3,6-Dimethylphthalic Anhydride.—To a well-stirred suspension of 49 g. (0.5 mole) of freshly distilled maleic anhydride in 50 cc. of dry ether was added slowly 48 g. (0.5 mole) of 2,5-dimethylfuran.[10] After stirring for four and one-half hours at room temperature, during which the maleic anhydride dissolved and crystals of adduct began to separate, the mixture was cooled in an ice–salt-bath for one hour. The liquid was drawn off through a filter stick using cheesecloth and the air-dried pinkish crystals, m. p. 59–63°, weighed 82.7 g. (85%).[8] The neutral equivalent of this crude product was 96.6 (calcd. 97.1). Dehydration was best accomplished by slowly adding 81.6 g. (0.42 mole) of the above powdered adduct to 800 cc. of 90% sulfuric acid at −6 to 0°. The solution was agitated for one-half hour at 0° and the temperature then allowed to rise to 10°. After pouring on 2 kg. of ice the light brown precipitate was collected, washed with ice water, and dissolved in 600 cc. of water containing 30 g. of sodium hydroxide. Upon addition of 50 cc. of glacial acetic acid 5.3 g., m. p. 132–134°, of crude 2,5-dimethylbenzoic acid was obtained. From the filtrate 38.4 g. (52%) of crude 3,6-dimethylphthalic anhydride, m.p. 139–142°, was obtained by strongly acidifying with hydrochloric acid. On crystallization from benzene 21.8 g. (29%) of pure anhydride, m. p. 142–143°, and 12.0 g. (16%) of anhydride, m. p. 140–142°, were obtained. Some reagents found unsuitable for dehydration included dry hydrogen chloride and phosphorus pentoxide in benzene, sodium sulfate, acetyl chloride, and acetic anhydride. Although it is reported that[11] the addition of hydrochloric acid to a solution of the sodium salt of 3,6-dimethylphthalic acid precipitated the free acid, we were unable to confirm this fact. In our hands, such treatment precipitated white plates which melted without any evidence of dehydration at 142–143° and showed no depression when mixed with authentic anhydride, m. p. 142–143°. Samples of supposed acid, precipitated at 0° and dried over calcium chloride at room temperature or recrystallized from ether by cooling with dry-ice showed the correct neutralization equivalent (88) and carbon–hydrogen values[b] (C, 67.9, 67.8; H, 4.3, 4.5) for the anhydride.

Grignard Reactions.—One molar equivalent of the appropriate Grignard reagent in ether was added to a stirred benzene solution of the anhydride. The mixture was heated until the ether was removed and then refluxed for the indicated time (see Table I). An ether–benzene solution of the hydrolyzed reaction products was shaken with carbonate. The keto-acid was liberated with acetic acid and crystallized once from a suitable solvent. The unreacted anhydride was recovered after strong acidification with mineral acid. The original ether–benzene extract contained varying amounts of phthalide-like material not further examined.

Friedel–Crafts Reactions.—A slight excess of anhydrous aluminum chloride (Calco Standard) was added to a suspension of the anhydride in the reacting hydrocarbon, with or without added solvent. The reaction mixture was stirred for varying times before warming produced moderate or copious evolution of hydrogen chloride. Heating and stirring were then increased as dictated by gas evolution. When this slowed considerably the mixture was poured on ice and the products isolated as described under Grignard reactions.

2-Benzoyl-3,6-dimethylbenzoic Acid.—This acid was recrystallized from benzene and finally from alcohol for analysis to a constant melting point of 182.6–183.2° cor. It formed dense colorless plates.

Anal. Calcd. for $C_{16}H_{14}O_3$: C, 75.5; H, 5.6. Found[a]: C, 75.9, 75.6; H, 5.7, 5.7.

2-(2,4-Dimethylbenzoyl)-3,6-dimethylbenzoic Acid.—This acid, m. p. 165.2–165.8° cor., was crystallized from benzene for analysis.

Anal. Calcd. for $C_{18}H_{18}O_3$: C, 76.6; H, 6.4. Found[b]: C, 76.5, 76.4; H, 6.7, 6.5.

2-(2,4,6-Trimethylbenzoyl)-3,6-dimethylbenzoic Acid.—This acid separated from benzene as transparent prisms which became opaque on drying to constant weight, evidently losing benzene of crystallization. The pure crystals melted at 174.8–175.6° cor.

Anal. Calcd. for $C_{19}H_{20}O_3$: C, 77.0; H, 6.8. Found[b]: C, 76.9, 76.9; H, 6.9, 6.9.

2,2′,4,5′,6-Pentamethylbenzophenone (by Decarboxylation).—A mixture of 0.78 g. of the above acid and 0.66 g. of its copper salt was heated at 192–195° for one hour. On vacuum distillation and crystallization from ether by cooling in dry-ice 0.28 g. of white needles, m. p. 74–78°, was obtained. Recrystallization from alcohol yielded the pure ketone, m. p. 77.0–78.0° cor.

By Friedel–Crafts Reaction.—To a cold solution of 8.6 g. of pure mesitylene and 6.5 g. of pure 2,5-dimethylbenzoyl chloride in 50 cc. of carbon bisulfide was added in portions 5.7 g. of aluminum chloride. Immediate gas evolution was followed by the appearance of a bright orange complex. After stirring at room temperature for twenty-five minutes

(8) Diels and Alder, *Ber.*, **62**, 554 (1929).

(9) All melting points, except those corrected, were taken with the same thermometer which was calibrated within one degree of a standard thermometer. All benzene used in condensations was sulfur-free. Analyses marked *a* by J. E. Varner and *b* by Jean Anderson.

(10) The authors thank Professor C. E. Boord for gifts of purified dimethylfuran and *m*-xylene by the American Petroleum Institute Project at the Ohio State University.

Digitized by Arya Samaj Foundation Chennai and eGangotri

and refluxing for one hour, the reaction mixture was poured on ice. Vacuum distillation yielded 9.0 g. (90%) of a pale green liquid, b. p. 147–148° at 3 mm., m. p. 76–78°. A sample recrystallized from alcohol for analysis melted at 77.0–78.0° cor. A mixed melting point with the decarboxylation product was not depressed.

Anal. Calcd. for $C_{18}H_{20}O$: C, 85.7; H, 8.0. Found[b]: C, 85.7, 85.6; H, 7.9, 8.0.

Summary

Evidence is provided that when Grignard reagents react with phthalic anhydride types, the mechanism involves reaction both by addition to the carbonyl group and metathetical reaction by cleavage of the carbon–oxygen single bond. A series of reactions of 3,6-dimethylphthalic anhydride with Grignard reagents and with aromatic hydrocarbons is described.

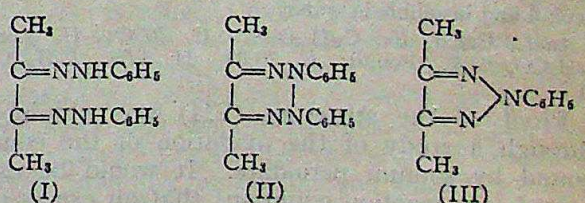
The Action of Copper Sulfate on Phenylosazones of the Sugars. Phenyl-D-glucosotriazole

BY RAYMOND M. HANN AND C. S. HUDSON

In a previous communication[1] it was shown that the phenylhydrazides of the aldonic acids of the sugar group are readily decomposed in hot aqueous copper sulfate solution with the production of nitrogen, benzene and the free sugar acid; the reaction appears to proceed quantitatively, as is evident from the fact that upon removal of the inorganic materials and concentration of the solution, a nearly theoretical yield of lactone of the acid is obtained. It seemed of interest to test the action of copper sulfate solutions on the phenylosazones of the sugars. They are known to reduce Fehling solution but no record has been found of a test with copper sulfate under acid conditions.

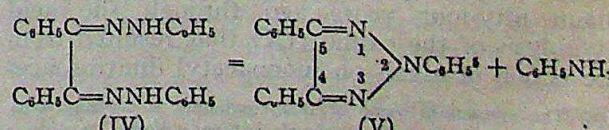
In the initial experiments a suspension of pulverized phenyl-D-glucosazone (5.0 g.) in 600 cc. of an aqueous solution containing two molecular equivalents (7.0 g.) of copper sulfate pentahydrate was boiled under reflux,[2] most of the osazone dissolved in one hour and as the reaction progressed the precipitation of a small amount of copper or cuprous oxide was noted and the color of the solution changed from blue to green. At the end of a second hour only traces of undissolved osazone remained; the mixture was filtered hot and from the filtrate, while still warm, glistening needle crystals separated. They were filtered from the cooled solution and a second crop was obtained by concentration of the mother liquor to 100 cc.; the total yield of product, which proved to be nearly pure though its color was tan from adsorbed dye, was 2–3 g. It was obtained as colorless pure asbestos-like crystals by recrystallizing once or twice from one hundred parts of boiling water and filtering through a bed of decolorizing carbon in a steam-heated Buchner funnel. The substance melts sharply at 195–196° without decomposition and the cooled melt crystallizes; the compound is very stable. It is not sufficiently soluble in water at ordinary temperatures to permit observation of its rotation, but in pyridine its specific rotation $[\alpha]^{20}D$ was −81.6° (*c*, 0.8). The crystals are anhydrous and their analysis showed 54.44% carbon, 5.71% hydrogen and 15.78% nitrogen (Dumas), values which lead to the formula $C_{12}H_{15}O_4N_3$.

It will be observed that the empirical formula of the substance differs from that of phenyl-D-glucosazone by the elements of aniline, as though the reaction might be $C_{18}H_{22}O_4N_4 = C_{12}H_{15}O_4N_3 + C_6H_5NH_2$. Aniline was indeed detected in the mother liquor by removing the copper as sulfide, making the solution alkaline, extracting it with ether and converting the oily residue from the evaporation of the ether extract to acetanilide (yield, 20%). The evidence led to the possibility that the substance might belong to the class of osotriazoles of v. Pechmann,[3] which are very stable substances. In the case of diacetyl diphenylhydrazone (I), he showed that it was converted by oxidation with potassium dichromate in dilute acetic acid to an osotetrazone (II), which with stronger acidity (HCl) gave a 20% yield of the osotriazole (III). The latter reaction is evidently complex; much tar was produced and aniline was detected.



(I) (II) (III)

A direct conversion of an osazone type of compound to the corresponding osotriazole was reported by Auwers and Victor Meyer,[4] who heated benzil diphenylhydrazone (IV) in alcohol solution at 200° and obtained 2,4,5-triphenylosotriazole (V) and aniline.



(IV) (V)

(1) Hann and Hudson, THIS JOURNAL, 56, 957 (1934).

(2) The osazone is difficult to wet and foaming during the first half hour was troublesome; in later experiments this was much reduced by the addition of a few cc. of *n*-butyl alcohol. It was also found that the reaction proceeds equally well but somewhat slower on the steam-bath; the best solvent that has been found so far is acidified 40% isopropyl alcohol at its boiling point, as is described further on.

(3) v. Pechmann, *Ber.*, **21**, 2751 (1888); *Ann.*, **262**, 265 (1891).

(4) Auwers and Victor Meyer, *Ber.*, **21**, 2806 (1888).

(5) The numbering is that of formula No. 77 of Patterson and Capell's "The Ring Index," Reinhold Publishing Corporation, New York, N. Y., 1940. The name osotriazole, introduced by v. Pechmann, implies the 2,1,3-triazole that is related to osazones.

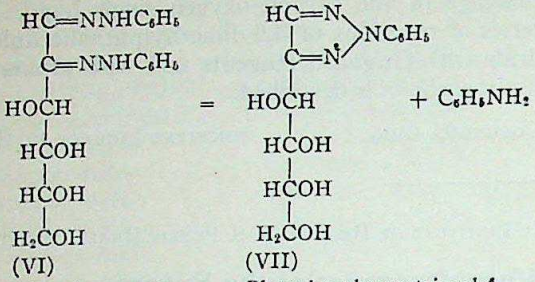
An analogous course for the phenyl-D-glucosazone reaction would be expressed by formulas (VI) and (VII).



(VI) Phenyl-D-glucosazone

(VII) Phenyl-D-glucosotriazole[6]

As previously mentioned, the analysis of the derivative agrees well with this postulated osotriazole structure; it was also found that the substance yields a crystalline tetraacetate and tetrabenzoate, as would be expected if it possesses this structure.

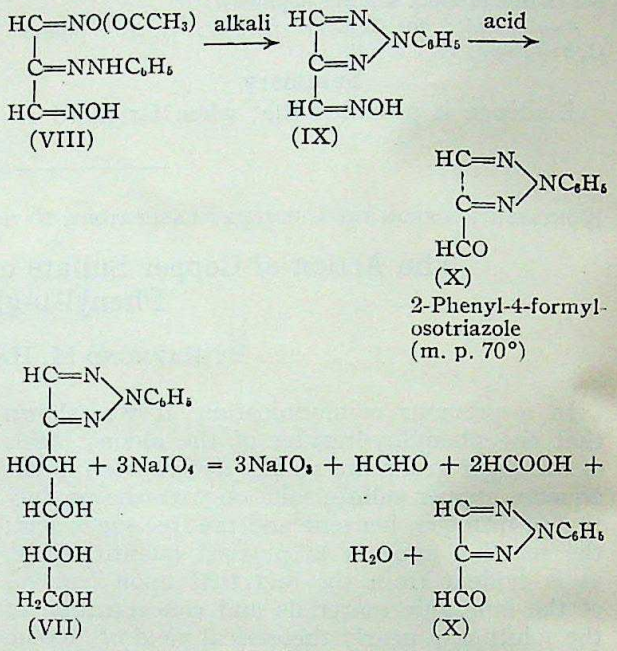
Phenyl-D-glucosotriazole Tetraacetate.—A solution of 1.0 g. of the osotriazole in a mixture of 15 cc. of pyridine and 15 cc. of acetic anhydride was kept at 25° for eighteen hours and then poured upon crushed ice; the product, which was obtained in nearly quantitative yield, was recrystallized from 5 parts of methyl alcohol. The pure substance melts at 81–82°, shows $[\alpha]^{20}D$ −25.6° in chloroform (*c*, 0.92), and its minute needle crystals are easily soluble in acetone and ethyl acetate and insoluble in water.

Anal. Calcd. for $C_{20}H_{23}O_8N_3$: C, 55.42; H, 5.35; CH_3CO, 39.7. Found: C, 55.53; H, 5.49; CH_3CO, 39.7.

Phenyl-D-glucosotriazole Tetrabenzoate.—Benzoyl chloride (4.0 cc.) was mixed with an ice-cold solution of 1.1 g. of the osotriazole in 15 cc. of pyridine and the mixture kept at room temperature for eighteen hours. On pouring it into water the gummy benzoate precipitated; this mass was repeatedly triturated with fresh water and after several days it crystallized in nearly quantitative yield, and was recrystallized from 15 parts of alcohol. The fine needles show m. p. 112–113° and $[\alpha]^{20}D$ +3.0° in chloroform (*c*, 0.92); they are soluble in acetone, ether and hot alcohol and insoluble in water.

Anal. Calcd. for $C_{40}H_{31}O_8N_3$: C, 70.47; H, 4.58; C_6H_5CO, 61.7. Found: C, 70.34; H, 4.63; C_6H_5CO, 61.7.

Proof of the structure (VII) was obtained through a study of the oxidation of the compound by sodium periodate. It would be expected (see reaction equation) that an excess of the oxidant would generate in quantitative manner one mole of formaldehyde, two moles of formic acid and one mole of the aldehyde (X), and that three moles of the oxidant would be reduced. Luckily, the substance having structure (X) is known; it was produced by v. Pechmann fifty-four years ago through the acid hydrolysis of the oxime (IX) that resulted from the action of alkali on monoacetyl dinitrosoacetone phenylhydrazone (VIII). The quantitative measurements confirmed these expectations, and v. Pechmann's aldehyde (X) was obtained from this oxidation in a high yield.



(VIII) (IX) (X)

2-Phenyl-4-formyl-osotriazole (m. p. 70°)

Sodium Periodate Oxidation of Phenyl-D-glucosotriazole.—A suspension of 0.5078 g. of phenyl-D-glucosotriazole in a mixture of 50 cc. of water and 15 cc. of 0.428 *M* aqueous sodium periodate solution (3.35 molecular equivalents) was agitated at 25° for twenty-four hours; the appearance of the suspended crystals changed from that of long fine needles to shorter and more thickened ones; the crystals were removed by filtration and washed well with cold water, the filtrate and washings being finally adjusted to a volume of 100 cc. and analyzed as described in the following paragraph. The crystals melted at 68–69° and this value was not changed by recrystallization, which was accomplished by dissolving them in sixteen parts of alcohol and adding thirty-two parts of water. The substance possesses a faint sweetish odor, as was noted by v. Pechmann, who records the m. p. as 70°. Warming the crystals in the closed palm of the hand accentuates the odor, which we would describe as being suggestive of that from geraniol. The crystals weighed 0.28 g., which corresponds to 0.84 mole per mole of phenyl-D-glucosotriazole. The method makes this rare and interesting aldehyde, 2-phenyl-4-formyl-osotriazole, easily available from common phenylglucosazone through the easily prepared phenylglucosotriazole.

(VII) (X)

Anal. Calcd. for $C_9H_7ON_3$: C, 62.41; H, 4.07. Found: C, 62.46; H, 4.07.

The filtrate from the crystals of the aldehyde was analyzed for other oxidation products as follows: one 20-cc. aliquot was titrated for excess periodate by the usual iodine–arsenite procedure and it was found that 3.03 molecular equivalents of oxidant had been reduced; a second 20-cc. aliquot was titrated with 0.1 *N* sodium hydroxide, using methyl red as indicator, and the observed 7.38 cc. of alkali indicated the production of 1.93 molecular equivalents of formic acid; a third 20-cc. aliquot was added to 100 cc. of 0.4% dimethone solution and the 0.1130 g. of formaldimethone which crystallized corresponded to the formation of 1.01 molecular equivalents of formaldehyde.

The transformation of phenyl-D-glucosazone to phenyl-D-glucosotriazole (m. p. 195–196°, yield 67%) by copper sulfate is apparently a general reaction with all the sugar phenylosazones.

(6) The systematic name of this compound is 2-phenyl-4-[D-*arabino*-tetrahydroxybutyl]-osotriazole, which indicates in only a veiled way the genetic relationship of the substance to phenyl-D-glucosazone. We give it an alternative common name **phenyl-D-glucosotriazole.** An additional reason for such a designation is the fact that the systematic names in the disaccharide group are so very complicated that common names (phenyllactosotriazole, etc.) seem necessary in those cases and advisable consequently in the monose series.

Crystalline phenylosotriazoles, the sharp melting points and yields of which are indicated, have been prepared by this reaction from the phenylosazones of the following additional sugars; L-sorbose (158–159°, 50%), D-galactose (110–111°, 47%), D-altrose (134–135°, 62%), D-xylose (88–90°, 40%), cellobiose (164–165°, 62%), lactose (180–181°, 62%), and turanose (193–194°, 70%). These will be described at length in a later article. All of them are much more soluble in water than the glucose derivative. The exceptionally low solubility of phenyl-D-glucosotriazole, its ease of spontaneous crystallization, stability and sharply characteristic m. p., rotation and crystalline appearance, lead us to recommend this substance for use in confirming the identity of phenylglucosazone, especially in the case of small samples.

Confirmatory Test for Phenyl-D-glucosazone.—A suspension of 0.2 g. of powdered osazone in a solution composed of 18 cc. water, one cc. 0.5 *N* sulfuric acid, 0.6 g. of copper sulfate pentahydrate and 12 cc. of isopropyl alcohol, is refluxed for one hour, using a piece of porous plate to ensure even boiling. The osazone dissolves within fifteen minutes and the solution shows a deep red color. During the next half hour the red fades to orange and finally to yellowish green. The solution is concentrated on the steam-bath by an air current to about 5 cc.; crystallization of the osotriazole occurs during this operation and is increased by keeping the mixture three hours in the refrigerator. The tan colored precipitate is removed by filtration, washed with water, boiled with 30 cc. water and 0.1 g. decolorizing carbon, and the solution filtered hot. On keeping the colorless filtrate cold overnight the long needle crystals of pure osotriazole separate; wt. 20–40 mg., m. p. 195–196°; 18.3 mg. in 25 cc. pyridine solution rotated α_D −0.23° in a 4-dm. tube, the calculated value being −0.24°. Methyl alcohol may be substituted for isopropyl alcohol in these directions if the refluxing time is increased to two hours; yield, 56 mg., m. p. 195–196°, observed rotation for 50 mg. in 25 cc. of pyridine solution, 4-dm. tube, −0.64°, calculated −0.65°. Obviously, the test would be applicable likewise to a small sample of phenyl-L-glucosazone, and dextro-rotation would be observed for its osotriazole; any aid to the positive detection in nature of the L-forms of glucose, mannose or fructose seems worth mentioning because of the biological interest that is involved.[7]

Phenyllactosotriazole is hydrolyzed by acids at nearly as fast a rate as lactose; on cooling the hydrolysis solution, phenyl-D-glucosotriazole crystallizes rapidly and the filtrate from this substance yields crystalline D-galactose readily after removal of the mineral acid.

Curiosity naturally arises concerning the mode of action of copper sulfate in bringing about so easily this splitting of the phenylosazone molecule to phenylosotriazole and aniline. The gross equation of the reaction does not show any role of the copper salt. Some reduction of the latter is always noticed but this may be the result of side reactions, the occurrence of which is indicated by the fact that the yields of osotriazole are always much below quantitative. The great stability of the osotriazole ring may be the factor underlying the reaction; apparently the presence of the copper salt opens a path by which the reaction can proceed at good speed. Independent of speculations, it is demonstrable that the main reaction takes place in two successive stages, which are visually apparent if conditions are favorable for fairly rapid solution of an osazone. Phenylturanosazone (8.6 g.) was readily soluble in 170 cc. water at 90° to form an ordinary yellow osazone solution; a hot solution of 13 g. of copper sulfate pentahydrate in 90 cc. water was prepared separately; on mixing the two solutions an intense red color appeared instantly, indicating that the formation of the osazone–copper ion complex is instantaneous when the components are in solution; on the steam-bath the solution lightened in color to become orange and finally green, all within ten minutes, which gives an approximate measurement of the speed of the second stage of the reaction in the case of this osazone. The complex is red colored, the osotriazole is colorless and the green color is that of residual copper sulfate in the presence of aniline and products from the side reactions. The following experiment shows the formation of the complex at room temperature: when a mixture of 2 g. of phenyllactosazone and 1 g. of copper sulfate crystals was shaken with 200 cc. of 85% methyl alcohol the osazone and some copper sulfate dissolved in one hour to yield a clear brownish-red solution, which did not change in twenty-four hours. Decanting this solution and removing the copper from it as sulfide, left a light yellow filtrate from which crystalline phenyllactosazone was recovered in good yield by concentration *in vacuo* to 50 cc. When phenylglucosazone is refluxed with aqueous copper sulfate solution no red color is noticed; evidently the rate of solution is so slow that the complex is never present in sufficient quantity to affect the blue or green color of the copper salt. However, in the confirmatory test for phenylglucosazone the rate of solution is rapid and the gradual change of color from red to orange and finally green, is observed. The rate of the second stage of the reaction is doubtless a characteristic of each osazone as it appears to be more rapid for phenylturanosazone than for phenylglucosazone; mild mineral acidity appears to increase the rate of this second stage. The various experiments lead us to believe that the role of the copper sulfate in the osazone–osotriazole reaction is that of a promoter which forms an unstable complex with the osazone and thereby opens a path for a speedy formation of the highly stable osotriazole ring by the splitting out of aniline from the osazone.

Thanks are expressed to Dr. W. T. Haskins for assistance in the experimental work and to Dr. A. T. Ness for carrying out the microchemical analyses.

(7) Although L-glucose has been reported to occur in *Grindelia robusta* [Power and Tutin, *Pub. Wellcome Chem. Research Lab.*, **57**, 1 (1905)], in capsularin, a glycoside from jute (*Corchorus capsularis*) [Saha and Choudhury, *J. Chem. Summary

The preparation of a new type of sugar derivative is described. The heating of a suspension of phenyl-D-glucosazone with an aqueous solution of copper sulfate causes the production of aniline and a very stable substance which proves to be a substituted osotriazole, now named phenyl-D-glucosotriazole. Proof of the structure of the substance has been obtained through the oxidation by sodium periodate to yield v. Pechmann's 2-phenyl-4-formyl-osotriazole. The role played by the copper sulfate apparently concerns an osazone–copper ion complex, of deep red color, the formation of which is readily observable in the case of easily soluble osazones. Phenyllactosotriazole is hydrolyzed by mineral acids at nearly as fast a rate as lactose and yields phenyl-D-glucosotriazole and D-galactose. The phenylosotriazoles from several other sugars are mentioned, in advance of later full publication; the reaction is a general one for sugar phenylosazones and the yields are good. Owing to the very low solubility of phenyl-D-glucosotriazole and its high tendency to crystallize, its production from phenyl-D-glucosazone is a useful confirmatory test for the latter substance, especially for small quantities of it.

The Hydrolysis of Trimethylethylene Bromide. Mechanism of Ketone Formation

BY C. M. SUTER[1a] AND HARRY D. ZOOK[1b]

It has long been known that the hydrolysis of certain olefin bromides results in the formation of carbonyl compounds. Eltekoff[2] obtained acetaldehyde and ethylene glycol from ethylene bromide or chloride, acetone and propionaldehyde from the propylene halides, isobutyraldehyde from isobutylene bromide and methyl isopropyl ketone from trimethylethylene bromide. His procedure consisted in heating the halide with lead oxide and water to 140–150°. The formation of methyl isopropyl ketone also has been studied by Ipatieff[3a] and more recently by Whitmore and Evers,[3b] who found the use of lead oxide or a high temperature unnecessary. This reaction is now the most convenient source of the ketone.[4] Some other olefin bromides give aldehydes or ketones on hydrolysis but the yields are not large.[5]

Little consideration has been given to the mechanism by which the olefin halides are converted to the carbonyl compounds. Eltekoff[2] found that the longer a halide was heated with water and lead oxide the larger the yield of aldehyde or ketone and the smaller the amount of glycol. He concluded, therefore, that the dehydration of the glycol in the slightly acidic solution was the source of the carbonyl compound. He further found that trimethylethylene glycol was converted to the ketone when its aqueous solution was heated to 220°. Ayres[6] has shown that tetramethylethylene bromohydrin when heated to 100° in the dry state or when shaken with aqueous silver nitrate or oxide yields pinacolone directly without intervention of the glycol. Some time ago Whitmore[7] suggested that ketone formation from a dibromide occurred without involving either a bromohydrin or glycol as an intermediate.

$$(CH_3)_2CBrCHBrCH_3 \xrightarrow{H_2O} [(CH_3)_2C^+CHBrCH_3] \longrightarrow$$
$$[(CH_3)_2CHC^+BrCH_3] \xrightarrow{H_2O} (CH_3)_2CHCOCH_3$$

However, behavior of indene bromide where the halogen adjacent to the benzene ring shows about the same activity as that of a tertiary alkyl halide, is not in accord with this mechanism.[8] Here indene bromohydrin is the primary hydrolysis product and this may be converted to 1-indanone or through the glycol to 2-indanone. If the bromohydrin were an intermediate in the hydrolysis of trimethylethylene bromide, ketone formation could occur either directly with the shift of a methyl group or indirectly by way of the glycol, but in the case of isobutylene bromide, the bromohydrin should give methyl ethyl ketone, whereas only isobutyraldehyde has been observed. Here, at least, it seemed clear that if the bromohydrin is an intermediate, so also is the glycol. In the present investigation a detailed study has been made of the hydrolysis of trimethylethylene and isobutylene bromides, mostly in dioxane–water mixtures.

As was pointed out recently by Vaughan and Rust,[9] pure trimethylethylene bromide has not been described. The action of bromine upon *t*-amyl alcohol gives a product from which a mix-

ture of isomeric dibromides may be separated by distillation but these resist further purification by this means. The bromination of trimethylethylene gives a mixture of substitution and addition products from which by fractional distillation and crystallization the dibromide has now been isolated in a state of satisfactory purity. To get an equally pure product from the isomeric dibromides obtained directly from *t*-amyl alcohol required some thirty crystallizations and gave a low yield.

In a preliminary experiment involving 0.058 *M* trimethylethylene bromide in 50% by volume aqueous dioxane at 80°, it was found that over 90% of the theoretical amount of hydrobromic acid was formed in twenty-five minutes but that no appreciable amount of ketone had appeared. After ten hours ketone formation still amounted to less than 20% of the theoretical amount. This at once indicated that the hydrolysis of the bromides was in no way directly related to the formation of methyl isopropyl ketone. That the ketone arises from trimethylethylene glycol through the catalytic action of the hydrogen ions in the solution was confirmed by preparing the pure glycol and measuring the rate at which it was converted to the ketone under various conditions. In dilute (0.11 *M*) sodium carbonate solution at reflux temperature no detectable amount of ketone resulted in thirteen hours. In distilled water the odor of ketone became noticeable within an hour and at the end of six hours, the ketone present corresponded to 1.2% of the theoretical amount. The solution had, however, become slightly acidic due to some side reaction and it appears that some decomposition with formation of a trace of acid preceded ketone formation. Measurements in sulfuric and hydrobromic acid solutions showed that the reaction rate was dependent upon the hydrogen ion activity. The rate of ketone formation in a solution made by dissolving trimethylethylene bromide in water by stirring for some time at 80° was in agreement with that in a solution obtained by adding the glycol to hydrobromic acid. The value of K, the first order constant, showed some decrease as the reaction progressed, probably due to side reactions among which was the formation of the unidentified acidic substance already mentioned. At 80° the initial value of K was 0.20 hours^{-1} decreasing to 0.18 hours^{-1} at half reaction where

$$K = \frac{2.3}{t\gamma[H^+]} \log \frac{a}{a - x}$$

Several methods of estimating methyl isopropyl ketone were investigated in some detail.[10] It was found that precipitation with 2,4-dinitrophenylhydrazine was unsatisfactory since ketone solutions less than 0.01 *M* in 3:2 dioxane–water mixtures gave negative tests. Messinger's iodoform method[11] which works well for acetone gave somewhat variable results. The amount of iodine consumed in 3:2 dioxane–water solutions for ketone concentrations ranging from 0.01 *M* to 0.1 *M* corresponded to 50 ± 5% of the theoretical amount based upon the equation

$$C_6H_{10}O + 4I_2 + 5NaOH \longrightarrow (CH_3)_2CICOONa + CHI_3 + 4H_2O + 4NaI$$

The analytical method finally adopted was based upon that of Marasco[12] for acetone. The reaction of the ketone with hydroxylamine hydrochloride was found to be 66 ± 3% complete for ketone solutions of concentrations ranging from 0.01 *M* to 0.1 *M* made up in 3:2 dioxane–water solution. In distilled water the reaction was 58 ± 2% complete. In both cases the percentage decreased rapidly for lower concentrations being 51% for 0.005 *M* ketone in water.

The formation of hydrogen bromide from trimethylethylene bromide occurred at a convenient rate at 45° and most of the hydrolysis measurements were made at this temperature. It was first found that acid formation occurred by a first order reaction since changing the initial concentration did not change k_1. This is a characteristic of the halogen in simple tertiary alkyl halides.[13] Under some circumstances olefin formation is known[14] to accompany hydrolysis but this was unimportant for the dibromide.[15] However, when the value of k_1 for the hydrolysis of the dibromide to the bromohydrin was determined for various time intervals on the assumption that no other reaction was taking place, the value increased regularly with time. This is what would be expected if the bromohydrin were undergoing conversion to the glycol at a rate comparable to that of the first reaction. A satisfactory value was obtained for k_1 by plotting its apparent value against time and extrapolating to zero time.

$$(CH_3)_2CBrCHBrCH_3 \xrightarrow[H_2O]{k_1} (CH_3)_2COHCHBrCH_3 \xrightarrow[H_2O]{k_2} (CH_3)_2COHCHOHCH_3$$

With k_1 known, the quantity of hydrobromic acid formed at a given time from the first hy-

(10) It is interesting to note that although methyl isopropyl ketone is the only carbonyl compound that has been isolated from this hydrolysis, 2,3-dihydroxybutane gives some dimethylacetaldehyde along with methyl ethyl ketone when heated with aqueous sulfuric acid. The former compound is formed by a methyl rearrangement of the pinacol–pinacolone type. Akabori, *J. Chem. Soc. Japan*, **59**, 1132 (1938); *Chem. Abs.*, **33**, 2106 (1939). NOTE ADDED IN PROOF: Cook, Krimmel and Whitmore have just reported (A. C. S. meeting at Cleveland) that up to 1% of trimethylacetaldehyde is formed in the hydrolysis of trimethylethylene bromide.

(15) This was evident since heating trimethylethylene bromide with water gave only water soluble products and gave also the theoretical amount of hydrobromic acid. 2-Methyl-3-bromo-2-butene would be water insoluble and inert to further hydrolysis. Ipatieff[2] has shown that alcoholic potassium hydroxide acts with the dibromide to produce this unsaturated compound.

drolysis was calculated and subtracted from the quantity found by titration. The excess was a measure of the extent to which the bromohydrin had hydrolyzed and the difference between the concentration of acid from the first reaction and that of the second gave the concentration of bromohydrin. The value of k_2 was then obtained by a graphical method[16] from the equation for two consecutive first order reactions

$$y = a + \frac{ak_1}{k_1 - k_2}e^{-k_1t} - \frac{ak_1}{k_1 - k_2}e^{-k_2t}$$

Here y is the concentration of hydrobromic acid from the second reaction at time t and a is the initial dibromide concentration. The calculation of k_2 for various time intervals showed a decrease with time but the initial value corresponded approximately to that of k_1.

The decrease of k_2 with time led us to consider another mechanism for the formation of glycol from dibromide. If it is assumed that the second bromine hydrolyzes at the same time as the first or that the second reaction occurs with great rapidity compared with the first, the hydrolysis data could be expressed by $k^*t = 2.3 \log a/(a - 0.5\ z)$, where a is the initial concentration of dibromide and z is the concentration of hydrobromic acid. As may be seen in Table I this hypothesis fits the experimental results with considerable accuracy.

TABLE I

Time, min.	$k_1 \times 10^4$ (apparent value)[a]	$k_2 \times 10^4$	$k^* \times 10^4$

[a] Extrapolation to zero time in this and other experiments gave $k_1 = 0.0021$ at 45°.

Trimethylethylene bromohydrin was then prepared and its hydrolysis studied. In brief, its hydrolysis rate was in agreement with that deduced from the experiments on dibromide hydrolysis, the rate exhibiting the same decrease with time. It was therefore necessary to decide experimentally between the two mechanisms. If k_1 and k_2 were approximately equal, the concentration of bromohydrin in the solution would reach an appreciable value whereas if the glycol were formed directly, the bromohydrin's concentration would be negligible. A method for determining the bromohydrin was therefore devised. In separate experiments it was found (1) that a bromohydrin could be titrated with standard alkali in hot solution using phenolphthalein as the indicator and (2) the distribution ratio of the bromohydrin between the two phases of a system containing water, dioxane and carbon tetrachloride was convenient for analysis of the aqueous layer. It was necessary to add the carbon tetrachloride to remove any unreacted dibromide, as this also reacts with hot dilute alkali. The distribution ratio of trimethylethylene bromohydrin was determined by shaking the carbon tetrachloride layer after the first separation again with a dioxane–water mixture and titrating a second time for bromohydrin. From these data both the total amount of bromohydrin present and the distribution ratio were readily calculated. The ratio for the isobutylene bromohydrin mentioned later was obtained by starting with a known quantity of pure compound. Application of this procedure to a sample of a hydrolysis mixture of trimethylethylene bromide showed that the bromohydrin was actually present and the quantity was in fair agreement with that calculated from the value of k_1. The approximate equality of k_1 and k_2 was therefore a coincidence. As a further check on this, the hydrolysis rates of isobutylene bromide and isobutylene bromohydrin were investigated. These compounds reacted at a much lower rate than the trimethylethylene homologs, k_1 being 12×10^{-5} compared with 21×10^{-4} and k_2 3×10^{-5} as compared with 16×10^{-4}. It is to be noted that here the bromohydrin hydrolyzes much more slowly than the dibromide. The rate of aldehyde formation from isobutylene glycol was not investigated.

Since the hydrolysis rate of a tertiary alkyl halide is not modified by either hydrogen or hydroxyl ions, it was of interest to determine the behavior of the trimethylethylene bromide in this respect. While the values of k_1 and k_2 both remained unchanged in acid solution, in alkaline solution the dibromide hydrolyzed at a much more rapid rate. This was not investigated in detail. The rapid action of alkali with the bromohydrin has already been mentioned.

The first rate determinations made on the hydrolysis of the bromohydrins were later found to be seriously in error. This was caused by the fact that when 0.1 N sodium hydroxide is added to a solution containing hydrogen ions and a bromohydrin, the latter reacts to a marked extent before neutralization of the alkali has taken place. This was not at all obvious in carrying out the titration since with methyl red–methylene blue indicator a sharp end-point was obtained. However, when 0.01 N or 0.001 N alkali was employed and the titration conducted at 0° a quite different curve resulted. The values obtained with 0.1 N alkali fell on a smooth curve so long as a standard titration procedure was used. Variation in the rate of adding the alkali or in stirring the solution gave erratic results. Titration of the hydrolysis mixtures from the dibromides gave less trouble

as here the bromohydrin concentration was apparently low enough to reduce the alkali reaction to a minor factor.

Experimental

Preparation of Olefin Bromides.—The isobutylene bromide was prepared by fractionation of the product obtained by bromination of *t*-butyl alcohol. The sample used for rate determinations distilled constantly at 61° (40 mm.) and had $n^{25}D$ 1.5070.

Bromination of 435 ml. (4 moles) of *t*-amyl alcohol[4] and fractionation of the product through a 150 cm. column packed with glass helices gave 192 ml. of product distilling at 55° (17 mm.) and having a m. p. of −3 to +5° along with lower and higher boiling fractions that could not be solidified at −12°. Fractional crystallization involving thirty crystallizations gave 30 ml. of dibromide, m. p. 9–12°.

To 165 g. (2.36 moles) of trimethylethylene (obtained by fractionation of the olefins resulting from the dehydration of *t*-amyl alcohol with oxalic acid[17]) dissolved in 200 ml. of carbon tetrachloride was added slowly with stirring at 10–20° during two hours 124 ml. (2.3 moles) of bromine dissolved in 150 ml. of carbon tetrachloride. Fractionation gave 195 g. (125 ml.) of product distilling at 59.5–61° (19 mm.) and melting at 3–7°. Refractionation through a 60 cm. packed column gave 14 ml., m. p. 9–12° and other fractions with lower melting points. Systematic fractional crystallization of these gave 23 ml., m. p. 12–13°, $n^{25}D$ 1.5078, d^{25}_4 1.663 and 32 ml., m. p. 9–12°. The fraction melting at 12–13° was used for rate studies. The highest melting point previously reported[18] is 7°. Recently, a very pure product has been obtained directly by more careful fractionation of both the trimethylethylene and the dibromide. Twenty-three fractions boiled constant at 63°, $n^{20}D$ 1.5090, m. p. 14–16°.

Preparation of Olefin Bromohydrins.—Trimethylethylene bromohydrin has been prepared previously[19] in an impure state but isobutylene bromohydrin has not been described.

To a vigorously stirred mixture of 232 g. of trimethylethylene in 7 liters of water was added 200 ml. of bromine dissolved in 8 liters of water containing 600 g. of potassium bromide. The water layer was removed from 100 ml. of heavy oil (found later to be 76% dibromide) and subjected to a continuous ether extraction for eight hours. When the oily layer containing dibromide was not separated, it was found impossible to get pure bromohydrin, probably due to the formation of a constant boiling mixture. Distillation of the residue remaining after evaporation of the ether gave eight fractions of material all distilling at 48° (14 mm.) but ranging in refractive index from $n^{25}D$ 1.4680 to 1.4710. The last two fractions, $n^{25}D$ 1.4710, amounting to 46 ml. were combined and analyzed.

Anal. Calcd. for $C_5H_{11}OBr$: Br, 47.87. Found: Br, 47.70.

The pure bromohydrin proved to be unstable, a brown color developing within a few days and after thirty days a dark green mixture remained which upon distillation gave fractions apparently containing methyl isopropyl ketone, bromohydrin and dibromide. There remained a dark green water-insoluble residue. Redistillation of the bromohydrin before the green color developed regained the pure compound. It was necessary to keep the temperature below 60° during distillation or decomposition became appreciable. When heated at 100°, the characteristic odor of methyl isopropyl ketone became evident.

In the preparation of isobutylene bromohydrin, isobutylene from 600 ml. of *t*-butyl alcohol was passed through a flask containing 1500 ml. of water. A solution of 150 ml. of bromine and 400 g. of potassium bromide in 8 liters of water was added as fast as reaction took place as was indicated by the disappearance of the bromine color. The contents of the flask were stirred vigorously during the reaction. The aqueous solution of bromohydrin was decanted from an oily layer of 95 ml. and extracted three times with ether using 1 liter each time. The ether solution was dried over anhydrous magnesium sulfate and fractionated. Obtained were: fractions 2–4, 62 g., b. p. 48–49.5° (17 mm.), $n^{25}D$ 1.4680–1.4705; fractions 5–8, 164 g., b. p. 49.5° (16 mm.), $n^{25}D$ 1.4710, d^{25}_4 1.437. In contrast to trimethylethlene and tetramethylethylene[6] bromohydrins this material was stable almost indefinitely.

Trimethylethylene Glycol.—The following procedure was based upon the patented method of Schering.[20] Trimethylethylene bromide (62 ml., m. p. 9–12°) was stirred for three days at 50° with 1.5 liters of water containing 45 g. of sodium hydroxide. The water layer was separated from 5 ml. of a heavy oil and saturated with potassium carbonate (approximately 1 kg.). The glycol layer was taken up in ether and the salt solution continuously extracted with ether for five hours. From the combined ether solutions was obtained after distillation 21.5 g. (57%) of glycol, b. p. 75–76° (14 mm.), $n^{25}D$ 1.4375.

Purification of Dioxane.—The dioxane purified by the method of Eigenberger[21] after careful fractionation distilled at 100.3° (750 mm.) but still had appreciable iodine consumption.[11] This was reduced by fractional crystallization. It was noted that the crystals were white and translucent until the iodine consumption fell to zero when they became transparent.

Estimation of Methyl Isopropyl Ketone.—Solutions containing known concentrations of methyl isopropyl ketone in water and in water–dioxane mixtures were prepared. The acid liberated when 25-ml. samples of each of these solutions reacted with 400 ml. of neutralized hydroxylamine hydrochloride solution[12] was then determined by titration and the per cent. reaction plotted against concentration of ketone. The acid liberated amounted to 66 ± 3% for ketone solutions ranging from 0.01 to 0.1 *M* in 3:2 dioxane–water mixtures, decreasing to 54% for a 0.005 *M* solution. For ketone solutions in water the percentages were 58 ± 2% and 51%. The dioxane employed in making up the solutions had no iodine consumption and gave no test for carbonyl compounds with dinitrophenylhydrazine reagent. Making use of these data the extent of ketone formation in various reaction mixtures was determined.[10]

Ketone Formation from Trimethylethylene Bromide and Glycol.—A preliminary hydrolysis of the dibromide in dioxane–water solution at 79.8° showed practically quantitative formation of hydrobromic acid in one hour while ketone formation amounted to 10.3%. In a second experiment 2 ml. of the dibromide was added to 248 ml. of water at 79.8° and stirred until solution was complete. Then 25 ml. (24.4 ml. at 25°) samples were analyzed at various time intervals for ketone. In Table II $K = \frac{2.303}{t\gamma[H^+]} \log \frac{a}{a-x}$ where $\gamma = 0.812$[22] and $[H^+] = 0.113$. In a similar experiment in sulfuric acid solution in which 1.91 g. (2 ml.) of trimethylethylene glycol was added to 248 ml. of 0.119 *N* acid the average value of *K* to 50% reaction time (ninety-five hours) was 0.21 hours^{-1}. Here $\gamma = 0.341$.[23] In a solution made in the same way from 0.117 *N* hydro-

bromic acid the value of K decreased markedly with time from 0.20 to 0.14 hour^{-1} at 36% ketone formation.

A solution containing 4.78 g. (5 ml.) of glycol in 100 ml. of water was refluxed for 5.75 hours. The characteristic odor of methyl isopropyl ketone became evident within one hour. A 25-ml. sample of the solution required 0.45 ml. of 0.141 N sodium hydroxide to neutralize the acid produced. Analysis for ketone indicated a yield of 1.2%. In another experiment where 1.2 g. of sodium carbonate was added at first, no ketone was formed.

Refluxing and stirring 16.63 g. (10 ml.) of trimethylethylene bromide with 200 ml. of water and 10 g. of sodium carbonate for six hours gave no detectable amount of ketone. The dibromide phase, however, disappeared in two hours.

Summary

The mechanism by which trimethylethylene bromide is converted into methyl isopropyl ketone has been studied. The reaction proceeds in steps through trimethylethylene bromohydrin and trimethylethylene glycol as evidenced by rate measurements on the hydrolysis of the bromide and bromohydrin and on the conversion of glycol to ketone.

Preliminary experiments with isobutylene bromide indicate that a similar mechanism holds for the hydrolysis of this compound.

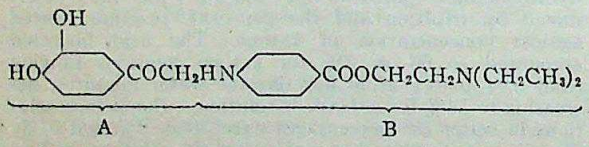
Amines Related to Epinephrine. I. Some Amines of the "Eprocaine" Type[1]

BY RALPH HILL[1] AND GARFIELD POWELL

Among local anesthetics which have pressor action, a compound appears[2] under the name of "Eprocaine." It is a particularly simple combination of a well-known pressor residue (A) and an anesthetic residue (B), and is reported to have pressor and anesthetic activity.[2]



We have sought, in the work described below, a confirmation of the preparation and properties of "eprocaine" itself, and the synthesis of other compounds in which the residue A is unchanged and the residue B is varied to include other anesthetic residues which have been subjected to some physiological testing. "Eprocaine" itself has been studied, and also the di-*n*-propyl, di-isopropyl, di-*n*-butyl homologs on the aliphatic amino group. We have also prepared, for comparison, the compounds in which B is the "benzocaine" residue (ethyl *p*-aminobenzoate) and the homologs of this having *n*-propyl and *n*-butyl ester groups, together with derivatives. The ethyl ester[3] has previously been described (with a much lower melting point) but no mention has been made of derivatives or physiological testing.

"Eprocaine" was found to give a definite rise in blood pressure when injected intravenously into a pithed decerebrate cat anesthetized with nembutal. A 1% solution gave definite anesthesia, administered intracutaneously to the guinea pig, with evidence the next day of severe tissue damage at the point of injection.[4] On the second group of amines (with B as benzocaine and related residues), anesthetic testing was limited (because of the low solubility of the salts in water) to dusting on the exposed sciatic nerve of the frog. With benzocaine as control, absence of activity was indicated.[5]

Experimental

β-Diethylaminoethyl *p*-(3,4-Dihydroxyphenacylamino)-benzoate Hydrochloride, "Eprocaine."—Fifteen grams of procaine was dissolved in 75 cc. of boiling water and 11.8 g. of chloroacetylcatechol added. The mixture was refluxed for two hours and then concentrated *in vacuo* nearly to dryness. On addition of 75 cc. of alcohol the residue crystallized. Recrystallized from 85% alcohol it melted at about 205° with darkening; yield 73% from procaine.

Anal.[6] Calcd. for $C_{21}H_{27}O_5N_2Cl$: C, 59.9; H, 6.5; N, 6.6; Cl, 8.4. Found: C, 59.8; H, 6.4; N, 6.9; Cl, 8.7.

"Eprocaine" is only slightly soluble in hot alcohol, but quite soluble in water. With ferric chloride solution it gives an emerald green color, turning violet on careful addition of sodium carbonate solution. All compounds described in this paper derived from 3,4-dihydroxyphenacyl halides responded to this test, with addition of alcohol when needed for solubility purposes. The free base is precipitated by sodium hydroxide and is dissolved in excess. The base is soluble in alcohol, acetone, and hot water, insoluble in cold water and benzene.

Table I shows the results obtained in the preparation of homologs by the following general procedure, in each case using a corresponding amount of the proper ester. Four grams of ethyl *p*-aminobenzoate was dissolved in about 500 cc. of boiling water and 4.5 g. of chloroacetylcatechol added. The clear solution was boiled for four hours, keeping the volume constant by the addition of water. During this process the product separated out as white flocculent crystals. The crystals were filtered hot, washed with hot water, and recrystallized from alcohol.

Dibenzoate of β-Diethylaminoethyl *p*-(3,4-Dihydroxyphenacylamino)-benzoate.—A solution of 0.5 cc. of benzoyl chloride in 3 cc. of benzene was added to 0.5 g. of "eprocaine" dissolved in 20 cc. of water. One-half gram of sodium carbonate was added in portions with shaking and cooling. The product separated as a gummy mass which

solidified after an hour of shaking. The solid was filtered off, washed with benzene, air dried, and recrystallized from alcohol. The melting point was 150–150.5°.

Anal. Calcd. for $C_{35}H_{34}N_2O_7$: C, 70.7; H, 5.7. Found: C, 70.7; H, 5.6.

The corresponding acetyl derivative appears to be unstable to water.

Dibenzoate of β-Di-*n*-propylaminoethyl *p*-(3,4-Dihydroxyphenacylamino)-benzoate.—This was prepared in the same manner as the above and recrystallized from alcohol; m. p. 154–154.5°.

Anal. Calcd. for $C_{37}H_{38}N_2O_7$: C, 71.3; H, 6.2. Found: C, 71.6; H, 6.4.

Diacetate of Ethyl *p*-(3,4-Dihydroxyphenacylamino)-benzoate.—Three grams of ethyl *p*-(3,4-dihydroxyphenacylamino)-benzoate was suspended in 200 cc. of water to which ice had been added, and solution was effected by addition of 4.1 cc. of 20% sodium hydroxide solution (slight excess of three equivalents), and 2.8 cc. of acetic anhydride was added rapidly with stirring. A gelatinous precipitate formed. Sufficient acetic acid was added to give a clear solution on boiling. On cooling the product separated in crystalline form. The crystals were filtered, washed with 50% acetic acid followed by water, and recrystallized from alcohol; m. p. 179–181°.

Anal. Calcd. for $C_{21}H_{21}O_7N$: C, 63.1; H, 5.3. Found: C, 63.1; H, 5.5.

The Triacetates of Ethyl, Propyl, and Butyl *p*-(3,4-Dihydroxyphenacylamino)-benzoates.—These all were prepared by a procedure similar to the following, given for the ethyl ester, with results shown in Table II. One-half gram of ethyl *p*-(3,4-dihydroxyphenacylamino)-benzoate was suspended in 20 cc. of acetic anhydride, and two drops of concentrated sulfuric acid added. The mixture was warmed slightly and the suspended solid gradually dissolved. The solution was allowed to stand for an hour, and was then poured into about 125 cc. of water. As the excess acetic anhydride hydrolyzed, the product separated out as a white solid. It was recrystallized from dilute acetic acid.

Hydrolysis of β-Di-*n*-propylaminoethyl *p*-(3,4-Dihydroxyphenacylamino)-benzoate.—A quantity of this compound was dissolved in an excess of 0.1 *N* sodium hydroxide solution and allowed to stand at room temperature for several hours. On acidification with dilute hydrochloric acid, crude *p*-(3,4-dihydroxyphenacylamino)-benzoic acid separated as a white amorphous solid. This was washed free from chloride with water, by centrifuging and decanting the washings. The product was recrystallized first from dilute acetic acid and then from alcohol. It decomposed at 241° when placed in a melting point tube at 230° and heated at the rate of 3° per minute. The product was soluble in sodium bicarbonate with evolution of carbon dioxide. It gave an emerald green color with ferric chloride solution.

TABLE II

Compound	M. p., °C.	Formula	Analyses, % Calcd. C	Calcd. H	Found C	Found H
Ethyl ester	143–144	$C_{23}H_{23}O_8N$	62.6	5.2	62.7	5.5
Propyl ester	129–131	$C_{24}H_{25}O_8N$	63.3	5.5	63.3	5.7
Butyl ester	120	$C_{25}H_{27}O_8N$	64.0	5.8	64.2	5.9

Anal. Calcd. for $C_{15}H_{13}NO_5$: C, 62.7; H, 4.5. Found: C, 62.5; H, 4.6.

Hydrolysis of the ester linkage thus proceeds normally without affecting the phenacylamino group.

Summary

Diethylaminoethyl *p*-(3,4-dihydroxyphenacylamino)-benzoate, "eprocaine," and related esters in which the alcohol group is ethyl, propyl, butyl, β-diisopropylaminoethyl, β-di-*n*-propylaminoethyl, and β-di-*n*-butylaminoethyl were prepared by interaction of the suitable *p*-aminobenzoic ester with chloracetylcatechol. Dibenzoyl derivatives of the β-diethylaminoethyl and β-di-*n*-propylaminoethyl *p*-(3,4-dihydroxyphenacylamino)-benzoates were prepared, and also the di- and tri-acetates of ethyl *p*-(3,4-dihydroxyphenacylamino)-benzoate, as well as the triacetates of the propyl and butyl esters.

Some 4-(ω-Carboxyalkyl)-2-aminothiazoles and their Reaction with Acetylsulfanilyl Chloride

BY WILLIAM M. ZIEGLER

In a previous paper[1] it was shown that acetylsulfanilyl chloride would not react with 4-(α-carbethoxyalkyl)-2-aminothiazoles nor in one instance with the free acid itself. However, the 4-alkyl substituted aminothiazoles, obtained by the decarboxylation of these acids reacted readily with the chloride even though the side chain was seven carbons long. From this it was assumed that the carboxy or carbethoxy group exerted an inhibitory effect upon the amino group insofar as its reactivity with the sulfonyl chloride was concerned. Therefore, it was thought of interest to prepare several 4-(ω-carboxyalkyl)-2-aminothiazoles and to investigate their behavior toward acetylsulfanilyl chloride.

The aminothiazoles were prepared from the esters of acetodibasic acids by a method similar to the one previously reported[1] for the preparation of 4-alkyl-2-aminothiazoles. The preparation of 4-(β-carbethoxyethyl)-2-aminothiazole given herewith is typical.

To 86.5 g. (0.4 mole) of ethyl α-acetosuccinate[2] dissolved in two volumes of carbon disulfide and cooled in an ice–water mixture, 21 ml. (0.4 mole; 63 g.) of bromine was added. The flask was stoppered and allowed to stand for 18–24 hours. The solution was washed twice with water and the carbon disulfide removed under diminished pressure, holding the bath temperature at 35–40°. To this product was added 70 ml. of water, 30 g. of ice and 33 g. (0.43 mole) of thiourea, and the mixture shaken for one hour. Slightly more than the calculated quantity of ammonia water (30 ml.) was added and the mixture chilled. The crystalline product was removed by filtration, dissolved while moist in a minimum quantity of methyl alcohol and again chilled. The product thus obtained was recrystallized from 70% methyl alcohol.

Forty and eight-tenths grams (0.15 mole) of the above ester was refluxed with 30 ml. of 95% alcohol, 50 ml. of water, and 20 ml. of concentrated hydrochloric acid until the evolution of carbon dioxide had ceased (three to five hours). To the hot solution some decolorizing carbon was added, the material filtered, and a further quantity of 20 ml. of concentrated hydrochloric acid added. The solution was then evaporated at 60° until crystals separated. It was then chilled, the product removed by filtration and recrystallized from water. The mother liquors were evaporated to a small volume and worked up in the same manner. The hydrochloride of the aminothiazole was thus obtained. The free base was liberated by dissolving the hydrochloride in hot water and adding the calculated amount of sodium hydroxide solution.

In a similar manner 4-(γ-carboxypropyl)-2-aminothiazole, 4-(δ-carboxybutyl)-2-aminothiazole, and 4-(λ-carboxyundecanyl)-2-aminothiazole, were prepared from ethyl α-acetoglutarate,[3] ethyl α-acetoadipate,[4] and α-aceto-α,λ-dicarbethoxyundecane.[5] Pertinent data concerning all the compounds may be found in the table.

[a] All products were recrystallized from water unless otherwise stated, and all melting points are corrected. [b] Recrystallized from 70% methanol. [c] Recrystallized from 70% ethanol. [d] Recrystallized from 95% ethanol. [e] After drying at 120°. The monohydrate melts at 99–101°. [f] With partial decomposition.

Some difficulty was experienced in the isolation of products from the reaction of the amines with acetylsulfanilyl chloride. Finally the following method was used.

Nineteen grams (0.11 mole) of 4-(β-carboxyethyl)-2-aminothiazole was dissolved in 70 ml. of pyridine and 28 g. (0.12 mole) of acetylsulfanilyl chloride was added. The solution was warmed for one hour on a steam-bath and then poured into 600 ml. of 2 *N* hydrochloric acid. There was no precipitate, so the mixture was refluxed for forty minutes. The product was decolorized with Norite and

(1) Ziegler, THIS JOURNAL, **63**, 2946 (1941).

(2) Conrad, *Ann.*, **188**, 218 (1877).

(3) Emery, *Ber.*, **24**, 285 (1891).

(4) Fichter and Gully, *ibid.*, **30**, 2047 (1897).

(5) The ester used was prepared from ethyl acetoacetate and ethyl ω-bromoundecylate in the usual manner. After the removal of the unreacted ethyl acetoacetate, an aliquot of the product, which would not distill at 8 mm., was titrated with bromine to estimate the concentration of the desired dibasic ester. Using this ester to prepare 4-(α,λ-dicarbethoxyundecanyl)-2-aminothiazole, it was necessary to allow the mixture to stand for one week in the refrigerator after neutralization to obtain a solid.

Digitized by Arya Samaj Foundation Chennai and eGangotri

filtered. It was then brought to a *p*H of 4.5–5.0 and evaporated at 60° to 300 ml., chilled and filtered. The residue was mainly sulfanilic acid. The filtrate was evaporated on a steam-bath until sodium chloride crystals appeared, and then chilled and filtered. The product obtained was recrystallized from water. The free base was obtained by treating a warm solution of the hydrochloride with the calculated amount of sodium hydroxide in a little water.

In this manner fair yields of product were obtained from 4-(β-carboxyethyl)-2-aminothiazole, and poor yields were obtained from 4-(γ-carboxypropyl)-2-aminothiazole. The mother liquors from the latter reaction were combined and evaporated to dryness. The product obtained was recrystallized from a small quantity of water. This proved to be identical with 4-(γ-carboxypropyl)-2-aminothiazole sulfanilate, which was also produced by heating the free base with sulfanilic acid in a small quantity of water and allowing it to crystallize. The product was obtained in over 50% yields in all batches. With 4-(δ-carboxybutyl)-2-aminothiazole, 75% of the amine was recovered, indicating a lack of or very little reaction. 4-(λ-Carboxyundecanyl)-2-acetylsulfanilamidothiazole was isolated from the pyridine reaction mixture of the corresponding amine and acetylsulfanilyl chloride. This product was incompletely hydrolyzed by 2 *N* hydrochloric acid, while refluxing with 2 *N* sodium hydroxide destroys it.

That the sluggishness of reaction is a characteristic of the amine rather of the other reactants or some possible conditions is supported by the following facts. The sulfonyl chloride used was of a good grade and gave excellent yields of sulfanilamide and sulfanilanilide. Further, the 4-(δ-carboxybutyl)-2-aminothiazole did not react with *p*-toluenesulfonyl chloride in the refluxing pyridine; 70% of the amine was recovered unchanged. That the acetylsulfanilamide may have been formed and hydrolyzed[6,7] does not seem probable since no hydrolysis was run in the reaction with the *p*-toluenesulfonyl chloride just mentioned; nor did a sample of 4-(γ-carboxypropyl)-2-sulfanilamidothiazole change when refluxed for two hours with 2 *N* hydrochloric acid.

(6) Winterbottom, THIS JOURNAL, **62**, 160 (1940).

(7) Lur'e, Starobogatov, and Nikitskaya, *J. Gen. Chem.* (U. S. S. R.), **11**, 545 (1941); *C. A.*, **35**, 6938 (1941).

Thus, since 2-amino-4-propylthiazole and 2-amino-4-amylthiazole react well with acetylsulfanilyl chloride, it seems that the conversion of the end carbon in the chain to the carboxy group had a decided inhibitory effect upon the reaction. Also, this effect varies greatly with the position of the carboxy group in the chain. Very striking is the fact that, except for the acetic acids, the interference increases as the carboxy group is moved outward from the ring, to a maximum at five or possibly six carbons and then probably decreases, since the carboxyundecanyl derivative gave yields comparable to the carboxyethyl compound.

The 4-(β-carboxyethyl)-2-sulfanilamidothiazole was found ineffective against experimental streptococcus and pneumococcus infections in mice.

The author wishes to thank Dr. G. H. A. Clowes of Eli Lilly and Company for having the pharmacological work done and the American Philosophical Society for financial support of the work.

Summary

1. Several 4-(ω-carboxyalkyl)-2-aminothiazoles were prepared from the ethyl esters of α-acetodibasic acids.

2. The yields of sulfonamides from these aminothiazoles decreased as the alkyl group increased, to a certain point, from two to four carbons, increasing again when it contained eleven carbons.

3. It is concluded that the conversion of the end carbon of a 2-amino-4-alkylthiazole to a carboxy group has a decided inhibitory effect upon the reaction of that amine with acetysulfanilyl chloride and the interference increases as the chain increases to five or possibly six carbons, then decreases.

Antispasmodics and Anticonvulsants. III.[1] Miscellaneous Amides and Esters

BY JOHN H. BILLMAN AND JOHN L. RENDALL[2,3,4]

A large portion of the work that has been done in the field of antispasmodics and anticonvulsants has been concerned with the preparation and testing of amides and esters. As we were interested in a study of compounds having the above physiological activity, we decided to prepare a number of miscellaneous esters and amides in an attempt to find some compounds not previously reported as having antispasmodic or anticonvulsant activity. Since benzyl alcohol and 2-diethylaminoethanol have been used frequently in making active esters, we treated these alcohols with a number of different substituted acids.

(1) II, John H. Billman and John L. Rendall, THIS JOURNAL, **66**, 540 (1944).

(2) Submitted to the Faculty of the Graduate School in partial fulfillment of the requirements for the degree, Doctor of Philosophy, in the Department of Chemistry, Indiana University.

(3) Eli Lilly Fellow for the years 1941–3.

(4) Present address: B. F. Goodrich and Co., Akron, Ohio.

At the same time we decided to prepare *p*-dibenzylacetaminoacetophenone and *p*-dibenzylacetaminobenzophenone. It was felt that these amides might be active inasmuch as they are derivatives of acetophenone or benzophenone, which are both active by themselves. Two benzyl substituted ureas were prepared and submitted for testing.

The compounds which have been prepared are listed in Table I.

Acknowledgment.—The authors wish to thank Eli Lilly and Company for the generous grant which made this work possible.

Experimental

General Procedure for Esters.—The esters with the exception of benzyl dibenzylacetate were prepared by refluxing a xylene solution of the acid and alcohol and measuring the water evolved in a calibrated water trap to ascertain the extent of completion of the reaction. Benzyl di-

[a] Anticonvulsant activity: 0, inactive; +, poor; ++, moderate; +++, good; −, no test reported to date. [b] Antispasmodic activity: same symbols. [c] Prepared from diketene and β-diethylaminoethanol. [d] Prepared from acetoacetic ester and β-diethylaminoethanol by *trans*-esterification.

benzylacetate was prepared by the action of dibenzylacetyl chloride on benzyl alcohol in pyridine.

General Procedure for Amides.—The amides were prepared by the reaction of the acid chloride with the amine in pyridine.

2-Pyrrolidone-5-carboxylic Acid.—2-Pyrrolidone-5-carboxylic acid was prepared by heating glutamic acid at 170° for two hours similar to the procedure described by Haitinger.[10]

Benzyl 2-Pyrrolidone-5-carboxylate.—A mixture of 14.7 g. (0.10 mole) of 2-pyrrolidone-5-carboxylic acid and 72.0 g. (0.655 mole) of benzyl alcohol in 100 ml. of xylene was refluxed for eight hours, the water evolved being caught in a water trap. Distillation *in vacuo* yielded 15.0 g. (68.5% of theoretical) of the ester boiling at 202–204° (2 mm.).

p-Dibenzylacetaminoacetophenone.—Fourteen grams (0.058 mole) of dibenzylacetic acid and 16.9 g. (0.14 mole) of thionyl chloride were mixed and allowed to stand ten hours. The mixture was heated for two hours in a water-bath maintained at 50°. The excess thionyl chloride was removed *in vacuo*. A solution of 10.0 g. (0.074 mole) of p-aminoacetophenone in 10 g. of pyridine was added slowly to the acid chloride (cooled in ice.). The reaction mixture was heated in a water-bath at 40–5° for three hours and then added to a mixture of ice and water. The semisolid which formed was crystallized twice from alcohol yielding 8.5 g. (50.0% of theoretical) of the amide melting at 35–36°.

Benzyl Urea.—Benzyl urea was prepared in a quantitative yield by heating an aqueous solution of benzylamine hydrochloride with potassium cyanate.

N-Triphenylmethyl-N′-benzylurea.—A solution of 18.0 g. (0.0644 mole) of triphenylchloromethane and 9.68 g. (0.0644 mole) of benzyl urea in 75 ml. of pyridine was refluxed for five hours and then added to a mixture of ice and water. The solid which formed was recrystallized from absolute alcohol twice to give 4.9 g. (18.0% of theoretical) of product melting at 228°.

The Preparation of 1-(3,4-Dihydroxyphenyl)-2-amino-1-butanol[1]

By C. M. Suter and A. Wayne Ruddy

In the prolonged search that has been made for sympathomimetic amines, which possess pharmacological actions similar to but more desirable than epinephrine, 1-(3,4-dihydroxyphenyl)-2-amino-1-butanol has aroused considerable interest. Under the names ethylnorsuprarenin and ethylnoradrenalin it has been tested in several laboratories and a number of papers have been published on the pharmacology of this compound by Tainter and co-workers,[2] Raymond-Hamet,[3] and Bacq.[4] Unpublished work by Tainter, Cameron, and Whitsell indicates that it is equally as effective as epinephrine in the relief of acute asthmatic attacks in doses one-half larger, and this relief is accompanied by fewer side effects; that it is approximately one one-hundredth as toxic as epinephrine; that it neither excites the central nervous system nor raises systolic blood pressure, but instead lowers diastolic pressure and increases the pulse rate, thus improving circulation without a proportionate rise in cardiac work.

There is little doubt that the compound tested pharmacologically was 1-(3,4-dihydroxyphenyl)-2-amino-1-butanol, but a thorough search of the literature has thus far failed to reveal any description of its synthesis or physical constants. Consequently its synthesis was attempted in these laboratories, and successfully completed. A new process was used which may have a general application.

In a search for a suitable means of obtaining this amine the usual methods of introducing a primary amino group proved unsatisfactory. Although Hartung[5] has described α-isonitroso-3,4-dihydroxybutyrophenone, our attempts to nitrosate both 3,4-dihydroxybutyrophenone and 3,4-dibenzyloxybutyrophenone were unsuccessful. Treatment of α-bromo-3,4-dibenzyloxybutyrophenone with ammonia was unsatisfactory as a synthetic method. The reaction of the bromoketone with hexamethylenetetramine was too slow to be practical.

In the present investigation the possibility of forming a primary amine by hydrogenolysis of a secondary amine has been studied. Since the catalytic hydrogenolysis of a tertiary benzylmethylamino compound has been generally used for producing a methylamino compound, it was believed that a high molecular weight secondary amine might behave similarly to produce a primary amine. It was found that a benzhydryl group could be removed readily by hydrogenation in the presence of a palladium catalyst. Benzhydrylamine was allowed to react with a bromoketone and the benzhydrylamino compound successfully reduced to the desired primary amine.

3,4-Dihydroxybutyrophenone has been prepared by the Fries isomerization of catechol dibutyrate and guaiacol butyrate in nitrobenzene or carbon disulfide.[6,7,8] The methods either gave low yields or required a high reaction temperature and tedious manipulation. Catechol was treated with *n*-butyryl chloride and aluminum chloride in chlorobenzene to give a 68% yield of 3,4-dihydroxybutyrophenone with no difficulties encountered. The product was benzylated readily with benzyl chloride and the 3,4-dibenzyloxybutyrophenone obtained in excellent yield. α-Bromo-3,4-dibenzyloxybutyrophenone has been previously prepared,[9] but has not been characterized. The dibenzyloxyketone was brominated without difficulty and its identity was established. The bromoketone was treated with benzhydrylamine and the resulting α-benzhydrylamino-3,4-dibenzyloxybutyrophenone hydrochloride was hydrogenated to yield 1-(3,4-dihydroxyphenyl)-2-amino-1-butanol.

Experimental

3,4-Dihydroxybutyrophenone.—To 165 g. (1.5 moles) of catechol in 660 ml. of dry chlorobenzene was added 200 g. (1.87 moles) of *n*-butyryl chloride and the mixture heated at 50° for thirty minutes. It was then cooled and 426 g. (3.2 moles) of anhydrous aluminum chloride added in small portions. Then the temperature of the mixture was gradually raised to 110° and held there for three hours. The mixture was hydrolyzed in ice and hydrochloric acid, and the chlorobenzene removed by steam distillation. While still warm, 75 ml. of concentrated hydrochloric acid and 125 ml. of toluene were added. After thorough cooling, the product was filtered and washed well with water and toluene. When recrystallized from water it melted at 146–146.5°. It is reported to melt at 146–147°.[6] The yield of 3,4-dihydroxybutyrophenone was 68% of the theoretical. A small amount of 4-chlorobutyrophenone, m. p. 34–35°, was isolated from the toluene washings.

3,4-Dibenzyloxybutyrophenone.—A mixture of 184.5 g. (1.023 moles) of 3,4-dihydroxybutyrophenone, 278.5 g. (2.2 moles) of benzyl chloride, 187 g. (1.35 moles) of anhydrous potassium carbonate, 13.5 g. (0.09 mole) of sodium iodide in 500 ml. of alcohol and 8 ml. of water was refluxed and stirred five hours, when all effervescence had ceased. The alcohol was distilled and any unreacted benzyl chloride removed by steam distillation. The warm mixture was poured into dilute sodium hydroxide, cooled, filtered, and

washed with water until neutral to litmus. Recrystallization from alcohol gave a 90% yield of 3,4-dibenzyloxybutyrophenone, m. p. 86–87°. It is reported to melt at 88°.[10]

α-Bromo-3,4-dibenzyloxybutyrophenone.—This bromoketone was prepared by the procedure of Bockmühl, Ehrhart and Stein,[9] who prepared and used the compound without isolating and characterizing it. To 335.5 g. (0.93 mole) of 3,4-dibenzyloxybutyrophenone dissolved in 1500 ml. of methylene chloride was added 110 g. (1.1 moles) of powdered calcium carbonate and then 149 g. (0.93 mole) of bromine in 400 ml. of methylene chloride. The excess calcium carbonate was dissolved with dilute hydrochloric acid, the methylene chloride layer separated, washed with water, and dried over sodium sulfate. After removing the solvent under reduced pressure the residue was recrystallized from alcohol. A 70% yield of cream-colored crystals, m. p. 100–101° was obtained.

Anal. Calcd. for $C_{24}H_{23}O_3Br$: C, 65.61; H, 5.28. Found: C, 65.48; H, 5.14.

α-Benzhydrylamino-3,4-dibenzyloxybutyrophenone Hydrochloride.—To 57.1 g. (0.13 mole) of α-bromo-3,4-dibenzyloxybutyrophenone in 175 ml. of absolute alcohol was added 47.7 g. (0.26 mole) of benzhydrylamine and the mixture refluxed three hours. The alcohol was completely removed under reduced pressure and 400 ml. of dry ether added. The precipitated benzhydrylamine hydrobromide was filtered and washed with dry ether. The ether solutions were combined and thoroughly shaken with 10% hydrochloric acid. An oil separated which slowly crystallized. It was filtered off, washed with water and with ether to remove traces of color. A 75% yield of cream-colored needles, m. p. 175–176° dec., was obtained.

Anal. Calcd. for $C_{37}H_{36}O_3NCl$: N, 2.42; Cl, 6.13. Found: N, 2.38; Cl, 6.09.

1-(3,4-Dihydroxyphenyl)-2-amino-1-butanol Hydrochloride.—To 28.9 g. (0.1 mole) of α-benzhydrylamino-3,4-dibenzyloxybutyrophenone hydrochloride, dissolved in 150 ml. of absolute alcohol, was added 0.5 g. of palladium sponge catalyst.[11] It was shaken at 55–70° under fifty pounds pressure until three equivalents of hydrogen had been used. After the alcohol was removed the residue was dissolved in water and the toluene and diphenylmethane removed by extracting with ether. The aqueous solution was boneblacked and further hydrogenated until the fourth equivalent of hydrogen had been used. The catalyst was removed and the solution taken to dryness under reduced pressure. The residue was boneblacked in absolute alcohol, an equal volume of acetone added and then dry ether until precipitation was complete. A 60% yield of colorless material was obtained. When completely dry it melted with decomposition at 199–200° (uncor.).

Anal. Calcd. for $C_{10}H_{16}O_3NCl$: N, 5.99; Cl, 15.17. Found: N, 6.17; Cl, 15.08.

Summary

1. The synthesis and characterization of 1-(3,4-dihydroxyphenyl)-2-amino-1-butanol has been described.

2. It has been shown that the intermediate benzhydrylaminoketone readily undergoes hydrogenolysis to the desired primary amine.

The Chemistry of Allergens. IX. Isolation and Properties of an Active, Carbohydrate-Free Protein from Castor Beans[1]

BY JOSEPH R. SPIES, E. J. COULSON, DORRIS C. CHAMBERS, HARRY S. BERNTON AND HENRY STEVENS

The method of isolation, amino acid content and chemical and immunological properties of a non-toxic, allergenic, protein-polysaccharidic fraction, CB-1A, from castor beans were recorded in a previous publication.[1b]

The importance of the role of carbohydrate in the immunological specificity of pneumococcus organisms[2] and recognition of a possible analogous relationship in allergenic specificity[3] led to the isolation and chemical characterization of an essentially carbohydrate-free protein (CS-60C) from cottonseed.[4]

To determine similarly the significance of the polysaccharidic portion of the castor bean allergen, an attempt was made to isolate a carbohydrate-free protein from CB-1A, by electrophoresis, analogously to the previously described fractionation of CS-1A from cottonseed.[4,5] However, the final cathodic fraction, CB-60C, so obtained, contained 0.47% carbohydrate. Therefore, CB-1A was subjected to a varied and prolonged series of procedures involving chromatographic adsorption of the picrate, electrophoretic recovery of the protein from the picrate, electrophoresis of the protein, and solvent fractionation. The final active fraction, CB-65A, contained only a trace of carbohydrate as shown by chemical tests. The present paper describes the isolation of CB-60C and CB-65A and compares their chemical and immunological properties with those of CS-60C from cottonseed.

Experimental

Apparatus.—The high voltage electrophoresis apparatus described and illustrated in papers IV[5] (Fig. 1) and VI[4] of this series was used except that 250, 125, 50 or 25 ml. cells

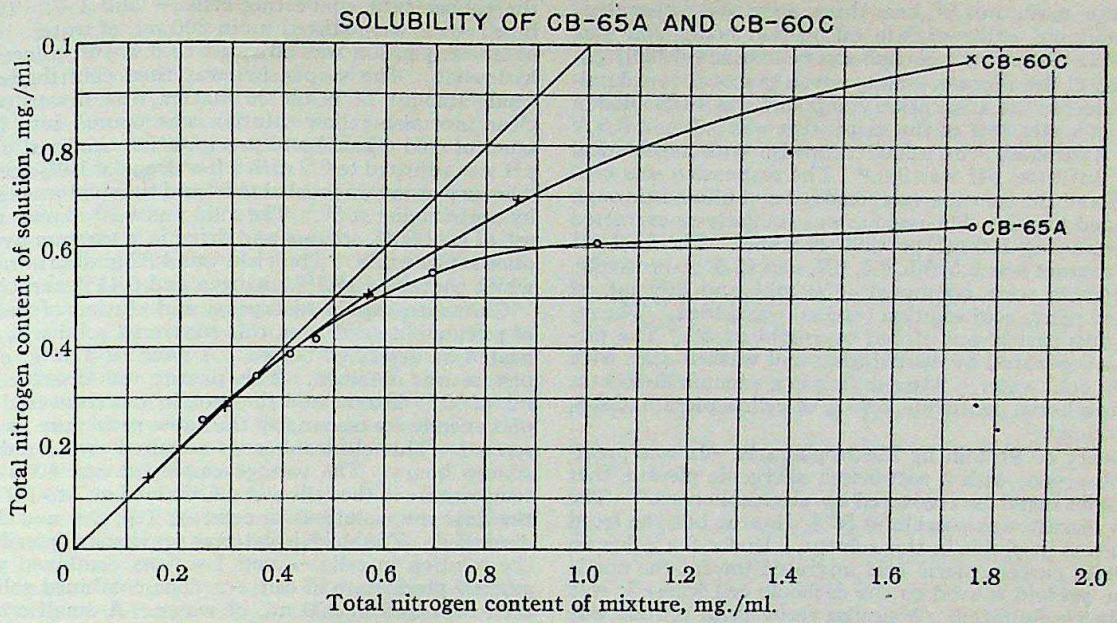

Fig. 1.—Solubility curves of CB-60C and CB-65A: weighed quantities of the protein fractions were placed in glass stoppered tubes. Samples of CB-60C were dissolved in 1.5 ml. of 0.05 *M* acid potassium phthalate buffered at *p*H 5.0. One ml. of absolute ethanol was added to each solution. Samples of CB-65A were dissolved in 0.75 ml. of the same buffered solution and 0.75 ml. of absolute ethanol was added to each. The tubes were fastened in a larger stoppered tube and the suspensions were equilibrated by slowly rotating the tubes in a water-bath at 5 ± 0.1° for at least twenty hours. The excess solid collected on the walls of the tubes during equilibration, leaving a clear supernatant solution, which was decanted and analyzed for total nitrogen content.

were employed, depending on the quantity of material fractionated. Cylindrical (10 × 25 mm.) platinum gauze electrodes were used in terminal cells.

Preparation of CB-60C.—CB-60C was obtained from CB-1A[6] by an electrophoretic fractionation similar to that used to obtain CS-60C [4] from the cottonseed allergen, CS-1A. That portion of CB-1A which migrated toward the cathode was used as starting material in five successive fractionations. The principle of the procedure has been discussed before[4,5] and, therefore, will not be given in detail here. However, pertinent data are assembled in Table I. In the initial fractionation a solution of 15.3 g. of CB-1A dissolved in 200 ml. of water was used. In each fractionation the starting solution was placed in cell 2— of a 6-cell apparatus and an equal volume of distilled water was placed in each of the other cells. The volumes of the cells used were 250, 125, 50, 50 and 25 ml. for fractionations numbered one to five, respectively. Direct current at voltages ranging from 2500 to 7500 was employed. Temperature within the cells was maintained at 15 to 25°. Anodic and cathodic fractions were precipitated by pouring the respective solutions into five volumes of ethanol followed by adjustment of the *p*H to 6.0–6.5 with dilute acetic acid or sodium hydroxide. Fractions, separated by centrifuging, were dried in a vacuum over phosphorus pentoxide. The dried fractions were ground to pass a 100-mesh sieve and were equilibrated with air before analysis.

[a] The *p*H of solutions was determined with a Beckman *p*H meter. [b] The anodic *p*H range is for solutions taken from cells +, 1+ and sometimes 2+. In each case the anodic fraction was isolated from the combined contents of these cells. [c] The cathodic *p*H range is for solutions taken from cells —, 1—, 2— and sometimes 2+. In each case the cathodic fraction was isolated from the combined contents of these cells. [d] This fraction was designated CB-60C. [e] Percentages are on an ash and water free basis.

Picrate Formation.—A 10-g. composite sample, consisting of 3.6 g. of CB-1A and 6.4 g. of anodic fractions of CB-1A (obtained in preparing CB-60C), was dissolved in 200 ml. of water. To the solution was added 300 ml. of a saturated water solution (25°) of picric acid. The resulting suspension was stored overnight at 5° and the picrate was separated by centrifuging at 5°. The yellow picrate was washed once by stirring it up with 75 ml. of cold water followed by centrifuging. The solid (CB-3) was dried in a vacuum over phosphorus pentoxide. The yield of CB-3 was 12.43 g.

Chromatographic Adsorption.—CB-3 (12.43 g.) was dissolved in 1500 ml. of 50% ethanol (volume concentration) by warming and stirring. The slightly turbid solution, obtained by filtering, was passed slowly through a 44 × 135 mm. column of activated aluminum oxide (Brockmann).[7] The column was washed with 100 ml. of 50% ethanol. The picrate was adsorbed in a well-defined 30 mm. layer at the top of the column. Two smaller 2-mm. layers formed

Preparation of CB-65A.—CB-65A was obtained from CB-1A by a prolonged series of procedures involving chromatographic adsorption of the picrate, electrophoretic recovery of protein from its picrate, electrophoresis of the protein and solvent fractionation.

(6) Isolation and properties of CB-1A from castor beans have been described.[1b] CB-1A contained 18.4% nitrogen, 2.33% sulfur and 3.12% polysaccharidic carbohydrate.

under the main one,[8,9] but these were not separated. The aluminum oxide–picrate adsorption compound was removed and dried over phosphorus pentoxide (yield 67 g.).

Elution of the Picrate.—Sixty-seven grams of the aluminum oxide–picrate adsorption compound was suspended in 150 ml. of water (*p*H of the suspension was 5.0) and 0.5 *N* sodium hydroxide was added dropwise with mechanical stirring until the *p*H was 9.0.[10] The suspension was centrifuged and the solution was removed and filtered through a hardened paper. The residue was similarly re-extracted five times using 100 ml. portions of water. The final *p*H of each extract was 9.5, 9.5, 9.5, 9.7, and 10.0, respectively. The extracts were combined (650 ml.) and 300 ml. of saturated picric acid solution (excess) was added. The resulting suspension was stored overnight at 5°. The picrate was separated by centrifuging and washed once with 50 ml. of cold water. After drying in a vacuum desiccator over phosphorus pentoxide, 6.99 g. of yellow picrate, CB-5, was obtained.[11]

Recovery of Protein by Electrophoresis.—It was previously observed, with a cottonseed allergenic picrate, that the protein could be recovered by electrophoresis.[12] The protein picrate was soluble in 50% dioxane but the freed protein was insoluble in this solvent. Under the influence of a direct current picric acid migrated toward the anode and the protein moved to the cathodic cell where it was partially precipitated. A similar recovery of protein was carried out on CB-5 as follows:[13]

A solution of 6.80 g. of CB-5 in 200 ml. of 50% aqueous dioxane was placed in cell 2− (250 ml. volume) of a 6-cell apparatus. An equal volume of 50% dioxane was placed in each of the other cells. Direct current at 4000 to 5000 volts was applied at the electrodes for twenty-seven hours. The current, initially at 5.1 ma., increased to a maximum of 18.5 ma. The temperature in the cells was kept at 14 to 21°. After the electrophoresis, the orange solution in anodic cell + was removed and replaced with 200 ml. of fresh solvent. Electrophoresis was continued at 4000 volts for twenty-six hours. The orange solution in cell + was again replaced with fresh solvent and electrophoresis continued for twenty-two hours. Solution in cells + and 1+ was then replaced with fresh solvent. Electrophoresis was continued at 5000 volts. At twenty-six, twenty-two and twenty-six hour intervals solvent in cells +, 1+ and 2+ was replaced with fresh solvent. After a final seventy-two hour period at 6000 volts, during which the current was 4.0 to 4.1 ma., the electrophoresis was stopped. Solutions in cells +, 1+, 2+ and 2− were discarded. Solutions in cells − and 1− were decanted and poured into 600 ml. of cold ethanol. Precipitation occurred when the *p*H was adjusted to 6.0–6.5 with dilute sodium hydroxide. The suspension was cooled to 10° and the solid was separated by centrifuging. This solid was combined with the gummy substance which had precipitated in cell − and in the rubber tube connecting cells − and 1−. The combined solids were stirred up in 200 ml. of water. The *p*H of the suspension was adjusted to 6.4 with dilute sodium hydroxide. The suspension was then centrifuged and a small amount of insoluble matter was discarded. The clear brownish-yellow solution was poured into five volumes of cold ethanol and precipitation occurred when the *p*H was adjusted to 6.2 with a few drops of 10% acetic acid. The suspension was cooled to 5° and the solid was separated by centrifuging at 5°. The solid was washed once with 150 ml. of cold 80% ethanol and dried in a vacuum over phosphorus pentoxide. The yield was 4.82 g. of brownish solid which contained 18.7% nitrogen and 0.41% carbohydrate.

Chromatographic adsorption and elution of the 5.77 g. of picrate obtained from this recovered solid was then repeated as described before. A yield of 3.97 g. of eluted picrate was obtained. This picrate was dissolved in 200 ml. of 50% dioxane and the protein was recovered electrophoretically by essentially the same procedure as just described. This electrophoresis required two hundred and sixteen hours. The voltage employed was 4000 and the temperature in the cells was maintained at 7 to 12°. After the final run, solutions in cells +, 1+, 2+ and 2− were discarded. The solid, isolated as previously described from the solution in cells − and 1−, was combined with the gummy precipitate in cell −. The combined solids were then dissolved in 200 ml. of water. A small amount of insoluble matter, separated by centrifuging, was discarded. Solid was isolated from the solution by ethanol precipitation and centrifugation. A yield of 3.01 g. of brownish colored substance containing 18.9% nitrogen and 0.31% carbohydrate was obtained.

Electrophoresis of the Protein.—A solution containing 2.91 g. of solid, recovered from the picrate and containing 0.31% carbohydrate, in 50 ml. of water (*p*H of the solution was 5.65) was placed in cell 2− (50 ml. volume) of a 6-cell apparatus. Fifty ml. of water was placed in each of the other cells and direct current at 3500 volts was applied to the system for twenty-three hours. The temperature was kept at 15 to 19°. A small amount of dark-colored precipitate separated in all of the cells. After the electrophoresis the *p*H of solutions in the cells was: +, 4.94; 1+, 5.30; 2+, 5.44; 2−, 5.93; 1−, 6.33; −, 7.00. The solutions in cells + and − were replaced with 50 ml. of water and electrophoresis was continued at 6000 volts for forty-eight hours at a temperature of 16 to 17°. The *p*H of solution in the cells was then: +, 4.63; 1+, 5.17; 2+, 5.39; 2−, 5.73; 1−, 6.25; −, 7.19.

The solution removed from cell −, after the first run, and the solution from cells −, 1−, 2− and 2+ of the second run were combined (*p*H 5.92). The combined solution, after boiling for fifteen minutes with 1 g. of activated charcoal, was cooled and centrifuged. Then it was filtered through a hardened paper and solid was isolated from the filtrate by ethanol precipitation. A yield of 1.45 g. of solid containing some colloidal carbon was obtained.

Solvent Fractionation and Reprecipitations.—The solid obtained by electrophoresis (1.45 g.) was dissolved in 50 ml. of water and boiled with 300 mg. of carbon. The carbon, removed by centrifuging, was washed with 10 ml. of water. The wash solution was combined with the main solution which was filtered through a Seitz sterilizing pad.[14] Solid was separated from the clear slightly yellow solution by precipitation with five volumes of ethanol. A yield of 1.27 g. was obtained. This solid was dissolved in 50 ml. of water and decolorized with carbon. This combined solution and washings (75 ml.) was passed through a Seitz sterilizing pad and 25 ml. of ethanol was added to the filtrate. This solution was kept at −6° overnight. The white suspension which formed on standing was decanted from a small amount of gummy solid that had collected on the bottom of the container. This residual solid, which contained most of the color, was discarded. The decanted suspension was poured into 350 ml. of cold ethanol. The

(8) A similar layering was observed in a previous study of CS-5, the analogous picrate of the cottonseed allergen, Spies, Coulson, Bernton and Stevens, THIS JOURNAL, 62, 1420 (1940). No difference was demonstrable in clinical activity of the three layers from CS-5. Therefore, in this study the layers were not separated.

(9) The filtrate from the adsorption was evaporated to dryness and 845 mg. of yellow powder (CB-10) was obtained. Clinical tests on castor bean sensitive subjects, using solid obtained from previous similar adsorptions, showed that CB-10 was completely inactive. The solid (CS-10) similarly obtained from cottonseed also showed no clinical activity, and was not antigenic.

(10) A commercially available *p*H meter employing a glass electrode with mechanical stirrer was used.

(11) CB-5 from another similar adsorption contained 18.9% total nitrogen and 31.6% picric acid. See Spies, Bernton and Stevens, THIS JOURNAL, 62, 2793 (1940), for the method used for determining picric acid.

(12) Spies, *ibid.*, 63, 1166 (1941).

(13) The rapid method of recovering the allergenic protein from its picrate by ethanol precipitation at the isoelectric point, reference 8, was not used, in this case, because protein recovered from CB-5 by this method contained 0.93% carbohydrate whereas that recovered by electrophoresis contained 0.41%.

(14) Seitz pads were washed before use by filtering through them 100 ml. of boiling water and 130 ml. of cold water to remove traces of soluble carbohydrate.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

resulting suspension was cooled to 4° and centrifuged. The solid was washed once with cold 80% ethanol and dried as usual. A yield of 601 mg. of almost colorless material was obtained. This solid was dissolved in 35 ml. of water and stirred at room temperature with 200 mg. of carbon. The carbon was removed and the solid was isolated as usual. A yield of 503 mg. of solid containing 19.0% nitrogen and 0.22% carbohydrate was obtained.

Four hundred and twenty-two mg. of this solid was dissolved in 25 ml. of water. The practically clear, colorless solution was filtered through a washed hardened filter paper into a 250 ml. conical centrifuge cup. To this solution was added 8.3 ml. of ethanol. The solution, which remained clear at room temperature, was cooled at −7° for three hours. The resulting suspension was centrifuged at −7°. The supernatant solution was discarded. The solid was washed once with 25 ml. of cold 80% ethanol and dried in a vacuum over phosphorus pentoxide. A yield of 314 mg. of white solid (CB-65A) was obtained. This solid was ground to pass through a 100-mesh sieve and equilibrated with air before analysis.

CB-65A was completely soluble in water. Results of color tests on a 1% solution of CB-65A were: pinkish biuret, deep purple ninhydrin, positive Millon, and Benedict test for reducing sugars, negative.

Determination of Carbohydrate.—Carbohydrate was determined on protein fractions by the orcinol method of M. Sørensen and Haugaard[15] as modified by Heidelberger and Kendall.[16] Galactose, $[\alpha]^{20}D$ +79.7; *C*, 3.00 g./100 ml., was used as a standard and color comparison was made with a Duboscq colorimeter. Test showed that no color (blank) developed on heating protein fractions in the acid solution without orcinol.

Carbohydrate in CB-65A was determined by the orcinol method, using a photoelectric colorimeter for measuring the color developed. Twenty-eight mg. of CB-65A was placed in a 125-ml. Erlenmeyer flask with 1.0 ml. of water, 2.0 ml. of a 2% orcinol solution in 25% sulfuric acid, and 15.0 ml. of 60% sulfuric acid. The solution was heated in a water-bath, in the dark, at 80° for twenty-five minutes. After cooling at −7° the solution was warmed to room temperature and the intensity of the color was read on an Evelyn photoelectric colorimeter using filter No. 520. The reagent (blank) contained 1.0 ml. of water, 2.0 ml. of the orcinol reagent and 15.0 ml. of 60% sulfuric acid. Negligible color developed when a blank was run on a solution containing 27.8 mg. of protein,[17] 1.0 ml. of water, 2.0 ml. of 25% sulfuric acid and 15.0 ml. of 60% sulfuric acid. The carbohydrate content of CB-65A, calculated from color readings in comparison with the curve obtained with solutions containing 0.01, 0.05, and 0.10 mg. of galactose was 0.11%.

A Molisch test on a 1% solution of CB-65A, while difficult to read, was considered doubtfully positive.

Comparison of Antigenic Potency of CB-1A and CB-65A, Using Guinea Pigs.—Comparison of CB-1A and CB-65A with regard to the median sensitizing dose (SD-50) and the median lethal dose (LD-50) in previously sensitized guinea pigs, was made from dosage-response curves according to the method of computation of Bliss.[18] The Bliss method, originally developed for the evaluation of toxicological studies, has been adapted to the quantitative comparison of antigenic potency of cottonseed allergenic fractions.[19]

The SD 50's of CB-1A and CB-65A were 63.6 ± 13γ and 746 ± 240γ (on ash and water free basis), respectively. From the complete dosage response curve the LD 50 of CB-1A was found to be 2.38 ± 0.36γ. Owing to the limited quantity of CB-65A available the mortality ratio was determined at only the critical level. Each of 10 guinea pigs (previously sensitized with 1.0 mg. of CB-1A) was injected intravenously with 2.7γ of CB-65A. The mortality ratio was six fatal to four non-fatal anaphylactic reactions. This mortality ratio was identical with that previously observed when similarly sensitized animals were injected with 2.7γ of CB-1A. The shocking capacity of CB-65A is, therefore, very close to that of CB-1A.

Discussion

Results of elementary analyses and some properties of CB-65A and CB-60C are compared, in Table I, with those of the analogous protein fraction CS-60C, from cottonseed. The nitrogen content of CS-60C was higher than that of CB-60C or CB-65A, probably because of the higher proportion of arginine in the cottonseed allergen.[1b] Carbon and hydrogen contents of the three fractions were of the order of magnitude usually found in proteins. Like CS-60C, both CB-60C and CB-65A were levorotatory. There was, however, no marked difference between the rotatory power of CB-60C and CB-65A. This indicated that changes which might have occurred in CB-65A as a result of the more drastic fractionation had not taken place in that part of the molecule which determines optical rotation. The solubility curves of CB-60C and CB-65A, Fig. 1, indicated that neither was chemically homogeneous. CB-65A, however, was more nearly homogeneous, by this criterion, than was CB-60C.

Eighty-seven per cent. of the nitrogen of CS-60C was precipitable by trichloroacetic acid (TCA) in contrast with only 27% for CB-60 and none for CB-65A. No radical change in constitution or composition of CB-60C appeared to have occurred as a result of fractionation because 22.5% of the nitrogen of precursor fraction CB-1A was precipitable by TCA. However, some change appeared to have occurred in CB-65A either by molecular rearrangement as a result of the drastic fractionation or by the

TABLE II

COMPARISON OF CHEMICAL COMPOSITION AND PROPERTIES OF CB-65A AND CB-60C WITH CS-60C[a]

Determination[b]	Fraction CB-65A	CB-60C	CS-60C
Nitrogen	19.0	19.1	20.4

[a] This serum (A. M.) gave positive passive transfer reactions to test with castor bean allergen when diluted $1:10^2$ but not when diluted $1:10^3$; *cf.* Coca and Grove, *J. Immunol.*, **10**, 445 (1925). [b] Quantity of fraction (contained in 0.025 ml. of sterile physiologic salt solution) injected into each sensitized site. [c] *Chemical and Engineering News*, **18**, 491 (1940). [d] Subjects who reacted negatively to cutaneous test with powdered de-fatted castor bean meal and also negatively to intracutaneous test with 0.1 γ of CB-1A were used as recipients. Recipients were uniformly sensitized with 0.05 ml. of serum in each of four sites on the upper arms. All tests of a series were conducted simultaneously. The size of the wheals which formed in fifteen to thirty minutes are in mm. A negative control test was made on the unsensitized skin of the recipient at the time of the passive transfer tests. [e] See Paper VIII, footnote *e* of Table V for comments on the ± reaction.

removal of constituents precipitable by TCA. Whichever possibility occurred CB-65A suffered no demonstrable loss in capacity to produce positive passive transfer reactions as compared with precursor fraction CB-1A. Results of this clinical comparison, Table III, show that 1×10^{-10} g. of both CB-1A and CB-65A produced positive passive transfer reactions of equal size. However, alteration in the antigenic potency of CB-65A was demonstrable, using guinea pigs as test animals. The median lethal dose of CB-65A was the same as that of CB-1A but the median sensitizing dose of CB-65A was more than eleven times as great as that of CB-1A.

An interpretation analogous to the conclusions drawn from more exhaustive studies of cottonseed allergenic fractions may explain these observations. From chemical evidence previously presented,[5] it was suggested that the cottonseed allergenic fraction, CS-1A, was a mixture containing principally a specifically active protein and compounds of this same protein chemically combined with varying proportions of polysaccharidic carbohydrate. Later the active, essentially carbohydrate-free protein, CS-60C, was isolated.[4] Antigenic studies on excised uterine muscle from sensitized guinea pigs substantiated the view that carbohydrate did not determine antigenic specificity.[20] Carbohydrate, however, had a marked influence on antigenic potency[21] of fractions separated from CS-1A which, as in the cases of CB-1A and CB-65A, was manifested only in the sensitizing capacity.[19] Thus the median lethal doses of CS-51R[5] and CS-56R,[5] which contained 0.9 and 35.2% carbohydrate, respectively, was 5.61 ± 0.39 γ of nitrogen and 6.75 ± 0.77 γ of nitrogen, respectively. The median sensitizing dose of CS-51R was 91.7 ± 15.7 γ of nitrogen or more than eight times as high as that of CS-56R which was 11.0 ± 2.0 γ of nitrogen. Fraction CB-65A retained the same antigenic specificity as characterized CB-1A. Therefore the decreased sensitizing capacity of CB-65A may be owing to the removal of protein-polysaccharidic compounds from CB-1A having relatively high molecular weight and being, therefore, more effective in sensitizing power.

An alternate explanation of the decreased sensitizing power of CB-65A is that sensitization and shock may be produced by different functional groupings in the antigenic molecule. One grouping might therefore be altered without causing change in the other.

It is noteworthy that analogous manifestations of antigenicity in humans (capacity to incite positive passive transfer reactions) and in animals (shocking power) were unaffected by the fractionation required to obtain CB-65A. No comparison of the sensitizing capacity of this fraction for human subjects and animals was attempted because of the hazard of establishing in human subjects a permanent hypersensitivity to castor bean allergen.

Final decision as to whether protein or carbohydrate is responsible for the allergenic specificity of such highly purified substances as CS-60C and CB-65A cannot be made on the basis of chemical tests for carbohydrate. Even if tests for carbohydrate were unequivocally negative the possibility would still remain that sufficient carbohydrate was present to produce clinical reactions. As shown in Table III, solutions of CB-65A containing 4.0×10^{-9} g./ml. were clearly detectable by passive transfer technique. This is beyond the sensitivity of chemical tests on solutions of pure sugars. If the activity of CB-65A were owing to the 0.1% carbohydrate indicated by the orcinol method, then the concentration of active substance in CB-65A detectable by passive transfer would be 4.0×10^{-12} g./ml. At present there is no basis for accepting either 4.0×10^{-9} or 4.0×10^{-12} g./ml. as the approximate sensitivity of a castor bean allergenic preparation by the passive transfer technique. More decisive than chemical tests is the fact that CB-1A, which contained at least thirty times as much carbohydrate as did CB-65A, was not

(20) Coulson, Spies and Stevens, *J. Immunol.*, **46**, 347 (1943).

(21) Antigenic activity of a compound consists of two measurable manifestations, capacity to sensitize and capacity to shock.

demonstrably more effective in producing passive transfer reactions, or in shocking sensitized guinea pigs.

The obvious fact that biological tests on castor bean allergenic preparations are more sensitive than chemical tests for a given constituent provides justification for having employed the involved procedures used to isolate CB-65A. That CB-65A was obtained by such prolonged, varied, and drastic fractionation must be regarded as substantiating evidence that its activity is inherent and not owing to the presence of a difficultly removable contaminant. Osborne, Mendel and Harris[22] used similar reasoning in deciding that the powerful toxic action of ricin, from castor beans, was inherent in the albumin fraction exhibiting maximum toxicity and not owing to a difficultly removable contaminant.

Summary

An essentially carbohydrate-free allergenic protein, CB-65A, has been isolated from fraction CB-1A from castor beans by a prolonged series of procedures involving chromatographic adsorption of the picrate, electrophoretic recovery of the protein from its picrate, electrophoresis of the protein, and solvent fractionation. Elementary analyses and properties of CB-65A are compared with those of an analogous fraction CS-60C from cottonseed.

Positive passive transfer reactions were produced by 1×10^{-10} g. of CB-65A. Fraction CB-65A was antigenic as shown by tests using guinea pigs. CB-65A was as potent as precursor fraction CB-1A in producing passive transfer reactions and in shocking guinea pigs, but its sensitizing capacity was approximately one-eleventh that of CB-1A. Available evidence indicates that the principal allergenic and anaphylactogenic specificities of both CB-1A from castor beans and CS-1A from cottonseed are inherent in the essentially carbohydrate-free protein fractions CB-65A and CS-60C obtained from them.

The Action of Ultraviolet Light upon Cellulose. I. Irradiation Effects. II. Post-Irradiation Effects[1]

BY ROBERT A. STILLINGS[2a,b] AND ROBERT J. VAN NOSTRAND[2a,3]

Irradiation Effects[2a,b]

Although a number of studies of the effect of ultraviolet light on cellulose have been reported, the results are in many ways contradictory and incomplete, especially with respect to the role of oxygen and the mechanism of the reaction. The objectives of this investigation were to clear up existing discrepancies and to gain information as to the reaction mechanism.

Apparatus, Materials and Methods

Irradiation Apparatus.—The apparatus used in this investigation (Fig. 1) consisted of a gas purification train, an exposure chamber with a magnetic stirrer and capable of being evacuated, a mercury vapor lamp, and a gas analysis train with provision for the quantitative estimation of water, carbon dioxide, formaldehyde, hydrogen, carbon monoxide and organic combustibles.

The gas used as the atmosphere surrounding the cellulose sample during the experiment was passed first through a calibrated flowmeter of the orifice type. The gas line leading from the flowmeter had a side connection leading to a bubbler, in which the water level was maintained about two inches above the gas outlet. This side tube served as a safety valve, never permitting the gas pressure in the exposure chamber to rise above two inches of water. From the flowmeter, the gas passed through a calcium chloride tower to remove water vapor, a copper gauze furnace to remove oxygen, an Ascarite–Anhydrone bottle to remove carbon dioxide and the last traces of water vapor and, finally, through a three-way stopcock into the exposure chamber. The copper gauze furnace was of the type described by Savage and Ordal[4]; it consisted of 40-mesh copper wire gauze wound on a Calrod heating element (General Electric Company), the assembly being encased in a tight-fitting Pyrex tube. When oxygen was used as the gaseous atmosphere, the furnace was turned off; otherwise, the gas received the same purification treatment.

The outer shell of the exposure chamber consisted of an open-top brass cylinder 2.25 inches high by 10.25 inches in diameter (inside dimensions). Inside of this was a concentric, rotatable, open-top brass cylinder 1.5 × 10 inches (outside dimensions) supported on ball bearings. Two pieces of soft iron were fastened to the bottom of the inner cylinder, so that it might be turned by a motor-driven electromagnet rotating in a horizontal plane below the outer shell. Direct current was fed to the coils of the magnet by means of slip rings, about 50 watts being required for satisfactory operation of the agitator. The cellulose was placed in the inner cylinder. When the latter rotated, the material was mixed by stationary plows attached to the upper rim of the outer shell. The plow holder was removable, allowing the inner cylinder to be taken out. A mercury-in-glass thermometer, shielded from direct radiation, was attached to the plow holder. To keep the temperature down during irradiation, a fan blew air over the exposure chamber.

The cover consisted of four pieces (each 5.625 inches square) of Vycor high-silica ultraviolet-transmitting glass (Corning Glass Works), sealed in place with beeswax–

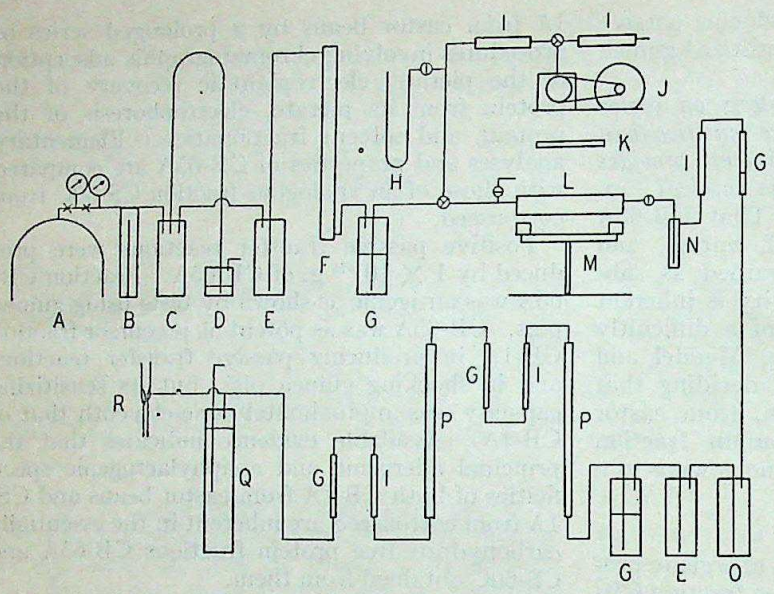

Fig. 1.—Schematic diagram of irradiation apparatus: A, nitrogen tank; B, flowmeter; C, trap; D, bubbler; E, $CaCl_2$ tube; F, copper gauze furnace; G, ascarite–anhydrone tube; H, manometer; I, anhydrone tube; J, Cenco pump; K, Uviarc lamp; L, exposure chamber; M, electromagnet; N, trap; O, NaOI tube; P, combustion tube; Q, pressure regulator (H_2O); R, aspirator.

rosin mixture at the start of each experiment. An auxiliary cover (consisting of a vacuum desiccator lid) was placed on top of the Vycor glass during evacuation, which was carried out with a Cenco Hyvac pump; the pressure was indicated by a closed-tube mercury manometer opening into the evacuation line, which also contained an Anhydrone tube to absorb water vapor.

A General Electric Portable Uviarc outfit, consisting of a UA-26A2 quartz tubular, A. C. Uviarc in a mat aluminum reflector, was used as the source of radiation. Technical data for this 360-watt discharge tube have been given by Johnson and Webster.[5] In all the experiments the distance from the discharge tube to the glass cover of the chamber was eight inches.

The gas emerging from the exposure chanber was passed through a glass-wool trap to remove any entrained particles of cellulose, through an Anhydrone tube for the estimation of water, an Ascarite–Anhydrone tube for the estimation of carbon dioxide, and an alkaline solution of standard iodine for the estimation of formaldehyde or other easily oxidizable substances. The mixture of gases then passed through a calcium chloride bottle to remove water, an Ascarite–Anhydrone bottle to remove any carbon dioxide and the last traces of water, and into the first cupric oxide-filled combustion tube. This tube was maintained at 260–270° for the combustion of carbon monoxide to carbon dioxide and hydrogen to water, which were estimated by absorption in Anhydrone and Ascarite–Anhydrone tubes. The gas was then passed into the second cupric oxide-filled tube, which was maintained at about 800° for the combustion of organic matter to carbon dioxide and water (estimated as before). The pressure drop through the gas analysis train was compensated by a pressure regulator connected to the end of the train, thus maintaining the pressure in the exposure chamber at the desired value.

The procedure followed in making a run on cellulose was as follows: The sample, which had been dried at room temperature in a vacuum desiccator over Anhydrone, was introduced into the exposure chamber. The latter was closed and the system evacuated. The cellulose sample was dried either by means of a small electric hotplate beneath the exposure chamber (35–40°) or by radiation from a 250-watt General Electric infrared drying lamp in a gold-plated reflector (60°), while passing through the chamber a current of air or nitrogen dried over Anhydrone. The first method permitted drying of the cellulose to 0.2% and the latter to less than 0.02% moisture (as determined by oven drying at 105°).

When the exposure was to be made in the absence of oxygen, the drying period was followed by repeated evacuation to a pressure less than 0.1 mm. of mercury and admission of purified nitrogen to a pressure of about 200 mm. of mercury. Calculation showed that seven of these cycles were sufficient to eliminate all oxygen which can be removed by the procedure. The entire system, including the gas analysis train, was then swept out by passing purified nitrogen through it for about five hours at a rate of 50 ml. per minute. The infrared lamp was then replaced by the mercury arc and the gas flow was continued at 50 ml. per minute throughout the exposure, except when the absorption tubes were being weighed.

Materials.—Hercules cotton linters, cut to an average fiber length of 0.4 mm. by the Clairemont Waste Manufacturing Co., had the characteristics given in Table I. Purified β-*d*-glucose[6] and β-cellobiose gave specific rotations of $[\alpha]^{0}D$ 20.0° (water, $C = 5.02$) and $[\alpha]^{20}D$ 35.8° (water, $C = 3.82$), respectively.

Tank nitrogen, after passage through the copper gauze furnace, contained about 0.002% by volume of oxygen as determined by the starch-iodine complex.[7]

Analytical Methods.—Copper number (according to Schwalbe), α-cellulose, ash and furfural were determined according to generally accepted methods. The reducing power of the glucose and cellobiose was determined by the method of Auerbach and Bodländer.[8] Staudinger's viscosity method was used to determine the average chain length of the cellulose, employing the apparatus and procedure described by Heuser and Green.[9] In calculating the degree of polymerization, (D. P.), 5×10^{-4} was used as the value of Staudinger's m constant.

Blank Tests.—To ascertain any increase in weight of the gas analysis absorption tubes when nitrogen or oxygen was passed through the system, blank tests were run before and after each exposure to ultraviolet light, and the small increases observed were taken into consideration. In addition, a gas mixture of known composition (consisting of carbon dioxide, hydrogen, carbon monoxide and methane) was allowed to pass through the apparatus while the chamber was being exposed to ultraviolet light and was analyzed as described above. The accuracy was quite satisfactory, and there was no indication that any appreciable interaction of these gases took place under the action of the ultraviolet light.

Standardization.—In all experiments with cellulose, the weight of sample used was 38.87 g. (oven-dry basis). The temperature of the cellulose during exposure was 45 ± 5°. In all experiments except 8, the rate of gas flow through the apparatus was maintained at 50 ml. per minute. A positive pressure of about one inch of water was maintained in the sample chamber during exposure. The time of irradiation varied between 24 and 336 hours.

[a] The values in the column headed "Elapsed Time" indicate the number of days elapsed between the beginning of the exposure and the determination. The ash content of the unexposed material was 0.086%; the copper content of the ash amounted to not more than 0.4 p. p. m. and its iron content was not more than 16 p. p. m. Where the atmosphere was part oxygen, the rest was nitrogen. [b] D. P. is used to signify degree of polymerization.

Experimental Results

Experiments 4, 5, 6, 8–10, as well as the blank test, in Table I, summarize the results of a series designed to discover the effect of oxygen during the irradiation of cellulose. As will be discussed later in more detail, the specific viscosities as well as the copper numbers and the α-cellulose contents, continued to change for several months after the samples had been removed from the exposure chamber and while they were being stored in stoppered glass bottles. These changes were quite unexpected and were observed incidentally only toward the end of this investigation. Nevertheless, the values quoted in Table I would seem to be fairly comparable, either because the analyses (copper number and α-cellulose) were made after approximately the same elapsed time or the elapsed time was sufficiently long to insure approach to the ultimate values (D. P.).

The fact that the blank experiment in the presence of oxygen without irradiation caused no significant increase in the copper number of the cellulose, eliminated heating (43°) during drying and exposure and also the presence of oxygen in itself as the cause of the effects observed in the other experiments. These effects, measured by changes in degree of polymerization, copper number, α-cellulose, and by the evolution of gases must, therefore, have been photochemical, and experiments 4, 5 and 8 show them to be considerable, even in samples exposed in nitrogen with all possible precautions to exclude and remove oxygen. When oxygen-containing atmospheres were used (Experiments 10, 9 and 6), the rate of degradation of the cellulose increased over the whole range of oxygen concentration.

In spite of the precautions to remove and exclude oxygen during the exposures in nitrogen, significant amounts of oxygen could have been present in the nitrogen atmosphere or the cellulose. A comparison of experiments 4 and 8 eliminates the first possibility. The two experiments were identical, except that in experiment 4 nitrogen was passed continuously through the system, whereas in experiment 8 the nitrogen-filled chamber was sealed off. If the oxygen in the nitrogen were responsible for the degradation, the effect should have been greater in experiment 4, but this was not the case. In experiment 8, the calculated amount of oxygen introduced with the nitrogen (0.002% by volume of oxygen) was 0.024 millimole or 1.8×10^{-4}%, based on the cellulose. To prepare an oxycellulose of the same copper number as exposed sample 8 by other methods would require at least 0.05% oxygen, or 280 times the amount which was present in the nitrogen in experiment 8.

If oxygen retained by the cellulose had been

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the sole cause of the degradation, the rate of reaction would be expected to be maximum at the beginning and fall off to zero as the oxygen was consumed. This was not the case. During experiment 12, the rates of evolution of water, carbon dioxide, and carbon monoxide actually *increased* continuously during the course of the irradiation.

Kinetics and Mechanism of the Reaction in Nitrogen.—A study of the kinetics of the reaction was based upon experiments 2–8 and 12 of Table I.

Decrease in Chain Length.—For the early stages of a chain-splitting reaction, Sakurada and Okamura[10] developed the following equation relating the average number of scissions per molecule to the change in average degree of polymerization as determined by the viscosity method.

$$P^1/P = (2/S^2)(S - 1 + C^{-s})$$

where P = original D. P.
P^1 = D. P. after the reaction, and
S = average number of scissions per molecule.

Although the application of this equation to the present case would appear to be somewhat hampered by the instability in which the samples are left after irradiation, an attempt was made to calculate S by taking P^1 as the ultimate D. P.—*i. e.*, that reached after the post-irradiation effect had practically come to an end.

If the photolysis proceeded as a first order reaction, the rate of cleavage (rate of change of S) should have been essentially constant over the limited range studied. Figure 2 is a comparison of the actual rate of decrease of chain length with a theoretical, first-order rate chosen to make the curves intersect at the two-day mark. It is apparent that the reaction cannot be regarded as first-order, as the actual rate was too fast near the start and became too slow as the degradation progressed.

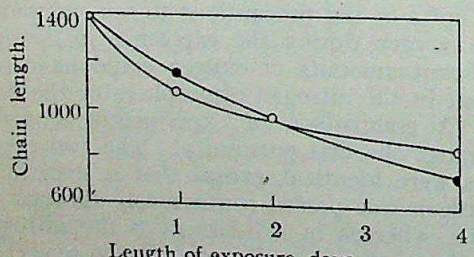

Fig. 2.—Actual (○) and theoretical (●) decrease in degree of polymerization during irradiation in nitrogen.

Possible explanations of this difference are the presence of oxygen in the system at the start of each exposure, and the formation of products of reaction having a higher absorption of ultraviolet light than the original material.

If some oxygen were present at the start of each experiment, the rate of cleavage would be higher at the start and would come to a constant rate only after all the oxygen was consumed. A correction for such an effect might be applied by subtracting a constant from the calculated S values. When 0.45 is used as the constant, the corrected curve is first-order for the first forty-eight hours, but the ninety-six-hour value is still significantly off. Thus, the deviation from the first-order rate cannot be completely explained by assuming the presence of oxygen, although oxygen as a contributing factor is not ruled out. With regard to the second possibility, the irradiated material did indeed show a decreased reflectance in the blue end of the visible spectrum, and indications were that the difference was even greater in the ultraviolet.

A third possibility is that the difference is the result of the presence in cellulose of cross linkages which, according to Steurer,[11] could have undergone cleavage at a faster rate than did the predominating 1,4-glycosidic linkages.

Increase in Copper Number.—The above considerations are equally applicable in explaining the fact that the increase in copper number (increase in reducing groups) proceeded at a decreasing rather than at a constant rate.

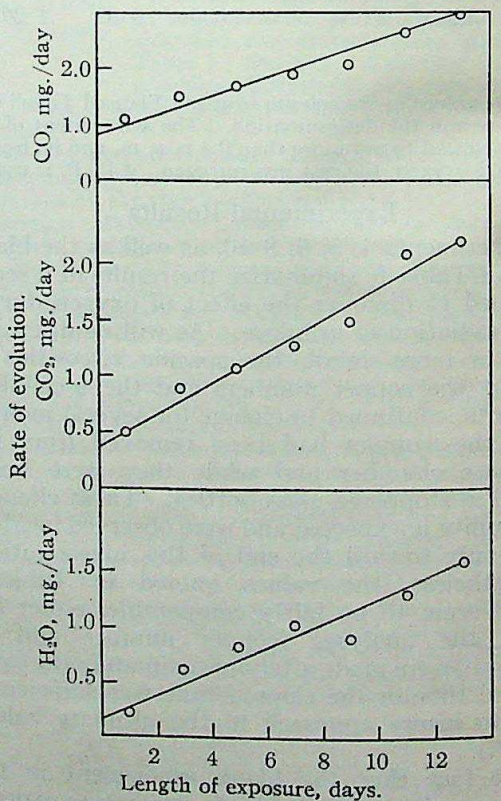

Fig. 3.—Ratio of evolution of gaseous products from cellulose during irradiation in nitrogen.

Formation of Gaseous Products.—Figure 3 shows that the rates of evolution of carbon monoxide, carbon dioxide, and water increased continuously during the course of the longest ex-

posure made (experiment 12 of Table I). In the case of the first two, the increasing rate indicates that they were the products of secondary reactions or of both primary and secondary reactions. As the curves extrapolate to an appreciable rate at zero time, the latter alternative is more probable. The increasing rate of liberation of water may have been merely a result of the hygroscopic nature of the dried cellulose.

Control experiments were made in which glucose was irradiated for forty-eight hours and cellobiose for one hundred and eight hours. The rates of carbon monoxide and carbon dioxide evolution in millimoles per day were only 0.03 and 0.04 for glucose and 0.02 and 0.02 for cellobiose. As the rates for cellulose were 0.09 and 0.07, respectively (*i. e.*, roughly three times higher), it was concluded that these gases did not result from the photolysis of hemiacetal groups or glycosidic bonds in cellulose. The reducing power of both sugars remained constant to ± 0.2% during irradiation, but water solutions of both showed an increase in light absorption in the ultraviolet range.

Instability of Exposed Samples.—As mentioned above, degradation of the irradiated samples continued after the conclusion of the actual exposure—*i. e.*, during storage in air in screw-top glass bottles. No degradation occurred in the unexposed material stored under the same conditions during the investigation.

A portion of exposed sample 12 stored in nitrogen in the dark showed no decrease in chain of length during a two-week period, whereas the portion stored in air in the light of the laboratory underwent a drop in D. P. from 780 to 700. Two portions of another sample which had been irradiated 48 hours in the nitrogen atmosphere and had a D. P. of 1280 were stored in nitrogen and in air in the light of the laboratory. After six days of storage the sample in nitrogen showed a D. P. of 1310, whereas the sample in air had dropped to 1200. These results seem to suggest that the post-irradiation effects were due to oxidation by atmospheric oxygen. This conclusion is borne out further by the results of an experiment in which the viscosity of the last mentioned sample was determined as soon as possible after irradiation (about one hour's contact with air during the necessary manipulations). The D. P. thus determined was 1280 as compared with the original value of 1400 and with the ultimate D. P. after the post-irradiation effect of 960.

Reaction Mechanism.—If only the reducing end groups were involved in the primary reaction, no appreciable decrease in chain length would result unless the attack continued progressively along the chain, in which case the α-cellulose would show a decrease corresponding to the decrease in D. P. This was not the case. Another indication that the reducing end groups were not appreciably affected is the fact that irradiation of glucose and cellobiose resulted in no measurable change in reducing power.

Other investigators[12] have shown that, in the absence of oxygen, simple alcohols are stable to light of wave length above 200 mμ (lower wavelength limit in the present investigation was 230 mμ). This, together with the fact that no hydrogen was formed during irradiation of cellulose, indicates that photolysis of the alcohol groups did not occur, at least not in the usual manner.

If the decrease in chain length (measured immediately following exposure) was not caused by oxidation effects, it was, in all probability, the result of a photolysis of glycosidic linkages. The fact that the number 1 carbon atom is the only one linked to two oxygen atoms suggests this as the source of the carbon dioxide formed. Whether or not the photolysis of glycosidic linkages occurred as a primary reaction, there must have been some other primary reaction which did not break the chains but left them unstable to atmospheric oxygen, as evidenced by the post-irradiation decrease in chain length. The possibility that, under the action of ultra-violet light, the oxygen was converted into ozone (in which form it is known to degrade cellulose without the aid of ultraviolet light) is ruled out because no ozone could be detected inside the exposure chamber, although the surrounding atmosphere was pregnant with ozone while the lamp was operated.

The question arises whether the other measured changes in the cellulose were concerned in the reaction which led to chain splitting. Some indication may be obtained by comparing the *S* values calculated by the Sakurada equation with the formation of gases and reducing groups expressed as millimoles per millimole of cellulose (227 g. in this case). Table II is a tabulation of such a comparison. There is a fairly good correspondence between the *S* values and the carbon monoxide and dioxide values. This is a strong indication that the formation of these gases was involved in the reaction which led to chain cleavage, one molecule of each gas being produced per scission.

TABLE II

RELATIONSHIP OF ANALYTICAL RESULTS

Expt.	D. P.	*S*	Reducing power,[a] milliequiv.	CO,[a] millimoles	CO_2,[a] millimoles
5	1070	0.87	5.0	0.47	0.35

However, the reducing power values (calculated from the increase in copper number) are about ten times the *S* values, corresponding to the production of five aldehyde or similar groups per chain split, which seems improbable. More likely, the reducing groups were formed, at least in part, from some other reaction not ultimately resulting in chain cleavage.

The fact that carbon dioxide and monoxide were formed, necessarily means that anhydroglucose units were decomposed. No change in pentosan content could be detected, but the possibility remains that desoxypentoses or carbohydrate units of fewer carbon atoms were formed.

Post-Irradiation Effect[2a,3]

To establish more firmly the conditions under which the post-irradiation effect occurred, portions of the exposed cellulose samples were analyzed immediately after exposure, whereas the remainder were stored in the desired atmosphere by transferring them—immediately after exposure—to round-bottom flasks which were evacuated, subsequently flushed, filled with purified nitrogen, air, or oxygen and finally sealed. The analysis of the samples was confined to the degree of polymerization, the copper number, and the α-cellulose content. The time of irradiation was, except in one case, ninety-six hours, whereas the storage time varied.

The equipment used in the first part of this investigation was improved in various respects. Particularly, the construction of the irradiation chamber was such that it withstood a considerably higher vacuum than previously employed to remove the air from the system as far as possible. The vacuum amounted to 25–30 microns as read from a Pirani gage.

Evacuation and flushing with nitrogen were repeated five times, after which only 4.38×10^{-17}% of the original atmosphere was present.

For the purification of the tank nitrogen, the copper gauze was replaced by colloidal copper deposited upon diatomaceous earth in accordance with the suggestion made by Meyer and Ronge.[13] In this way, the oxygen content of the tank nitrogen was reduced to as low a value as 3.4×10^{-4} (against 2×10^{-3} in the first part of the investigation).

Because the Uviarc lamp had lost a good deal of its efficiency in the previous experiments, the effect of irradiation was relatively small, as was the post-irradiation effect during storage of the irradiated sample in air at room temperature (Table III, run N2). However, the latter effect was considerably increased when the temperature during storage in air was raised to 70° (run N5) or when the air at room temperature was replaced by oxygen (run N4). Only a small part of the increased post-irradiation effect at 70° was due to the temperature alone, as may be seen from the extent to which an unirradiated sample was attacked when subjected to 70° in air for about the same length of time as was used for storing the irradiated sample (run N3).

(13) Meyer and Ronge, *Angew. Chem.*, **52**, 637 (1939).

TABLE III

CHANGE OF CHARACTERISTICS OF CELLULOSE ON IRRADIATION AND SUBSEQUENT STORAGE IN VARIOUS ATMOSPHERES

Experimental runs	Description	Degree of polymerization	Copper number	α-Cellulose content, %
	Original	1250	0.31	97.5
	Irradiated in nitrogen	1155	.62	94.9
N2	Stored in air for 25 days	1072	.67	..
	Stored in air for 60 days	1079	.61	94.4
	Irradiated in nitrogen	1100	.61	94.8
N5	Stored in air at 70° for 60 days	688	1.07	92.0
N3	Original cellulose, merely heated at 70° for 55 days	1060	0.37	..
	Irradiated in nitrogen	1130	.61	95.1
	Stored in nitrogen for 20 days	1155	.60	..
N4	Stored in nitrogen for 30 days, followed by 10 days in oxygen	904	.68	..
	Same as above, followed by 20 days in oxygen	854	.75	93.2

It is of interest that, even if the effect of temperature on the unirradiated cellulose sample is taken into account, the results show that irradiation in nitrogen had sensitized the cellulose to a far greater extent than could be derived from the drop in degree of polymerization from 1250 to 1155 or from that which occurred when the irradiated sample was stored in air at room temperature (from 1155 to 1072). It is seen also from Table III that the post-irradiation effect becomes practically constant if the oxygen is given sufficient time to act (N4, last two columns).

The irradiation effect from a new and stronger Uviarc lamp (600 as compared with 300-watt)

TABLE IV

CHANGE OF CHARACTERISTICS OF CELLULOSE ON IRRADIATION IN NITROGEN AND SUBSEQUENT STORAGE ALTERNATINGLY IN NITROGEN AND OXYGEN

Experimental Run N6

Description	Degree of Polymerization	Copper number	α-Cellulose Content, %

was much greater as seen from the data in Table IV. In addition, it is shown and further illustrated in Fig. 4 that the post-exposure effect could be deferred or produced *ad libitum*, depending upon whether the sample was stored first in nitrogen and then in oxygen, then again in nitrogen, and finally again in oxygen. If sufficient time was allowed for this last phase, the post-exposure effect, as judged from the change in degree of polymerization, came to an end.

In the following series of experiments, irradiation was allowed to take place in oxygen instead of in nitrogen. As would be expected, the irradiation effect was much enhanced under these conditions. The degree of polymerization dropped from 1250 to a value as low as 450, the copper number increased from 0.31 to 5.92, and the α-cellulose content decreased from 97.5 to 56.8.

When the sample irradiated in oxygen was subsequently stored in oxygen for forty days, further drop in the degree of polymerization and increase in the copper number (6.45) occurred. However, when the storage in oxygen was lengthened by ten more days, the degree of polymerization remained practically constant, showing that the post-irradiation effect had come to an end. The data are shown in Table V.

TABLE V

CHANGE OF CHARACTERISTIC OF CELLULOSE IRRADIATED IN OXYGEN AND SUBSEQUENTLY STORED IN OXYGEN

	D.P.
Irradiated in oxygen for 4 days	450
Stored in oxygen for 40 days	320
Stored in oxygen for 10 additional days	333
Irradiated in oxygen for 10 days	272
Stored in oxygen for 10 days	240

This table contains also the data which were obtained when the cellulose was irradiated in oxygen for ten instead of four days (as in all previous experiments) and when the sample thus treated was subsequently stored in oxygen for ten days. The degree of polymerization decreased to 272 on irradiation in oxygen but remained practically unchanged on subsequent storage in oxygen.

The results reported above seem to confirm the previously advanced hypothesis—namely, that two reactions take place during the action upon cellulose of ultraviolet light in the absence of oxygen, one which results in the rupture of glycosidic linkages and another which does not rupture these linkages but leaves them in an unstable condition to oxygen. That these two reactions should take place simultaneously would imply that the glycosidic linkages are attacked to a different extent. This difference is possibly a result of the difference in their accessibility in the micellar system. Thus, the assumption may be made that those glycosidic linkages which belong to chains exposed on the surface are broken down completely, whereas those which belong to

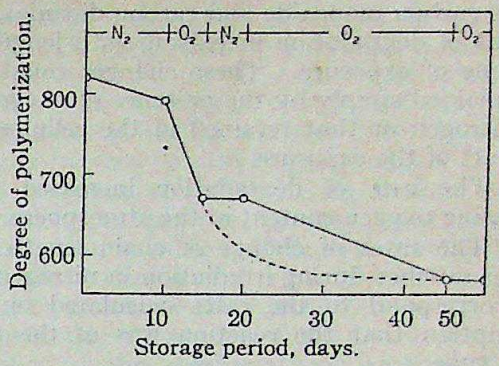

Fig. 4.—Change in degree of polymerization of cellulose previously irradiated in nitrogen and alternately stored in nitrogen and oxygen.

chains located in the interior of the micelles are only weakened. These weakened bonds are then completely ruptured by oxidation, either during irradiation in an oxygen atmosphere or during storage of the irradiated sample in oxygen. In other words, the activity of the oxygen may be eliminated from the irradiation stage and shifted to a subsequent and separate stage. Indeed, the two reactions—the action of oxygen during irradiation and the post-irradiation reaction—seem to be quite alike, the same changes being produced. Likewise, if a portion or all of the oxidation of weakened glycosidic linkages is allowed to take place during irradiation, only part or practically none of it occurs in the post-irradiation stage.

The mechanisms by which a portion of the glycosidic linkages is ruptured while another portion is left in an unstable condition and by which the weakened bonds are subsequently ruptured by oxidation are still obscure. Consideration also will have to be given to the possibility that the cleavage of glycosidic linkages is the result of hydrolysis caused by the small amount of water left in the cellulose and catalyzed by ultraviolet light energy.

Summary and Conclusions

An apparatus has been developed which is suitable for the ultraviolet irradiation of solids in powder form in various atmospheres and which provides for evacuation prior to exposure, continuous mixing and continuous analysis of gaseous products.

The influence of oxygen on the photolysis of cellulose has been studied, as have the kinetics of the reaction in nitrogen. In addition, samples of glucose and cellobiose have been irradiated in a nitrogen atmosphere under the same conditions.

The most important results obtained in the investigation may be summarized as follows.

1. Cellulose irradiated in nitrogen with all possible precautions to remove and exclude oxygen showed considerable degradation (chiefly, a drop in degree of polymerization and α-cellulose content, an increase in copper number and libera-

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

tion of carbon monoxide and carbon dioxide), the amount of degradation increasing with lengthening time of exposure. These changes could not be explained simply by the presence of oxygen in the nitrogen or that retained in the cellulose at the start of the exposure.

2. The rate of degradation increased with increasing oxygen content in the atmosphere.

3. The rates of change of chain length and copper number during irradiation in nitrogen did not correspond to the rates calculated on the assumption that the reaction was of the first-order type.

4. Exposure of β-*d*-glucose and cellobiose likewise resulted in the production of carbon monoxide and carbon dioxide, but at a considerably slower rate than in the case of cellulose. No change could be detected in the reducing power of these sugars, but exposed samples showed an increased absorption of ultraviolet light.

5. Cellulose irradiated in the absence of oxygen was left in an unstable state at the conclusion of the exposure—*i. e.*, the changes which the cellulose underwent during irradiation continued to occur during storage when air was present, but ceased when air was absent.

6. The post-irradiation effect was increased by raising the temperature to 70° and by replacing the air in the storage bottles with oxygen. A small portion of the increased post-irradiation effect at 70° was due to the temperature alone.

7. The post-irradiation effect was deferred or produced *ad libitum* by alternating the atmospheres several times between nitrogen and oxygen. If the time of storage in oxygen was sufficiently long, the post-irradiation effect came to an end.

8. Cellulose which had been irradiated in the presence of oxygen still underwent the post-irradiation reaction. However, the effect was smaller and became almost negligible when the time during irradiation in oxygen was extended from four to ten days.

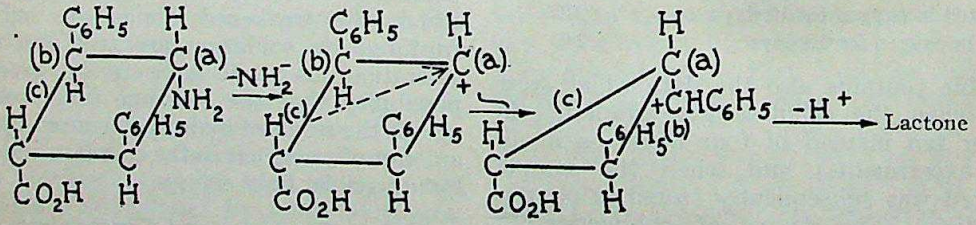
Studies in the Truxillic Acids. I. The Rearrangement of the Zeta-Truxinamic Acids and the General Theory of Molecular Rearrangements[1]

BY IRVING S. GOLDSTEIN[2] AND HERBERT I. BERNSTEIN

A general theory of molecular rearrangements was proposed by Whitmore[3] in 1932. The only essential modification since then has been that of the Walden inversion occurring on the carbon receiving the migrating group.[4]

Virtually all aliphatic rearrangements studied thus far fit into this theory. The evidence has been summarized briefly in a recent paper.[5]

It was further shown in that publication[5] that the amino acids of the truxillic and truxinic acid series lend themselves admirably for testing the stereochemical implications of the theory. Thus ε-truxillamic acid yielded the lactone of 1^c-carboxyl-2^c-benzoxyl-3^t-phenylcyclopropane upon treatment with nitrosyl bromide.[6] The theory would illustrate this as follows



The amino group is removed with its octet of electrons. Carbon a makes up for the resulting deficiency by taking a pair from the adjacent atom b, the pair constituting the bond c. The shifting electrons join carbon a opposite to the position held by the amino group. Thus carbon atom b, with only six electrons, is below the plane of the new cyclopropane ring. The missing electrons are supplied to b by a carboxyl oxygen and result from the loss of the carboxyl H, thus forming a lactone. The various steps need not be consecutive, but may all occur together, somewhat as in S_N2 substitution. Similar degradations of α-truxillaminic,[7] γ-truxillaminic,[8] β-truxinaminic,[9] and δ-truxinaminic acids[9] yielded isomeric cyclo-

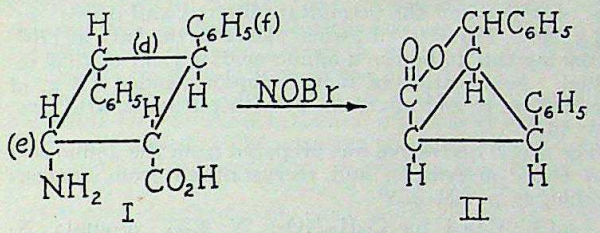
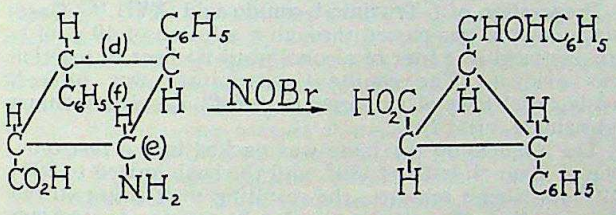
propane compounds whose configurations are explained readily by the general theory.

All of the possible stereoisomeric 1-carboxyl-2-benzoxyl-3-phenylcyclopropanes have been prepared and characterized by Schenck.[10] In this paper he also notes the fact that ζ-truxinic-a-amino acid (I) yielded a cyclopropane in which all three groups were *cis* (II), while the b-amino acid (III) gave an unknown bromo acid and a hydroxyl-acid having the phenyl group *trans* (IV).



I II

ζ-Truxinic-*b*-amino acid



III IV

ζ-Truxinic-*a*-amino acid

No experimental facts were given, and the only reference was to an unpublished Doctoral Dissertation.[11] These results can be explained by the theory illustrated above only by the additional assumption that the rearrangement is accompanied by an inversion of the ring-carbon bearing the phenyl group in the final cyclopropane compound. The pair of electrons making bond d (I) must shift onto carbon atom e. Therefore, regardless of whether retention or inversion of configuration occurred during the rearrangement, the a-amino acid should have yielded a cyclopropane with the phenyl f and carboxyl groups *trans* to each other, since neither of these groups is affected by the various changes. The b-amino acid (III) similarly should have yielded a three-membered ring with the phenyl and carboxyl groups *cis*. In other words, assuming inversion at e, we might have expected the a-amino acid (I) to yield IV, while the b-amino acid (III) should have given II.

The amino acids (I and III) have been prepared and are newly described in the present paper. They were degraded with both nitrosyl bromide and nitrous acid. ζ-Truxinic-a-amino acid (I) gave principally the lactone (II) upon treatment with both nitrosyl bromide and nitrous acid. From nitrosyl bromide and the b-amino acid (III) a good yield of an unknown bromo-acid was obtained, but no acid IV. Only oils were obtained from nitrous acid and III. The degradation of the a-amino acid (I) to II checks the statement of Schenck,[10] and cannot be explained merely by the general theory of molecular rearrangements.

The above conclusions are dependent upon the correctness of the structures. All eight 1-carboxyl-2-benzoxyl-3-phenylcyclopropanes have been prepared and their configurations characterized[10]. Furthermore, if they were confused, then the degradation experiments previously run with other truxillic and truxinic acids[5] would no longer substantiate the general theory.

There also seems to be little doubt of the correctness of the configurations assigned to the amino acids. These are based on the reactions of the two isomeric ζ-truxinic-methyl ester-acid chlorides with aluminum chloride.[12] The compound which formed a truxonic (IX) ester was called ζ-truxinic-a-acid chloride-b-methyl ester (V). No ketonic compounds resulted from similar treatment of the isomer (VI). It is possible, but improbable, that the above authors[12] confused the a and b acids.

The configurations of the ζ-truxinamidic acids then were deduced from the conversion of both the a-amido acid (VII) and the ζ-truxinic-a-acid chloride-b-methyl ester (V) to the same a-amido acid-b-methyl ester (VIII).

As was shown in a previous publication,[5] it may be safely assumed that the amino acids have the same configuration as the amido acids from which they were prepared by the Hofmann degradation.

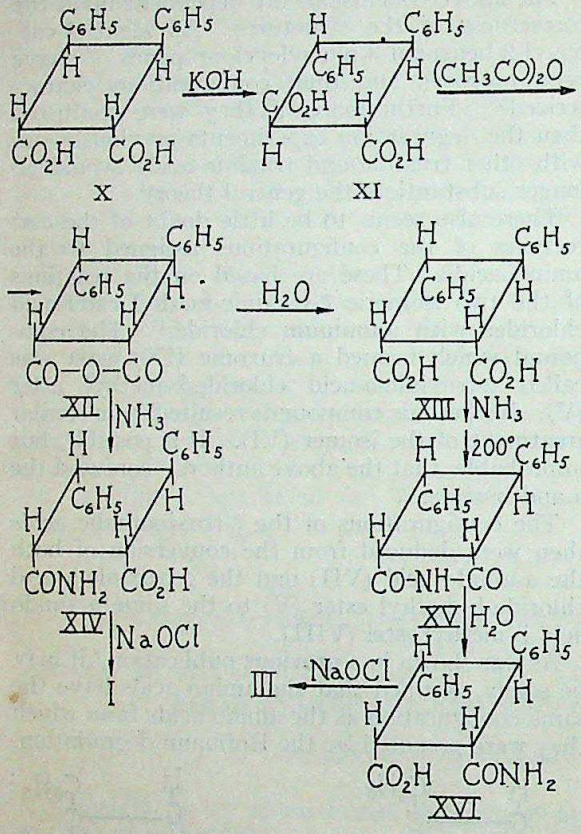
The flow sheet for the preparation of amino acids I and III from β-truxinic acid (X) is given below.



Experimental[13]

Preparation of δ-Truxinic Acid (XI).[14]—β-Truxinic acid (X)[15] was fused with eight times its weight of powdered potassium hydroxide. The fusion mixture became fluid, then pasty, then fluid again. At this point the flame was removed. The cooled fusion mixture was dissolved in water, and ice and hydrochloric acid were added. The resulting solid was filtered and recrystallized from aqueous methanol to yield crystals of δ-truxinic acid, m. p. 174–175°. From 127 g. was obtained 118 g. of δ-truxinic acid, a 93% yield.

Preparation of ζ-Truxinic Acid (XIII).[14]—To 169 g. of δ-truxinic acid was added 145 g. of fused sodium acetate and 365 g. of acetic anhydride. The mixture was refluxed for three hours at 200–210°. After cooling, it was poured into 2 liters of water, and the mixture heated to cause hydrolysis of the acetic anhydride. The flask was cooled as soon as a reaction had started. After standing overnight, the resultant solid was filtered off and dried, wt. 95.5 g. This was recrystallized from aqueous methanol to give crystals of m. p. 235–236° (d.). The recorded m. p. of ζ-truxinic acid is 239°.[12]

Preparation of ζ-Truxinic-a-amido Acid (XIV).[12]—A solution of 46.5 g. of crude ζ-truxinic acid and 140 g. of acetic anhydride was heated for two hours at 140–150°. The acetic acid formed and excess anhydride were removed by distillation *in vacuo*, and the residue dissolved in benzene. Ammonia was passed through the solution of the resulting anhydride until no more heat of reaction was evident. The voluminous precipitate was filtered, dried and dissolved in water. The resultant cloudy mixture was filtered until a clear yellow solution resulted. Acidification yielded a precipitate, which when filtered and dried weighed 30.5 g., m. p. 198–200°, yield 66%. Recrystallization from aqueous acetone raised the m. p. to 202–204°; literature,[12] m. p. 204°.

Preparation of ζ-Truxinic-a-amino Acid (I).—The method of Stoermer was used.[5] To 5.0 g. of ζ-truxinic-a-amido acid was added 70 cc. of 0.5 *N* sodium hypochlorite solution, and the resulting solution kept at 38–40° for two hours. It was then carefully neutralized, and made just basic with dilute sodium hydroxide. The small amount of insoluble precipitate was filtered off, and carbon dioxide passed into the clear filtrate. After an hour precipitation was complete and the precipitate filtered and dried; wt. 3.3 g., m. p. 178–180° (d.) when placed in the bath at 170°. Assuming this to be the a-amino acid, a yield of 73% resulted. Acidification of mother liquor yielded 1.2 g. of product, m. p. and mixed m. p. with ζ-truxinic acid 228–233° (d.).

The acetyl derivative was prepared from the amino acid and acetic anhydride, and recrystallized from aqueous alcohol, m. p. 224–225°.

Anal.[16] Calcd. for $C_{19}H_{19}NO_3$: N, 4.53. Found: N, 4.50.

Preparation of ζ-Truxinic-b-amido acid (XVI).[14]—Gaseous ammonia was passed through a solution of 49 g. of ζ-truxinic acid in 1 liter of alcohol until no heat of reaction was evident. The resultant precipitate was filtered, washed with alcohol, and dried to give 42.5 g. of **ammonium ζ-truxinate,** yield 78%.

The ammonium truxinate was packed into a test-tube, placed in an oil-bath at 180°, and the bath heated to 200–210° for fifteen minutes, the resulting melt being stirred occasionally. The tube was cooled, benzene and petroleum ether added, and the mixture thoroughly triturated and filtered. The residue was treated with sodium carbonate solution, and the insoluble material filtered off. This precipitate was recrystallized from alcohol to give **ζ-truxinimide** (XV), m. p. 167–168°; literature,[14] 168–168.5°. From 38.5 g. of ammonium ζ-truxinate fused in seven batches was obtained 20.5 g. of the imide, a yield of 63%. The sodium carbonate solution was acidified to give 8.5 g. of a solid, m. p. 165°. Recrystallization from aqueous alcohol did not change the m. p. The m. p. of pure δ-truxinic acid was 174–175°; mixed with the above solid was 165–168°. The acid fraction was possibly the impure δ-acid.

To 20.5 g. of the ζ-truxinimide was added 150 cc. of 10% alcoholic potassium hydroxide. After five hours of standing, the initially clear solution became a crystalline mass. This was dissolved in 2 liters of water, and the aqueous solution filtered clear. Acidification of the filtrate yielded a precipitate which was filtered and dried, wt. 21.0 g., m. p. 215–216° (d.) when placed in bath at 200°. This represented an over-all yield of 43% based on the crude ζ-truxinic acid. Recrystallization from aqueous acetic acid gave crystals of m. p. 229–230° (d.) when placed in bath at 220°; literature[14] m. p. 225–226° (d.) when placed in bath at 200°.

Preparation of ζ-Truxinic-b-amino Acid (III).—The reaction was run at 38–40° for two hours, after which most of the insoluble sodium salt of the b-amido acid had disappeared. The remaining solid was filtered, and the preparation continued as above. From 16.7 g. of the ζ-truxinic-b-amido acid was obtained 12.0 g. of the amino acid, m. p. 171–173°, and 3.5 g. of starting material. The mixed m. p. of the a- and b-amino acids was 162–168° (d.). The net yield was practically quantitative. The acetyl derivative of ζ-truxinic-b-amino acid from aqueous alcohol had m. p. 124–125°.

Anal. Calcd. for $C_{19}H_{19}NO_3$: N, 4.53. Found: N, 4.48.

Reaction of ζ-Truxinic-a-amino Acid with Nitrosyl Bromide.—A nitrosyl bromide solution was made by pass-

ing nitric oxide into a mixture of 5.6 g. of bromine in 200 cc. of dry ether in an ice–salt bath. The solution was then slowly added to 7.0 g. of ζ-truxinic-a-amino acid just covered with dry ether. The temperature was kept below −5°. After addition was completed, the reaction mixture stood until the evolution of nitrogen ceased. It was then shaken with a sodium bisulfite solution until the ether was colorless, followed by a similar shaking with a potassium carbonate solution. Acidification of this latter solution yielded only a small amount of an oil from which no crystals could be obtained.

The ether solution was dried over anhydrous potassium carbonate, then concentrated to give a total of 3.5 g. of white needles, m. p. 130–133°. Upon decolorizing with charcoal from a benzene solution, crystals were formed by the addition of petroleum ether (b. p. 60–70°), m. p. 133°. The known m. p. of lactone II was 133°.[8]

The lactone was boiled with 10% alcoholic potassium hydroxide for one minute, diluted with water, and hydrochloric acid added. The resulting precipitate was filtered, dried and recrystallized from benzene to give crystals of m. p. 148–149° (d.). The m. p. of 1^c-carboxyl-2^c-benzoxyl-3^c-phenylcyclopropane was reported[8] as 145–146°. Treatment of the above acid in methyl alcohol with diazomethane in ether yielded lactone II, m. p. and mixed m. p. 132–133°. This dehydrating action of diazomethane had been observed previously with the optically active acid.[5]

Reaction of ζ-Truxinic-b-amino Acid with Nitrosyl Bromide.—The nitrosyl bromide solution was added to 7.0 g. of the b-amino acid as described in the previous experiment. The reaction seemed slower. There was a small amount of ether insoluble material, m. p. 230–233°, possibly α,γ-diphenylbutadiene tetrabromide.[8] The ether was shaken with sodium bisulfite solution, then a potassium carbonate solution as above. Acidification of the latter solution yielded an oil which gradually solidified to yield 3.5 g. of crystals, m. p. 125–137°. Recrystallization from aqueous alcohol gave needles of m. p. 137–139°. Elementary analysis showed bromine to be present. This product will be thoroughly studied at a later date.

The ether solution was dried over potassium carbonate, and the ether evaporated off leaving an oil from which no crystals could be obtained. Treatment of the oil with boiling 10% alcoholic potassium hydroxide for one minute, dilution with water, and acidification also yielded an oil. From this oil, by means of decolorization with charcoal and two recrystallizations was obtained a small quantity of crystals, m. p. 168–169°.

Reaction of ζ-Truxinic-a-amino Acid with Nitrous Acid.—A solution of 1.5 g. of ζ-truxinic-a-amino acid in 150 cc. of dilute hydrochloric acid was warmed to 40°, and 1.5 g. of sodium nitrite in 10 cc. of water was slowly added. A solid gradually formed, and a gas was evolved containing oxides of nitrogen. One hour after addition had been completed, the flask was cooled, and the contents filtered. There was obtained 0.5 g. of crystals, which when decolorized and recrystallized from a benzene–petroleum ether solution had a m. p. of 131–133°. The mixed m. p. with the lactone II prepared above was 131–132°, demonstrating their identity.

Reaction of ζ-Truxinic-b-amino Acid with Nitrous Acid.—The reaction with nitrous acid was performed as above. The initial product was an oil, which was extracted from the solution using ether. The ether extract was washed with potassium carbonate solution. Only an oil resulted from acidification of the latter. Evaporation of the ether resulted in an oil, from which by recrystallization from a benzene–petroleum ether solution was obtained a few mg. of solid of m. p. 188–189°.

We wish to thank Dean Frank C. Whitmore of the Pennsylvania State College for his many helpful suggestions.

Summary

Deamination of ζ-truxinic-a-amino acid (1^c-carboxyl-2^c-amino-3^c,4^t-diphenylcyclobutane) with both nitrosyl bromide and nitrous acid gave the lactone of 1^c-carboxyl-2^c-benzoxyl-3^c-phenylcyclopropane. This change cannot be explained by any existing theory of molecular rearrangements without the assumption of an inversion of a carbon atom not directly involved in the reaction. Only a bromo-acid of unknown structure could be isolated from the reaction of nitrosyl bromide and ζ-truxinic-b-amino acid.

Reaction of Diazomethane with Ammonium Salts of Organic Acids

BY MAX FRANKEL AND EPHRAIM KATCHALSKI

In a previous paper[1] dealing with derivatives of N-carboxy α-amino acid esters, it has been shown that diazomethane reacts with the salt formed between N-carboxyglycine ester and glycine ester (I), yielding N-carbomethoxyglycine ester and glycine ester in about equimolecular amounts. The reaction proceeds according the scheme

$$\underset{\text{COOR}}{\overset{\text{CH}_2\text{NHCOOH}_3\text{NCH}_2}{|}}\text{COOR} \quad \underset{\text{I}}{} \quad + \text{CH}_2\text{N}_2 = \underset{\text{COOR}}{\overset{\text{CH}_2\text{NHCOOCH}_3}{|}}\text{COOR} + \text{H}_2\text{NCH}_2\text{COOR}$$

$$\text{R} = \text{CH}_3 \text{ or } \text{C}_2\text{H}_5$$

(I) is a substituted ammonium salt of an organic acid; thus the above scheme represents a reaction between diazomethane and an ammonium salt of an organic acid. As far as we are aware the literature does not contain any references to reactions between diazomethane and ammonium or N-substituted ammonium salts of organic or inorganic acids (*cf.* ref. 2); we therefore included in the paper mentioned[1] experimental results concerning the action of diazomethane on ammonium propionate and on ammonium benzoate. In both cases the methyl esters of the corresponding acids, and ammonia, were obtained.

The object of the present paper is to extend the investigation of this reaction to ammonium salts of dibasic acids and to N-substituted ammonium salts.

Di-(triethylammonium) phthalate[a,d]	Phthalate	72	278	31.96	32.10

[a] Solution of 0.8 g. of diazomethane in 70 ml. of ether used. [b] Reaction very slow. Ten ml. of alcohol added to accelerate. After standing for 48 hours, residue of 0.3 g. of ammonium salt was filtered off. Filtrate yielded 0.15 g. of product. [c] Residue of 0.05 g. remained after overnight treatment. [d] Fractionally distilled to remove triethylamine and redistilled twice for analysis.

Diazomethane was allowed to react with di-ammonium succinate, di-ammonium malonate, di-ammonium phthalate and with di-(methylammonium) phthalate, di-(ethylammonium) phthalate di-(dimethylammonium) phthalate and di-(triethylammonium) phthalate. The action of diazomethane on ammonium chloride, as representative of an inorganic ammonium salt, was also investigated.

In all cases a reaction analogous to that previously described[1] was observed, *i. e.*, the dimethyl esters of the corresponding dibasic organic acids were obtained, while ammonium chloride yielded methyl chloride. During these esterifications ammonia, methylamine, ethylamine, dimethylamine and triethylamine were evolved from the corresponding ammonium and substituted ammonium salts. In our experiments no appreciable methylation of the ammonia or amines liberated was observed.

Experimental

(a) Preparation of the Ammonium Salts.—The ammonium salts of malonic, succinic and phthalic acids were prepared by passing a stream of dried ammonia through an ethereal or alcoholic solution of the corresponding organic acid.[3] In the former case the ammonium salt was precipitated at once, while in the latter it was precipitated by the addition of ether.

The methylammonium, ethylammonium and dimethylammonium salts of phthalic acid were prepared by passing a stream of the appropriate dried gas through a suspension of 2 g. of *o*-phthalic acid in 10 ml. of alcohol. Di-(triethylammonium) phthalate was obtained by adding liquid triethylamine to a similar alcoholic solution of phthalic acid. After the addition was complete and the solution had cooled, separation of the salt was induced or completed by the addition of ether (generally 20 ml.). The products were filtered, washed with ether and dried.

All but the first of these salts seem to be described for the first time. Di-(methylammonium) phthalate has been obtained previously by a different method.[4] A tabulation of their yields and analyses is given in Table I.

(b) Reaction of Ammonium and N-Substituted Ammonium Salts with Diazomethane.—In all cases except those specified an ethereal solution of 1 g. of diazomethane in 70 ml. of ether prepared according to Adamson and Kenner[5] was used. This amount was greatly in excess of the theoretical quantity required in every instance. The ethereal solution of diazomethane was poured onto 0.5 g. of the solid ammonium salt. In general the evolution of nitrogen started immediately, but in some cases where the reaction was too slow it was accelerated by adding alcohol. The reaction mixtures were allowed to stand overnight at room temperature to complete the process. Moisture was excluded by means of a calcium chloride tube. The evolution of the ammonia or amines liberated in the reaction was indicated by their odor or their effect on litmus paper.

During the reaction the solid salt disappeared; the ethereal solution was filtered and the ether, excess of diazomethane and excess of ammonia were removed by distillation at normal pressure. The remaining viscous residue was dissolved in ether and dried over sodium sulfate. After filtration the ether was removed and the residue distilled to give the product. The esters thus obtained were redistilled before analysis. In addition to methoxyl determination a quantitative hydrolysis by alcoholic potassium hydroxide was carried out and the liberated carboxyl groups determined by back titration. In all cases this confirmed the formation of the methyl ester from the corresponding ammonium salt.

Data on the specific compounds are shown in Table II.

Action of Diazomethane on Ammonium Chloride.—One gram of diazomethane in 50 ml. of ether was added to 535 mg. of ammonium chloride. On adding 50 ml. of alcohol gas evolution started. The gases evolved were passed through a second vessel containing alcohol to absorb ammonia and methyl chloride which were only partly retained in the reaction vessel.

After twenty-four hours the residual solid ammonium chloride was filtered off (104 mg.). The alcohol–ether mixture of the reaction vessel contained a small amount of unchanged ammonium chloride in solution; this was de-

termined by a Volhard titration (43 mg.). The amount of ammonium chloride which underwent reaction was therefore 388 mg.

The methyl chloride was determined in both solutions as methyl iodide.[6] A total amount of 195 mg. of methyl chloride was found. Ammonia was determined by direct titration, 85 mg. was found. The yield of methyl chloride calculated on the basis of ammonium chloride which underwent reaction was 53%; that of ammonia 69%.

The authors acknowledge the assistance of Miss H. Berliner.

Summary

Diazomethane was allowed to react with di-ammonium malonate, di-ammonium succinate, di-ammonium phthalate, di-(methylammonium) phthalate, di-(ethylammonium) phthalate, di-(dimethylammonium) phthalate, and di-(triethylammonium) phthalate.

In all cases the dimethyl esters of the corresponding dibasic acids were obtained.

Reaction of diazomethane with ammonium chloride yielded methyl chloride.

During these esterifications ammonia, methylamine, ethylamine, dimethylamine and triethylamine were evolved from the corresponding ammonium and N-substituted ammonium salts.

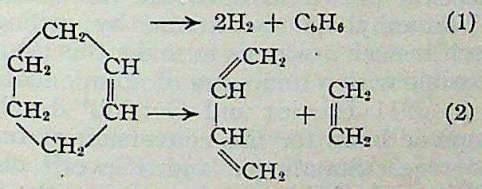
The Thermal Decomposition of Substituted Cyclohexenes[1]

BY F. O. RICE[2a] AND MARY THOMAS MURPHY[2b]

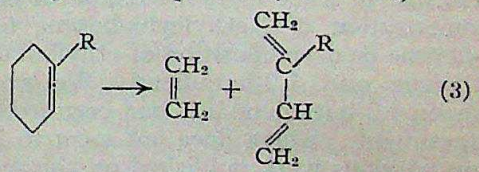
1. Introduction.—If cyclohexene is heated above its decomposition point, at low pressures and for a time sufficiently short that only a small fraction is decomposed, it undergoes a simple dissociation into smaller molecules. The particular conditions mentioned have been selected in order to avoid as far as possible bimolecular reactions of the products with each other or with the substrate. Several thermodynamically possible decompositions may occur such as



Reactions of these types have been discussed in a recent paper[3] in the light of a principle called the principle of least motion. In the case of several reactions such as those listed above which are all thermodynamically possible, the principle states that that reaction is favored which involves as little motion of the atoms as possible in passing from the old to the new configuration. The second half of the principle states that a reaction will be favored which involves least change of the electronic configuration of the reacting system. From both these standpoints, it is plausible to assume that the reaction will be favored which involves breaking or making as few bonds as possible.

On the basis of this principle we would predict with some confidence that reaction (2) would be greatly favored over reaction (1) and this has actually been found experimentally[4]; no benzene is found in the products but butadiene and ethylene are formed in almost theoretical yield. An investigation, therefore, of the decomposition of substituted cyclohexenes would provide not only a further test of the principle of least motion but also a method of preparing substituted butadienes.

2. 1-Methylcyclohexene.—We found that this compound decomposes to the extent of about 80% according to the equation (R = CH_3)



As might be expected, secondary reactions occur to a larger extent than in the decomposition of cyclohexene. For every 100 molecules of methylcyclohexene decomposed, about 40 molecules of hydrogen and 30 molecules of methane are formed in subsidiary reactions. Since separate experiments showed that isoprene itself is decomposed to the extent of only a few per cent. under the experimental conditions, doubtless the secondary reactions are due in greater part to attack of free radicals on the substrate.

Zelinski and co-workers[5] pyrolyzed a number of substituted cyclohexenes both alone and diluted with water vapor. They obtained a yield of 75% ethylene and 35.3% isoprene by heating 1-methylcyclohexene at 690°.

3. 1-Ethylcyclohexene.—There seems to be extensive decomposition which produces much methane and hydrogen; presumably there must be highly unsaturated C_8 or C_6 hydrocarbons formed although we could not identify anything in the higher fractions in spite of a careful search for ethylbutadiene which would be expected ac-

cording to equation 3 (R = C_2H_5). The large amount of methane formed indicates that there is a considerable amount of chain decomposition.

We must remember, however, that in a previous discussion of the principle of least motion[6] it was pointed out that a molecule having a long carbon skeleton, when ruptured by heat, could coil around and react with itself to produce an isomer. Considerations of this kind from the principle of least motion suggest as possibilities isomerization of 1-ethylcyclohexene to 3-vinyl-2-hexene or decomposition of ethylbutadiene into ethylene and 1,2-butadiene. We would have missed 1,2-butadiene if it had been formed in our experiment. There does not seem to have been any previous work published on the pyrolysis of ethylcyclohexene.

4. 1-Phenylcyclohexene.—We did only one experiment and obtained 41 molecules of phenylbutadiene for every 100 molecules of phenylcyclohexene decomposed. It is possible that the low yield is due to polymerization of the phenylbutadiene during distillation. The pyrolysis of 1-phenylcyclohexene does not appear to have been studied previously.

5. 3-Vinylcyclohexene.—We have proved that this compound decomposes from 80–85% into 1,3-butadiene. In view of the fact that this molecule would produce a radical having a long carbon skeleton which could react with itself and isomerize, it is not surprising that there are some side reactions. From the principle of least motion, we would predict the formation of 1,3,6-octatriene caused by the radical, $CH_2CHCHCH_2CH_2CH$-$CHCH_2$, coiling around and reacting with itself.

The gas phase dimerization of butadiene has been studied by several workers[7,8] but the reverse reaction does not seem to have been investigated experimentally although Kistiakowsky has made some calculations on the rate of dissociation.

6. Dipentene.—The yield of isoprene was 81% of the amount of dipentene decomposed. From some other work we estimate that 3–4% of the isoprene formed decomposed under our experimental conditions so that the small amounts of methylacetylene and butadiene found probably come from decomposition of the isoprene. It seems plausible also that dipentene can isomerize into 3,7-dimethyl-1,3,6-octatriene by coiling around itself in such a way as to make this isomerization possible with a minimum of atomic motion.

In 1911 Harries and Gottlob[9] developed the isoprene lamp for the conversion of terpenes to isoprene. Staudinger and Klever[10] obtained a 60% yield of isoprene by passing the vapors of dipentene, diluted with nitrogen, over a hot platinum coil at 20–30 mm. pressure.

7. 3-*p*-Menthene.—This material gave a good yield of propylene on pyrolysis but the expected 2-isopropylbutadiene could not be detected. The only previous work relating to this compound that we could find[11] is that 3-*p*-menthene is a product of the pyrolysis of menthol and is stable at 500°.

8. Experimental.—Our sample of 1-methylcyclohexene (b. p. 108–109°, $n^{20}D$ 1.4510) was prepared by Dr. J. Greenberg from 1-methylcyclohexanol. The 1-ethylcyclohexene used was prepared by Dr. P. M. Ruoff according to the method of Signaigo and Cramer[12] and had a b. p. 135.5–136.8° and $n^{20}D$ 1.4577. 1-Phenylcyclohexene was prepared by Dr. J. Greenberg, using cyclohexanone and phenyl bromide as starting points.[13] It had b. p. (5 mm.) 102–103°, m. p. 10–11°.

The 3-vinylcyclohexene was prepared by polymerizing butadiene at 450° and 600–700 mm. The dimer was twice distilled at 2 mm. pressure, the first and last samples being rejected each time. The sample had a b. p. 128–130° and $n^{20}D$ 1.4658. Our sample of limonene, b. p. (20 mm.) 67–68°, was purchased from Eastman Kodak Co. The 3-*p*-menthene was prepared by the dehydration of menthol. Sulfuric acid and aluminum oxide were both used as dehydrating agents but there was no difference in the products obtained by pyrolyzing the two samples. The material had a b. p. 168–169° and on hydrogenation gave 0.98 double bond.

The gaseous products were analyzed in a modified Shepherd[14] gas analysis apparatus containing a hydrogenation unit.[15] The products condensing in the traps were transferred to a low temperature Podbielniak still, fractionated, and then further analyzed in the gas analysis apparatus.

Isoprene was identified by its b. p., by giving two double bonds on hydrogenation and by the maleic anhydride derivative, m. p. 63°. 2-Phenylbutadiene was characterized by its b. p. and maleic anhydride derivative, m. p. 105°. 1,3-Butadiene was identified by its b. p. and hydrogenation value.

Summary

1. The thermal decomposition of a number of substituted cyclohexenes has been studied in the expectation that they would follow the pattern of the cyclohexene decomposition and yield a substituted butadiene and ethylene.

2. This was found to be the case for 1-methyl, 3-vinyl and 1-phenyl cyclohexene. In the case of ethylcyclohexene, we could not detect the expected ethylbutadiene.

3. Dipentene gave, as was to be expected, a high yield of isoprene. On the other hand, 3-*p*-menthene gave a high yield of propylene but no isopropylbutadiene could be detected.

The Effect of Dielectric Constant and Temperature on the Catalyzed Decomposition of Azodicarbonate Ion

BY CECIL V. KING AND JESSE J. JOSEPHS

In recent years much interest in reaction kinetics in solution has centered in two factors: (1) prediction by electrostatic theory of the effects of changing dielectric constant and ionic strength and (2) the interpretation of temperature coefficients in terms of activation energy and entropy.

(1) For a reaction between ions A and B present electrostatic theory may be summarized in the well-known Christiansen–Scatchard equation[1]

$$\log k = \log k_\infty - \frac{Z_A Z_B \epsilon^2 N}{2.3DRT} \cdot \frac{1}{r_A + r_B} + \frac{Z_A Z_B \epsilon^2 N}{2.3DRT} \cdot \frac{\kappa}{1 + a\kappa} \quad (1)$$

where the symbols have their usual significance and the last term refers to the salt effect, the next to last term to the dielectric constant effect. A similar equation has been developed by Eyring and his associates and includes a separate estimation of the radius of each ion and the critical complex.[2,3] (2) Introduction of the Eyring theory that rates may be expressed in terms of a universal frequency and an equilibrium constant K^* (reactants-critical complex) necessitates

$$k = RT/Nh \times K^*$$

defining the Arrhenius "energy of activation" as a free energy, and leads to the equation, for reactions in solution[4,5]

$$\log k = \log e \frac{RT}{Nh} - \frac{E_{exp.}}{2.3RT} + \frac{\Delta S^*}{2.3R} \quad (2)$$

where $E_{exp.}$ is the activation energy as determined from the slope of log k *vs.* $1/T$ plots and ΔS^* has been defined as the entropy of activation. This may be compared with the corresponding "collision theory" equation

$$\log k = \log Z - \frac{E_{exp.}}{2.3RT} + \log P \quad (3)$$

where the collision frequency Z may be calculated from the equations of the kinetic theory and P is the probability factor for effective collision.

As usually determined, in iso-composition solutions, both $E_{exp.}$ and ΔS^* contain factors due to the change in dielectric constant with temperature; and it has been suggested[6] that temperature coefficients for use in these equations should be determined in media of the same dielectric constant rather than the same composition.

Presumably there should be no entropy of activation unless the free energy of activation varies with temperature, or if the dielectric constant is kept unchanged as the temperature is varied (using rate constants at zero ionic strength).[7,8] However, since ΔS^* is deter-

mined as a difference it does not represent correct entropy values unless all other factors in equation (2) can be properly evaluated. For instance there may be a fractional "transmission coefficient" by which the Eyring frequency factor eRT/Nh should be multiplied in any particular case, but there is no independent method of ascertaining this. Also it has been suggested that the rate constant k should be based on mole fraction rather than volume concentrations for the calculation of $E_{exp.}$.[9,10,11]

The Azodicarbonate Decomposition.—This reaction has been studied in detail.[12] It is highly sensitive to general acid catalysis; the hydrogen ion catalyzed rate is measurable in dilute sodium hydroxide solutions, while catalysis by molecular water is small. The rate-controlling process is second order, presumably

$$N_2(COO)_2^{=} + H_3O^{+} \longrightarrow X^{-1}$$

while the stoichiometric equation is

$$2N_2(COO)_2^{=} + 4OH^{-} \longrightarrow N_2 + N_2H_4 + 4CO_3^{=}$$

The rate equation is, neglecting water catalysis and change in ionic strength μ during the reaction

$$\frac{k_\mu^H K_\mu^w t}{2.3(b-2a)} = \log\frac{a}{a-x} + \frac{2x}{2.3(b-2a)} \quad (4)$$

where a and b are initial molar concentrations of azodicarbonate and hydroxyl ions, respectively, k_μ^H and K_μ^w are molar rate constant and the water constant ($C_{H_3O^+}$ C_{OH^-}) at finite values of μ, and x and t have their usual meaning.

Experimental.—Sodium azodicarbonate was prepared as before[12]; two samples evolved 95 and 98% of the theoretical nitrogen, in acid solution. The rates were followed by measuring the pressure of the nitrogen evolved as before. Five temperatures were used, 14.9, 19.9, 24.9, 29.9 and 34.9°, each ±0.02°. Slight condensation of water vapor in exposed parts of the apparatus at the two higher temperatures did not seem to affect the measurements. Since the temperature coefficient is approximately 2% per 0.1° throughout, all rate constants were arbitrarily increased by 2% to correspond to round temperatures.

To vary the dielectric constant dioxane–water mixtures were used. Solutions were made up at approximately 25°, using, per 100 cc., 0, 10, 20, 30, 40, 50 and 60 cc. of dioxane (purified as described by Kraus and Fuoss.)[13] Using the density data of Hertz and Lorentz[14] these solutions are calculated to contain 0, 10.2, 20.2, 30.1, 39.9, 49.7 and 59.5% dioxane by weight. Dielectric constants of these mixtures were interpolated from the measurements of Åkerlöf and Short[15] and the water dissociation constants from a large plot of the data of Harned and Fallon.[16] The latter values were corrected to the volume concentration scale.

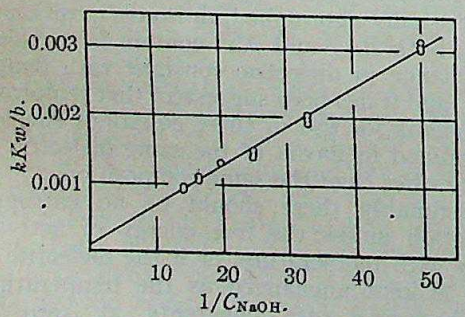

Fig. 1.—The rate in 30% dioxane, at constant ionic strength.

Solutions were made with carbonate-free sodium hydroxide and carbon dioxide free water and no attempt was made to study the effect of other acids than the hydrogen ion. All experiments were made at least in duplicate. Average values only are given except in Table I.

Results.—To check the nature of the reaction in dioxane mixtures experiments were carried out in 30% dioxane (by volume), with varying sodium hydroxide concentration and the ionic strength maintained constant at 0.1225 by additions of sodium chloride. The rates are given in Table I and plotted *vs.* the reciprocal of hydroxyl concentration in Fig. 1. The rate is proportional to the hydrogen ion concentration except for the small water catalysis whose value is obtained by extrapolation to $1/C_{OH^-} = 0$.

TABLE I

The rate in 30% dioxane (by volume) as a function of sodium hydroxide concentration; 25°, μ = 0.1225, C azo-salt = 0.0075 M.

C_{NaOH}, M	kKw/b	C_{NaOH}, M	kKw/b
0.02	0.00302	0.05	0.00131
	.00305		.00131
	.00314		.00130
.03	.00194		
	.00197	.06	.00106
	.00205		.00111
	.00205		
		.07	.000966
.04	.00141		.000938
	.00144		.000938
	.00147		.000966

In Table I rate constants are given as kKw/b since these values are comparable to first order rate constants with unchanging hydrogen ion concentration.[12] In Table II averaged constants with C_{OH^-} = 0.02 and varying temperatures and dioxane concentration are given in terms of $k_\mu^H K_\mu^w$ since these are used directly to evaluate k_0^H, the molar hydrogen ion catalytic constant at zero ionic strength.

In the application of equation (1) it is customary to evaluate and eliminate the last term (effect of ionic strength), usually by determining rate constants at a number of ionic strengths and extrapolating to $\mu = 0$. In the present case the accuracy attainable did not seem to justify the very large number of experiments necessary to make satisfactory extrapolations.

Instead, the salt effect term, including the effect of ionic strength on the water constant

TABLE II

The rate in dioxane mixtures. C azo-salt = 0.0075 M, C_{NaOH} = 0.02 M, μ = 0.0425.

Dioxane, vol. %	$k_\mu^H K_\mu^w \times 10^5$ 15°	20°	25°	30°	35°
0	3.25	6.78	13.54	26.8	43.3
10	3.34	5.95	11.32	23.0	41.0
20	2.75	4.91	8.96	18.1	35.5
30	2.12	3.46	6.60	14.3	26.1
40	1.47	2.53	4.94	10.2	16.8
50	1.00	1.78	3.51	6.40	12.9
60	0.64	1.12	2.19	3.94	8.30

(since this is known only at zero ionic strength), was calculated as follows. Introducing activity coefficients (f) for the ions involved

$$k_\mu^H K_\mu^w = k_0^H K_0^w f_2/f_1^2 \quad (5)$$

and using the Debye–Hückel "second approximation" for log f, k_0^H becomes

$$\log k_0^H = \log k_\mu^H K_\mu^w - \log K_0^w + \frac{\epsilon^2 N}{2.3DRT}\frac{\kappa}{1+a\kappa} \quad (6)$$

The value to be used for a was estimated from the salt effect experiments with sodium chloride recorded in Table II of the previous paper.[12] Log $k_\mu^H K_\mu^w$ was plotted *vs.* the last term of the equation

$$\log k_\mu^H K_\mu^w = \log k_0^H K_0^w - 1.02\sqrt{\mu}/(1 + 0.328a\sqrt{\mu}) \quad (7)$$

using various values for a (in Å.) until the points conformed to the slope 1.02. The plot, using a = 6 Å., is shown in Fig. 2. This method has the disadvantage of using one average a value for all the ions involved. Previous work indicates that a varies little with changing temperature or dielectric constant.

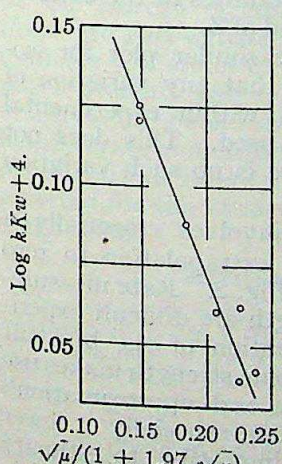

Fig. 2.—Evaluation of a from salt effect data; slope of line = −1.02.

Table III shows in detail the calculation of k_0^H. Equation (1) may now be put in the form

$$\log k_0^H = \log_{D=\infty} k_0^H - \frac{Z_A Z_B \epsilon^2 N}{2.3DRT}\frac{1}{r_A + r_B} \quad (8)$$

from which it is seen that a plot of log k_0^H *vs.* $1/D$, at each temperature, should be linear, with a slope from which ($r_A + r_B$) can be calculated.

These plots are shown in Fig. 3. The points approximate a linear relation at dielectric constant above 50. Previous work[5,6,17] has shown that departure from linearity at lower dielectric constant, in the direction found here, is to be expected. It has been possible to measure rate constants of some reactions with higher dielectric constants than in water, by the addition of amino-acids to the solutions, in which case the linear relation is found to hold over a wider range. That could not be done in this case because of the general acid catalysis.

From the slopes of the lines of Fig. 3, the average value of $(r_A + r_B)$ is calculated to be 3.42 Å.

The Temperature Coefficient.—Values of log k_0^H were plotted *vs.* $1/T$, and in Table IV the values of $E_{exp.}/2.3\ RT$ obtained from the slopes are given; also values of log A of the Arrhenius equation

$$\log k_0^H = \log A - E_{exp.}/2.3\ RT \qquad (9)$$

For comparison a plot was made of log k_0^H *vs.* dielectric constant and interpolated values at $D = 75$, 65, 55 and 45 (for 25°) are given in Table V with the corresponding values of $E_{exp.}/2.3\ RT$ and log A. Finally $\Delta S^*/2.3\ R$ was calculated from the equation

$$\log A = \log eRT/Nh + \Delta S^*/2.3R \qquad (10)$$

and these values are also given in Tables IV and V.

TABLE IV

VALUES DERIVED FROM THE TEMPERATURE COEFFICIENTS IN ISO-COMPOSITION MEDIA AT 25°

$\log e\frac{RT}{Nh} = 15.01$ with the minute as time unit.

Dioxane, vol.%	$E_{exp.}/2.3RT$	log A	$\Delta S^*/2.3R$
0	7.49	17.83	2.82

suggested by Davis and LaMer,[4] using the water solution at 25° as the reference

$$^Nk_0^H = k_0^H \frac{\Sigma \text{ moles(solution)/liter}}{\Sigma \text{ moles(standard)/liter}} \qquad (11)$$

Discussion.—The nature of the reaction studied and the approximations in the calculations involved do not justify extensive conclusions concerning the theory. The low values of ΔS^* in iso-dielectric media—the largest (from Table V) being −3.5 e. u.—suggest that entropy of activation may really be small or negligible; negative values actually found could be due to a fractional "transmission coefficient" or other factors. The use of "normalized" or mole fraction rate constants makes comparatively little difference. The value of log Z of the collision theory is 15.31 in terms of moles, liters and minutes at 25° with $r_A + r_B = 3.42$ Å., making log P of equation (3) 0.3 unit smaller (or more negative) than $\Delta S^*/2.3$ R. Here, as in other cases,[6] agreement with the collision theory is not unreasonable, considering the uncertainties in the calculation of the rate constants and of Z.

Figure 4, as well as the similar plot for iso-composition media, shows that any variation of $E_{exp.}$ with temperature is within experimental error over the 20° range used. This does not mean, of course, that there is no such variation but only that it is small.

The estimation of k_0^H involves essentially a long and rather uncertain extrapolation to zero ionic strength as shown in Fig. 2. Rate measurements at lower ionic strength are difficult experimentally, and the contribution of the bivalent azodicarbonate ion to the ionic strength makes use of the Debye–Hückel "second approximation" equation somewhat uncertain, especially at lower dielectric constant. It is impossible to estimate the error introduced in this way, but it is probable that the errors are consistent throughout and do not greatly affect the conclusions.

The previous interpretation of the nature and mechanism of the reaction[12] seems fully confirmed, and the reaction is essentially unaltered in the dioxane mixtures. As shown in Table II the effect of dioxane is to diminish the observed rate greatly, but this is due to the decrease in water concentration, the water constant and the hydrogen ion concentration; the molar catalytic constant increases exactly as required by the theory. As expected, the exceedingly high molar

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

rate constants are associated with low activation energies—*ca.* 5000 cal. in iso-dielectric media.

In conclusion, it may be said that the equations of Amis and Cook[18] and Amis and Potts[17] allow reasonably good calculation of the differences of log A in iso-composition and iso-dielectric media, and of the differences of $E_{exp.}$ in similar media. Also it should be mentioned that while the last term of equation (8) accounts reasonably for the variation in rate with dielectric constant it does not account for the variation with temperature. This situation has been studied in detail by Amis and Jaffe.[19]

Summary

The rate of decomposition of the azodicarbonate ion has been measured, in dilute sodium hydroxide in water and with addition of dioxane up to 60%, at five temperatures from 15 to 35°.

From these rates, molar hydrogen ion catalysis constants at zero ionic strength were calculated. Their variation with dielectric constant was found to agree satisfactorily with the predictions of electrostatic theory.

Temperature coefficients were determined for iso-composition and iso-dielectric solvents and energies and entropies of activation were calculated for comparison with the Eyring "absolute rate" and the collision rate theories. The results, especially in the isodielectric media, show agreement with theory quite comparable to that in other reactions reported in the literature.

Previous interpretation of the nature and mechanism of the reaction is substantiated.

Heats of Formation of Solid and Liquid $Mn(NO_3)_2 \cdot 6H_2O$[1]

BY C. HOWARD SHOMATE[2] AND FRANK E. YOUNG[2]

The heats of fusion of certain nitrates are important factors in thermal calculations pertaining to the nitrogen dioxide[3] process for extracting manganese from low-grade ores, now being studied by the Bureau of Mines. Available values for these nitrates antedate modern thermochemical methods and are of questionable accuracy. This paper presents new determinations of the heats of formation of solid and liquid manganous nitrate hexahydrate and of the heat of fusion of this compound. In a later paper, similar data will be reported for the nitrates of barium, calcium, and magnesium.

Method and Materials

The manganous nitrate hexahydrate used in this work was prepared by Dr. E. H. Huffman by dissolving electrolytic manganese (purity at least 99.9 per cent) in reagent-grade nitric acid. The manganese was added slowly to control the temperature until the acid had been largely used up. Finally, an excess of manganese was contacted until brown oxide of manganese just started to form, indicating virtually complete exhaustion of the acid. After filtration, a small amount of 30% hydrogen peroxide was added to clear up a slight discoloration remaining in the solution. The material then was evacuated with an oil pump and stored over a mixture of potassium hydroxide and calcium chloride. At this stage, the product was solid at room temperature, and analysis showed 4.13 moles of water per mole of manganous nitrate. Melting, with addition of enough water to bring the composition to the hexahydrate, yielded material with a melting point of 24.9°. Two fractional crystallizations produced crystals melting at 25.0°, which was not raised by further fractionation. The latter material constituted the final product. It analyzed 19.15% manganese (theoretical, 19.14%).

Heats of formation and the heat of fusion were determined by measuring the heat of solution of the salt in 1 N sulfuric acid in the apparatus described by Southard.[4] The 1.000 N sulfuric acid was prepared by dilution of reagent grade concentrated sulfuric acid and was standardized against sodium carbonate.

The calorimetric system was calibrated electrically, using a 100-ohm manganin heater. The heater current was measured by the potential drop across a 0.01-ohm standard resistance calibrated by the National Bureau of Standards. The usual heating period during a calibration was 600 seconds, which gave a temperature rise of about 400 μv. (about 0.36°). The temperature readings were estimated to 0.01 μv. from galvanometer deflections. All measurements were made with a White double potentiometer.

The results are expressed in defined calories (1 cal. = 4.1833 int. joules),[5] and all formula weights were calculated from the 1941 International Atomic Weights. All weights were corrected to a vacuum basis, using 1.8 for the density of solid manganous nitrate hexahydrate and 1.7 for the liquid.

Measurements and Results

The average sample weight of manganous nitrate hexahydrate (5.2895 g.) corresponds to the weight of manganese used in determinations of the heat of solution of manganese metal by Southard and Shomate,[6] whose value is adopted here. This sample weight corresponds to a dilution of 1 mole of anhydrous salt in $49.23H_2SO_4 \cdot 5{,}355H_2O$.

The skeleton equations necessary to calculate the heats of formation of solid and liquid man-

ganous nitrate hexahydrate and its heat of fusion are given in Tables I, II and III. The uncertainties given in the last column of each table are twice the standard deviations of the means of the experimental results involved. This method of calculating uncertainties was discussed by Rossini and Deming[7] and was adopted by Shomate[8] in a previous paper on the thermochemistry of manganese compounds. In the tables, the resulting values of the heats of formation and the corresponding uncertainties have been rounded to the nearest 10 calories.

Heat of Formation of $Mn(NO_3)_2 \cdot 6H_2O(l)$.—A summary of the data needed to calculate the heat of formation of liquid manganese nitrate hexahydrate is given in Table I.

TABLE I

HEAT OF FORMATION OF $Mn(NO_3)_2 \cdot 6H_2O(l)$ (CAL. PER MOLE)

Reaction	$\Delta H_{298.16}$	Uncertainty
(1) $Mn + 2H^+ \longrightarrow Mn^{++} + H_2$	−54,406	50
(2) $H_2 + N_2 + 3O_2 \longrightarrow 2H^+ + 2NO_3^-$	−97,853	305
(3) $Mn(NO_3)_2 \cdot 6H_2O(l) \longrightarrow Mn^{++} + 2NO_3^- + 6H_2O(l)$	−5,096	6
(4) $6H_2 + 3O_2 \longrightarrow 6H_2O(l)$	−409,908	60
(5) $Mn + N_2 + 6O_2 + 6H_2 \longrightarrow Mn(NO_3)_2 \cdot 6H_2O(l)$	−557,070	310

$\Delta H_5 = \Delta H_1 + \Delta H_2 - \Delta H_3 + \Delta H_4$

The heat of reaction (1) in 1.000 *N* sulfuric acid was obtained from the value of Southard and Shomate[6] by applying a small correction to change from their acid strength, 1.006 *N*, to the present strength, 1.000 *N*. This correction was estimated from the data of Grau and Roth[9] as 50 ± 10 cal. per mole to give $\Delta H_{298.16} = -54,406$ from Southard and Shomate's value of $\Delta H_{298.16} = -54,356$ for 1.006 *N* acid.

Reaction (2) represents the heat of formation of nitric acid in $MnSO_4 \cdot 48.23H_2SO_4 \cdot 5,355H_2O$. The heat of this reaction was obtained by considering the following series of reactions

(6) $H_2 + N_2 + 3O_2 + 26.50H_2O \longrightarrow 2HNO_3 \cdot 26.50H_2O$

(7) $2HNO_3 \cdot 26.50H_2O + MnSO_4 \cdot 48.23H_2SO_4 \cdot 5,355H_2O \longrightarrow Mn(NO_3)_2 \cdot 49.23H_2SO_4 \cdot 5,381.5H_2O$

(8) $Mn(NO_3)_2 \cdot 49.23H_2SO_4 \cdot 5,355H_2O + 26.50H_2O \longrightarrow Mn(NO_3)_2 \cdot 49.23H_2SO_4 \cdot 5,381.5H_2O$

The desired heat of formation is $\Delta H_2 = \Delta H_6 + \Delta H_7 - \Delta H_8$. The heat of reaction (6) is obtainable from the work of Becker and Roth,[10] who reported $\Delta H_{293.1} = -14,855$ for the reaction, $Aq + 1/2N_2 + 5/4O_2 + 1/2H_2O(l) = HNO_3(0.05M)$. Forsythe and Giauque[11] have corrected this value to 25°, making $\Delta H_{298.16} = -15,075$. Employing Rossini's[12] heat of formation of liquid water, there is obtained $\Delta H_{298.16} = -49,234 \pm 151$ as the heat of formation of $HNO_3(0.05M)$ from the elements. The correction to the degree of dilution of reaction (6) may be made from the data of Becker and Roth,[13] +37 ± 4 cal., to yield finally $\Delta H_{298.16} = 2(-49,197 \pm 152) = -98,394 \pm 304$ cal. for the heat of reaction (6).

The heats of reactions (7) and (8) were directly determined in the present work as 460 ± 21 and −81 ± 10 calories, respectively, thus yielding $\Delta H_{298.16} = -97,853 \pm 305$ for reaction 2.

Six determinations of ΔH_3 were made, the results being −5098, −5091, −5101, −5085, −5102, and −5085, with a mean of −5096 ± 6 calories, after applying a correction of +18 ± 2 calories for the directly determined heat of dilution of the solution by the water of hydration. The average final temperature of the solution experiments was 25.5°. Data are not available for making the minor correction to 25.0°. It was necessary to carry out the solution experiments at slightly above 25° to avoid freezing any of the liquid manganous nitrate hexahydrate before solution.

The heat of formation obtained by subtracting ΔH_3 from the sum of ΔH_1, ΔH_2, and ΔH_4 is −557,070 ± 310 calories per mole.

Heat of Fusion of Manganous Nitrate Hexahydrate.—The heat of fusion was determined from the heats of solution of the solid and liquid as shown in Table II.

TABLE II

HEAT OF FUSION OF $Mn(NO_3)_2 \cdot 6H_2O$

Reaction	ΔH, room temp.	Uncertainty
(9) $Mn(NO_3)_2 \cdot 6H_2O(c) \longrightarrow Mn^{++} + 2NO_3^- + 6H_2O$	+4,510	11
(10) $Mn(N_3)O_2 \cdot 6H_2O(l) \longrightarrow Mn^{++} + 2NO_3^- + 6H_2O$	−5,096	6
(11) $Mn(NO_3)_2 \cdot 6H_2O(c) \longrightarrow Mn(NO_3)_2 \cdot 6H_2O(l)$	+9,610	10

$\Delta H_{11} = \Delta H_9 - \Delta H_{10}$

The heat of solution (9) was determined in the same way as the heat of solution of the liquid (10), previously discussed as reaction (3). The value +4510 ± 11 for ΔH_9 is the mean of five results: +4499, +4500, +4520, +4504, and +4524. The correction for dilution by the water of hydration (+18 calories) is included. Because of glass formation when the liquid nitrate was frozen in ice, it was necessary to freeze each sample in a sealed glass bulb in carbon dioxide–ethyl alcohol mixture and allow it to warm slowly to about 21° before putting it into the calorimeter. It was found best to measure the heat of solution of the solid at a mean final temperature of 21.9°. Unfortunately, no data are available to permit accurate correction to 25°. For this reason, the calculated uncertainty, 10

calories, may be somewhat smaller than the true uncertainty in the heat of fusion.

Heat of Formation of Solid Manganous Nitrate Hexahydrate.—The heat of formation of the solid salt may be found by adding the heat of formation of the liquid and the heat of solidification. The skeleton equations for this calculation are shown in Table III.

TABLE III

HEAT OF FORMATION OF $Mn(NO_3)_2 \cdot 6H_2O(c)$

Reaction	$\Delta H_{298.16}$	Uncertainty
(12) $Mn + N_2 + 6O_2 + 6H_2 \longrightarrow Mn(N_3O)_2 \cdot 6H_2O(l)$	−557,070	310
(13) $Mn(NO_3)_2 \cdot 6H_2O(c) \longrightarrow Mn(NO_3)_2 \cdot 6H_2O(l)$	+9,610	10
(14) $Mn + N_2 + 6O_2 + 6H_2 \longrightarrow Mn(NO_3)_2 \cdot 6H_2O(c)$	−566,680	310

$\Delta H_{14} = \Delta H_{12} - \Delta H_{13}$

Reactions (12) and (13) were discussed above as reactions (5) and (11), respectively. The value of the heat of formation of solid manganous nitrate, −566,680 ± 310 calories, is subject to the same lack of correction to 25° as the heat of fusion discussed under equation (9). By comparison with the uncertainty of 310 calories, however, this correction probably is not significant.

Discussion.—The results of this investigation are summarized in Table IV. In the reactions involving liquid water, Rossini's[12] value of the heat of formation of water is used.

The previous values for the reactions in Table IV, as summarized in the compilation of Bichowsky and Rossini,[14] are not in good agreement with the present results and emphasize the necessity of being critical of the older heat of formation data of nitrates. They tabulate −564.2 kilocalories

TABLE IV

HEATS OF REACTION (CAL. PER MOLE)

Reaction	$\Delta H_{298.16}$	Uncertainty
$Mn + N_2 + 6O_2 + 6H_2 \longrightarrow Mn(NO_3)_2 \cdot 6H_2O(l)$	−557,070	310
$Mn + N_2 + 6O_2 + 6H_2(l) \longrightarrow Mn(NO_3)_2 \cdot 6H_2O(c)$	−566,680	310
$Mn + N_2 + 3O_2 + 6H_2O(l) \longrightarrow Mn(NO_3)_2 \cdot 6H_2O(l)$	−147,160	310
$Mn + N_2 + 3O_2 + 6H_2O(l) \longrightarrow Mn(NO_3)_2 \cdot 6H_2O(c)$	−156,770	310
$Mn(NO_3)_2 \cdot 6H_2O(c) \longrightarrow Mn(NO_3)_2 \cdot 6H_2O(l)$	+9,610	10

for the heat of formation of solid manganous nitrate hexahydrate based upon Thomsen's data for the heat of formation of manganous hydroxide, the heat of solution of manganous nitrate hexahydrate in water, for which Thomsen reported +6.15 kilocalories, and the heat of reaction of manganous hydroxide with nitric acid. Combining the above value for the solid with the heat of fusion, 8.26 kilocalories, from the data of Riesenfeld and Milchsack,[15] Bichowsky and Rossini give −555.9 kilocalories for the heat of formation of the liquid nitrate from the elements. These older data, except for the heat of fusion, are reported at 291.16°K.

Summary

The heats of formation from the elements of liquid and solid manganous nitrate hexahydrate and the heat of fusion of this compound have been determined at room temperature by measuring the heats of solution in 1 *N* sulfuric acid. The results are, respectively, $\Delta H_{298.16} = -557{,}070 \pm 310$, $-566{,}680 \pm 310$, and $+9{,}610 \pm 10$ calories per mole.

BERKELEY, CALIF. RECEIVED FEBRUARY 7, 1944

[CONTRIBUTION FROM THE WESTERN REGION, BUREAU OF MINES, U. S. DEPARTMENT OF THE INTERIOR, BERKELEY, CALIFORNIA]

Heats of Formation of $Mg(NO_3)_2$, $Mg(NO_3)_2 \cdot 6H_2O$, $Ca(NO_3)_2$, $Ca(NO_3)_2 \cdot 4H_2O$ and $Ba(NO_3)_2$[1]

BY FRANK E. YOUNG[2]

Thermal calculations pertaining to the nitrogen dioxide cyclic process for the hydrometallurgical extraction of manganese from ores require accurate values of the heats of formation of the nitrates of several constituents, particularly manganese, barium, calcium, and magnesium. No value of the heat of formation of anhydrous magnesium nitrate is available, and the existing heats of formation of the other nitrates are based largely on older data of uncertain reliability. New values of the heats of formation of solid and liquid manganous nitrate hexahydrate were reported in a previous paper.[3] The present paper records new determinations of the heats of formation of anhydrous magnesium, calcium, and barium nitrates, magnesium nitrate hexahydrate and calcium nitrate tetrahydrate.

Materials[4]

Magnesium nitrate hexahydrate was prepared from Merck C. P. product, containing a maximum of 0.07% impurities, by allowing it to stand for fifteen hours over potassium hydroxide to remove excess water and nitric acid. Analysis showed 9.50% Mg (theoretical, 9.48%). The average sample weight used in the present experiments was 6.0357 g.

Anhydrous magnesium nitrate was prepared by heating Merck C. P. magnesium nitrate hexahydrate *in vacuo*, beginning at 65° and raising the temperature gradually to 129° over a period of eleven hours, followed by fifteen hours at 129°. The flask then was opened and the solid cake broken up and pulverized, after which the heating at 129° was continued for six more hours. The temperature then was allowed to rise over a period of thirteen hours to 150°, and the heating was completed by a final half-hour at 150°. Analysis of the product showed 16.43% Mg (theoretical 16.40%) and 0.170% MgO (by titration). Correction was made in the thermal results for the presence of this oxide. The average sample size was 3.5024 g.

Calcium nitrate tetrahydrate was prepared by drying Mallinckrodt reagent-quality product over 78% sulfuric acid for twenty-two hours. Analysis showed 17.00% Ca (theoretical, 16.97%). No detectable amount of CaO was present. The average sample size was 5.2219 g.

Anhydrous calcium nitrate was prepared by melting Mallinckrodt reagent-quality calcium nitrate tetrahydrate and boiling off most of the water under reduced pressure. The material was then broken up and heated at 300° for twenty-four hours in an electric furnace. The product contained 24.43% Ca (theoretical, 24.42%) and 0.043% CaO. A correction was made for the presence of this calcium oxide. The average sample weight was 3.1962 g.

Calcium oxide was prepared by heating Mallinckrodt reagent-quality calcium carbonate to 900° for ninety hours in platinum, using an electric furnace. When the heating was completed, the calcium oxide was stored over dehydrite until the sample bulbs for the heats of solution were filled. These bulbs were filled allowing as little exposure to air as possible during filling and were sealed immediately after weighing. Analysis as sulfate showed 71.23% Ca, corresponding to 99.67% CaO. Titration gave 99.68% CaO. Samples of an average weight of 1.1156 g. were used.

Anhydrous barium chloride was prepared from Baker analyzed barium chloride dihydrate by drying at 135° for nineteen hours. Analyses by precipitation as barium sulfate gave an average of 65.90% Ba, corresponding to 99.92% $BaCl_2$. No oxide could be detected. The average sample weight was 8.3310 g. This size of sample was necessary because of the small heat of solution of barium chloride, the temperature rise being only 53.57 μv. with the sample used, corresponding to 0.04870°.

Anhydrous barium nitrate was prepared by grinding and drying Mallinckrodt analytical reagent barium nitrate at 115°. Analysis showed 99.89% $Ba(NO_3)_2$. The product was ground to pass an 80-mesh screen in order to decrease the time of solution. The average sample weight, 10.4550 g., corresponds to the weight of barium chloride used.

The 1.000 *N* hydrochloric acid used in the heat of solution measurements was prepared by dilution of reagent quality hydrochloric acid and standardization against sodium carbonate.

Method

The heats of formation were determined by measuring the heats of solution of the compounds in 1.000 *N* hydrochloric acid in the calorimeter previously described by Southard[5] and later by Shomate and Young.[3]

The results are expressed in defined calories (1 cal. = 4.1833 int. joules) and all formula weights were calculated from the 1941 International Atomic Weights. Corrections of weights to vacuum basis were made using the following densities: anhydrous magnesium nitrate, 2.2; magnesium nitrate hexahydrate, 1.46; calcium oxide, 3.40; calcium nitrate, 2.36; calcium nitrate tetrahydrate, 1.82; anhydrous barium chloride, 3.86; and anhydrous barium nitrate, 3.24. As the final temperature in each measurement was within a few hundredths of a degree of 25°, no correction of the results to 25° is necessary.

Measurements and Results

Each of the heats of formation has been obtained from the heats of the reactions represented by skeleton equations in the pertinent table below. The uncertainties, given in the last column of each table, are twice the standard deviations of the means of the experimental results involved. This method of calculating uncertainties has been discussed more fully by Rossini and Deming.[6] The final values for the heats of formation and the uncertainties have been rounded to the nearest 10 calories.

The Heat of Formation of Anhydrous Magnesium Nitrate.—The skeleton equations for the present method of obtaining the heat of formation of anhydrous magnesium nitrate are shown in Table I.

TABLE I

THE HEAT OF FORMATION OF $Mg(NO_3)_2$ (CAL. PER MOLE)

Reaction	$\Delta H_{298.16}$	Uncertainty
(1) $Mg + 2H^+ \longrightarrow Mg^{++} + H_2$	−111,322	41
(2) $H_2 + N_2 + 3O_2 \longrightarrow 2H^+ + 2NO_3^-$	−98,087	304
(3) $Mg(NO_3)_2 \longrightarrow Mg^{++} + 2NO_3^-$	−20,636	14
(4) $Mg + N_2 + 3O_2 \longrightarrow Mg(NO_3)_2$	−188,770	310

$\Delta H_4 = \Delta H_1 + \Delta H_2 - \Delta H_3$

The value for ΔH_1 was taken directly from the work of Shomate and Huffman,[7] who determined the heat of solution of magnesium metal under the same conditions as in the present measurements.

Reaction (2) represents the heat of formation of nitric acid in the final solution of reaction (1) or $MgCl_2 \cdot 75.2\ HCl \cdot 4190\ H_2O$. This value may be obtained by the use of the following equations:

(5) $H_2 + N_2 + 3O_2 + 26.5\ H_2O \longrightarrow 2\ HNO_3 \cdot 26.5\ H_2O$

(6) $2HNO_3 \cdot 26.5\ H_2O + MgCl_2 \cdot 75.2\ HCl \cdot 4190\ H_2O \longrightarrow Mg(NO_3)_2 \cdot 77.2\ HCl \cdot 4216.5\ H_2O$

(7) $Mg(NO_3)_2 \cdot 77.2\ HCl \cdot 4190\ H_2O + 26.5\ H_2O \longrightarrow Mg(NO_3)_2 \cdot 77.2\ HCl \cdot 4216.5\ H_2O$

The required heat of formation, ΔH_2, is equal to $\Delta H_5 + \Delta H_6 - \Delta H_7$. The value −98,398 ± 304 was adopted for ΔH_5. This value was obtained from the heat-of-formation and dilution data of Becker and Roth[8] as explained in the previous paper.[3] The values for ΔH_6 and ΔH_7 were determined in the present work by direct experiment as +198 ± 4 and −113 ± 4 calories, respectively.

(4) The materials used in this research were prepared by Dr. E. H. Huffman, formerly chemist in this laboratory.

Six determinations of ΔH_3 were made, giving $-20,619$, $-20,621$, $-20,639$, $-20,647$, $-20,627$, and $-20,664$, with a mean of $-20,636 \pm 14$. These results have been corrected by $+189$ calories for the presence of 0.170% magnesium oxide and for variations in sample size which had a noticeable effect on the heats of solution, the average correction being 12 calories.

The heat of formation of anhydrous magnesium nitrate, ΔH_4, obtained by subtracting ΔH_3 from the sum of $\Delta H_1 + \Delta H_2$ is $-188,770 \pm 310$ calories.

The Heat of Formation of Magnesium Nitrate Hexahydrate.—Table II summarizes the data necessary for obtaining the heat of formation of magnesium nitrate hexahydrate.

TABLE II

THE HEAT OF FORMATION OF $Mg(NO_3)_2 \cdot 6H_2O$ (CAL. PER MOLE)

Reaction	$\Delta H_{298.16}$	Uncertainty
(8) $Mg + 2H^+ \longrightarrow Mg^{++} + H_2$	$-111,322$	41
(9) $H_2 + N_2 + 3O_2 \longrightarrow 2H^+ + 2NO_3^-$	$-98,087$	304
(10) $Mg(NO_3)_2 \cdot 6H_2O \longrightarrow Mg^{++} + 2NO_3^- + 6H_2O$	$+5,095$	2
(11) $6H_2 + 3O_2 \longrightarrow 6H_2O$	$-409,908$	60
(12) $Mg + N_2 + 6O_2 + 6H_2 \longrightarrow Mg(NO_3)_2 \cdot 6H_2O$	$-624,410$	310

$\Delta H_{12} = \Delta H_8 + \Delta H_9 - \Delta H_{10} + \Delta H_{11}$

Reactions (8) and (9) are identical with reactions (1) and (2) which have been discussed previously.

Six determinations of ΔH_{10} were made, giving $+5096$, $+5092$, $+5094$, $+5096$, $+5096$, $+5095$, with a mean of $+5095 \pm 1$ calories after applying a correction of $+26 \pm 1$ calories for the heat of dilution by the water of hydration. The mean value for ΔH_{10} corresponds to a temperature drop of 76.34 μv. or 0.06940° in the calorimeter.

Rossini's[9] value for the heat of formation of water, $-68,318 \pm 10$ calories per mole, was multiplied by six to obtain ΔH_{11}, giving $-409,908 \pm 60$ calories.

$\Delta H_8 + \Delta H_9 - \Delta H_{10} + \Delta H_{11}$ gives the heat of formation of magnesium nitrate hexahydrate from the elements as $\Delta H_{12} = -624,410 \pm 310$ calories.

Anhydrous Calcium Nitrate.—Table III outlines the reactions for determining the heat of formation of anhydrous calcium nitrate.

The heat of reaction (13) was taken from the compilation of Bichowsky and Rossini,[10] the correction of 25° being negligible.

Six determinations were made of ΔH_{14}, giving $-46,220 \pm 14$ as the mean of: $-46,216$, $-46,235$, $-46,230$, $-46,204$, $-46,197$, $-46,240$. These values include a correction of -151 calories

TABLE III

THE HEAT OF FORMATION OF $Ca(NO_3)_2$ (CAL. PER MOLE)

Reaction	$\Delta H_{298.16}$	Uncertainty
(13) $Ca + {}^1/_2O_2 \longrightarrow CaO$	$-151,800$	200
(14) $CaO + 2H^+ \longrightarrow Ca^{++} + H_2O$	$-46,220$	14
(15) $H_2 + N_2 + 3O_2 \longrightarrow 2H^+ + 2NO_3^-$	$-98,087$	304
(16) $Ca(NO_3)_2 \longrightarrow Ca^{++} + 2NO_3^-$	$-3,740$	9
(17) $H_2 + {}^1/_2O_2 \longrightarrow H_2O$	$-68,318$	10
(18) $Ca + N_2 + 3O_2 \longrightarrow Ca(NO_3)_2$	$-224,050$	360

$\Delta H_{18} = \Delta H_{13} + \Delta H_{14} + \Delta H_{15} - \Delta H_{16} - \Delta H_{17}$

for the presence of impurities and a correction of $+4$ calories for the heat of dilution by the water formed in the reaction.

The heat of formation of nitric acid in $CaCl_2 \cdot 85.25\ HCl \cdot 4775\ H_2O$ is found in the same way as ΔH_2, discussed previously. The heats of solution of nitric acid and water in the calcium chloride solution were determined by direct experiment and were found to have the same values as corresponding heats of solution in the magnesium chloride solution discussed before, namely, $+194 \pm 4$ and -113 ± 4 calories, respectively.

The heat of solution of anhydrous calcium nitrate, ΔH_{16}, is the mean of seven results: -3742, -3759, -3736, -3742, -3749, -3725, and -3725 calories, after application of a $+57$-calorie correction for calcium oxide content. It was thought that the abnormally large spread in these results might be attributed to the effects of a transition of small thermal magnitude near room temperature. In order to test this the fifth sample (-3749 cal.) was heated to 110° for forty hours immediately before measuring its heat of solution; the sixth result (-3725) was obtained using a sample that had been kept at 0° for sixty-four hours and the seventh result (-3725) using a sample that had been cooled in a carbon dioxide–ethyl alcohol mixture and allowed to warm up over a period of twenty-four hours to 10° before it was put into the calorimeter. After completion of these heat of solution measurements, a minor transition actually was found in the heat capacity of anhydrous calcium nitrate at 288°K.[11] It thus appears that the larger heats of solution correspond to the high-temperature form and the smaller values to the low-temperature form, as might be expected.

ΔH_{17} is Rossini's[9] value of the heat of formation of water.

The heat of formation of anhydrous calcium nitrate from the elements, ΔH_{18}, is $-224,050 \pm 360$ calories per mole.

The Heat of Formation of Calcium Nitrate Tetrahydrate.—The skeleton equations representing the reactions necessary to obtain the heat of formation of calcium nitrate tetrahydrate are shown in Table IV.

The first three reactions, ΔH_{19}, ΔH_{20} and

TABLE IV

THE HEAT OF FORMATION OF $Ca(NO_3)_2 \cdot 4H_2O$ (CAL. PER MOLE)

Reaction	$\Delta H_{298.16}$	Uncertainty
(19) $Ca + {}^1/_2O_2 \longrightarrow CaO$	−151,800	200
(20) $CaO + 2H^+ \longrightarrow Ca^{++} + H_2O$	−46,220	14
(21) $H_2 + N_2 + 3O_2 \longrightarrow 2H^+ + 2NO_3^-$	−98,087	304
(22) $Ca(NO_3)_2 \cdot 4H_2O \longrightarrow Ca^{++} + 2NO_3^- + 4H_2O$	+8,360	3
(23) $3H_2 + {}^3/_2O_2 \longrightarrow 3H_2O$	−204,954	30
(24) $Ca + N_2 + 5O_2 + 4H_2 \longrightarrow Ca(NO_3)_2 \cdot 4H_2O$	−509,420	370

$\Delta H_{24} = \Delta H_{19} + \Delta H_{20} + \Delta H_{21} - \Delta H_{22} + \Delta H_{23}$

ΔH_{21}, were discussed above as ΔH_{13}, ΔH_{14} and ΔH_{15}, respectively.

ΔH_{22} is the mean of six results after applying a correction of +17 ± 1 calories for the heat of dilution by the water of hydration. These corrected heats of solution are +8353, 8361, 8360, 8358, 8363, and 8365, with a mean of 8360 ± 3 calories.

ΔH_{23} represents the heat of formation of 3 molecules of water or three times Rossini's[9] value for the heat of formation of water.

The heat of formation of calcium nitrate tetrahydrate, ΔH_{24}, is −509,420 ± 370.

The Heat of Formation of Anhydrous Barium Nitrate.—Table V summarizes the reactions used to obtain the heat of formation of anhydrous barium nitrate.

TABLE V

THE HEAT OF FORMATION OF $Ba(NO_3)_2$ (CAL. PER MOLE)

Reaction	$\Delta H_{298.1}$	Uncertainty
(25) $Ba + Cl_2 \longrightarrow BaCl_2$	−205,260	210
(26) $BaCl_2 \longrightarrow Ba^{++} + 2Cl^-$	−2,086	4
(27) $H_2 + Cl_2 \longrightarrow 2H^+ + 2Cl^-$	−78,466	100
(28) $H_2 + N_2 + 3O_2 \longrightarrow 2H^+ + 2NO_3^-$	−98,164	304
(29) $Ba(NO_3)_2 \longrightarrow Ba^{++} + 2NO_3^-$	+9,944	8
(30) $Ba + N_2 + 3O_2 \longrightarrow Ba(NO_3)_2$	−236,990	380

$\Delta H_{30} = \Delta H_{25} + \Delta H_{26} - \Delta H_{27} + \Delta H_{28} - \Delta H_{29}$

The heat of formation of barium chloride given by Bichowsky and Rossini,[10] corrected to 25°, was adopted for reaction (25).

Six determinations were made of the heat of solution of barium chloride in 1.000 *N* hydrochloric acid, reaction (26), giving −2088, −2080, −2086, −2090, −2084 and −2095 calories, with a mean of −2086 ± 4 calories per mole. It was necessary to correct these heats of solution for variations in sample size. The average correction was 5 calories.

Equation (27) represents the heat of formation of hydrogen chloride in $Ba(NO_3)_2 \cdot 45.5HCl \cdot 2474H_2O$. This heat of formation was estimated by assuming it to be the same in the above solution as in a solution in which the barium nitrate had been replaced by enough hydrogen chloride to maintain the same ionic strength, giving the equation:

(31) $48.5HCl \cdot 2474H_2O + H_2 + Cl_2 \longrightarrow 50.5HCl \cdot 2474H_2O$

The heat of reaction (31) may be calculated from the difference of the two reactions

(32) $24.25H_2 + 24.25Cl_2 + 2474H_2O \longrightarrow 48.5HCl \cdot 2474H_2O$

(33) $25.25H_2 + 25.25Cl_2 + 2474H_2O \longrightarrow 50.5HCl \cdot 2474H_2O$

using the heat of formation of hydrochloric acid at infinite dilution given by Rossini[12] and the heats of dilution reported by Sturtevant.[13] The heat of reaction (27) calculated in this manner is −78,466 for 2 moles of hydrochloric acid, in which the uncertainty is estimated as ±100 calories.

ΔH_{28} is found in the same way as ΔH_2 and ΔH_{15}, using the directly determined values of +115 ± 10 and −113 ± 4 for the heats of solution of nitric acid and the corresponding amount of water in the barium chloride solution, respectively.

The value given for ΔH_{29} is the mean of six results, +9950, 9950, 9931, 9951, 9930 and 9951, or 9944 ± 8 calories. As with the barium chloride, it was necessary to make a small correction for variations in sample weights. In this instance, the average correction was 2 calories.

The heat of formation of barium nitrate, $\Delta H_{30} = \Delta H_{25} + \Delta H_{26} - \Delta H_{27} + \Delta H_{28} - \Delta H_{29}$, is −236,990 ± 380 calories per mole.

Discussion.—The results obtained in this research are compared in Table VI with previous values taken from the compilation of Bichowsky and Rossini.[10]

TABLE VI

HEATS OF FORMATION (CAL. PER MOLE)

Substance	Heat of formation: From elements, This research	From elements, Previous value	From elements and $H_2O(l)$, This research	From elements and $H_2O(l)$, Previous value
$Mg(NO_3)_2$	−188,770	...	...	...
$Mg(NO_3)_2 \cdot 6H_2O$	−624,410	−622,500	−214,500	−212,590
$Ca(NO_3)_2$	−224,050	−224,040	...	...
$Ca(NO_3)_2 \cdot 4H_2O$	−509,420	−509,590	−236,150	−236,320
$Ba(NO)_3$	−236,990	−236,900	...	...

The previous values are for a temperature of 18° and have not been corrected to the base temperature of the present work, 25°. They are based on heats of solution of metallic calcium and barium reported by Guntz and Benoit,[14] the heat of solution of calcium oxide determined by Gautier,[15] the heat of solution of calcium nitrate tetrahydrate determined by Ewing, Rogers, Miller and McGovern,[16] and various heats of solution and reaction measured by Thomsen. The agreement is satisfactory, except for the mag-

nesium nitrate hexahydrate results. The difference between the values for this material again illustrates the necessity for redetermination of heats of formation which are based on data antedating modern methods, *i. e.*, the data of Thomsen in the present instance.

It will be noted that the part of the uncertainty in the heats of formation attributable to the heat of formation of the nitric acid alone ranges from 44 to 86% of the total uncertainty. Correction of the present results may be made readily whenever a better heat of formation of nitric acid becomes available.

Summary

The heats of formation of several nitrates of magnesium, calcium and barium have been determined at 25° by measuring heats of solution in 1.000 *N* hydrochloric acid. These heats of formation from the elements are: magnesium nitrate, −188,770 ± 310; magnesium nitrate hexahydrate, −624,410 ± 310; calcium nitrate, −224,050 ± 360; calcium nitrate tetrahydrate, −509,420 ± 370, and barium nitrate, −236,990 ± 380 calories per mole.

[CONTRIBUTION FROM THE WESTERN REGION, BUREAU OF MINES, U. S. DEPARTMENT OF THE INTERIOR]

The Heats of Formation of $Al(NO_3)_3 \cdot 6H_2O$ and $Al(NO_3)_3 \cdot 9H_2O$[1]

BY FRANK E. YOUNG[2]

The heats of formation of several metallurgically important nitrates have been determined recently at the Pacific Experiment Station of the Bureau of Mines. Previous papers have described determinations of the heats of formation of solid and liquid manganous nitrate hexahydrate[3] and the anhydrous nitrates of barium, calcium and magnesium, as well as calcium nitrate tetrahydrate and magnesium nitrate hexahydrate.[4] The present paper reports values of the heats of formation for two hydrated aluminum nitrates for which no previous results are available.

Materials and Method

The aluminum metal used in the measurements was cut from the center of a small ingot of 99.78% aluminum. The principal impurities were 0.10% magnesium and 0.10% iron. The only other impurity, except a negligible amount of surface oxide, was 0.02% copper. The magnesium and copper were determined chemically and the iron was determined both chemically and spectrographically. Titanium and manganese were shown to be absent by the spectrograph. After the aluminum was cut, it was washed several times with benzene, dried *in vacuo*, and weighed into bulbs which were sealed immediately. Corrections in the thermal measurements were made for the impurities.

Aluminum nitrate enneahydrate was prepared by Dr. E. H. Huffman, formerly of this Laboratory, by recrystallization of Mallinckrodt analytical reagent grade of aluminum nitrate from 4 *N* nitric acid. After air drying, the material was stored over 80% sulfuric acid for seventeen hours to remove excess water. Direct ignition to aluminum oxide, in platinum, over a gas–oxygen blast lamp, gave 13.58% Al_2O_3 (theoretical, 13.59%).

Aluminum nitrate hexahydrate was prepared by storing the enneahydrate over Dehydrite for five days. Analysis by direct ignition in platinum over the blast lamp gave 15.86% Al_2O_3 (theoretical, 15.87% Al_2O_3).

The heats of formation were determined by measuring the heats of solution in 4.000 *N* hydrochloric acid, which was prepared by diluting concentrated reagent quality hydrochloric acid and standardized against sodium carbonate.

To shorten the time required for taking the aluminum into solution, 1 ml. of chloroplatinic acid solution was added to the hydrochloric acid in the calorimeter before each determination. The chloroplatinic acid solution was prepared by dissolving 0.1002 g. of Mallinckrodt Analytical Reagent chloroplatinic acid hexahydrate in enough 4.000 *N* hydrochloric acid to make 100 ml. of solution. A correction was applied to the thermal results for the reduction of the chloroplatinic acid by the aluminum. The use of chloroplatinic acid reduced the solution time of the aluminum from several hours to twenty or thirty minutes.

The calorimetric measurements were made in the apparatus described by Southard[5] and later by Shomate and Young.[3] The results are expressed in defined calories (1 cal. = 4.1833 int. joules). All formula weights were calculated in accordance with the 1941 International Atomic Weights. Corrections of weights to vacuum were made using the following densities: aluminum metal, 2.70; aluminum nitrate enneahydrate, 1.4; aluminum nitrate hexahydrate, 1.7 (estimated).

Measurements and Results

The reactions by which the heats of formation of aluminum nitrate enneahydrate and aluminum nitrate hexahydrate were obtained are shown as skeleton equations in Tables I and II, respectively. The uncertainties in the last column of each table are twice the standard deviations of the means of the experimental results. This method of ascribing uncertainties has been discussed by Rossini and Deming.[6] The final values of the heats of formation and the corresponding uncertainties have been rounded to the nearest ten calories. The final temperatures in the solution measurements were always within a few hundredths of a degree of 25°, so that no correction was needed. The average sample weights, aluminum, 0.5394 g.; aluminum nitrate enneahydrate, 7.5028 g.; and aluminum nitrate hexahydrate, 6.4214 g., correspond to a dilution of 1 mole of anhydrous salt in $361.6HCl \cdot 4585H_2O$. The calorimetric

temperature changes accompanying solution of these samples were: aluminum, 1.67155°; aluminum nitrate enneahydrate, 0.13869°; and aluminum nitrate hexahydrate, 0.01310°.

The Heat of Formation of Aluminum Nitrate Enneahydrate.—Table I gives the skeleton equations of the reactions used in obtaining the heat of formation of aluminum nitrate enneahydrate.

TABLE I

THE HEAT OF FORMATION OF $Al(NO_3)_3 \cdot 9H_2O$ (CAL. PER MOLE)

Reactions	$\Delta H_{298.16}$	Uncertainty
(1) $Al + 3H^+ \longrightarrow Al^{+++} + {}^3/_2H_2$	−126,834	62
(2) ${}^3/_2H_2 + {}^3/_2N_2 + {}^9/_2O_2 \longrightarrow 3H^+ + 3NO_3^-$	−144,695	456
(3) $Al(NO_3)_3 \cdot 9H_2O \longrightarrow Al^{+++} + 3NO_3^- + 9H_2O$	+11,194	11
(4) $9H_2 + {}^9/_2O_2 \longrightarrow 9H_2O$	−614,862	90
(5) $Al + {}^3/_2N_2 + 9H_2 + 9O_2 \longrightarrow Al(NO_3)_3 \cdot 9H_2O$	−897,590	470

$\Delta H_5 = \Delta H_1 + \Delta H_2 - \Delta H_3 + \Delta H_4$

The heat of solution of aluminum in 4 *N* hydrochloric acid, ΔH_1, is the mean of six results: −126,810, −126,824, −126,727, −126,868, −126,884, and −126,875 cal. A correction of −143 cal. has been applied to these results for the presence of the impurities discussed above. It was also necessary to correct for the heat absorbed in the vaporization of water by the escaping hydrogen. This correction was made on the assumption that none of the hydrogen was left in the solution by the time thermal equilibrium was attained and that the hydrogen was completely saturated with water vapor when it left the solution. The partial pressure of water vapor over the solution was taken as 18.1 mm. and the heat of vaporization as 10,500 cal. per gram formula mass at 25°. Allowing an uncertainty of 10%, this correction was −376 ± 38 cal. for the 1.5 moles of hydrogen involved. The correction for vaporization of hydrogen chloride was nearly negligible, being only 1 cal. The total vaporization correction of −377 cal. has already been applied to the above results. The heat evolved in the reduction of the chloroplatinic acid used to increase the rate of solution of the aluminum made an additional correction of +16 cal. necessary. In making this correction, it was assumed that all of the chloroplatinic acid was reduced to the metal. Data for this correction were obtained from the compilation of Bichowsky and Rossini.[7]

Equation (2) represents the heat of formation of nitric acid in $AlCl_3 \cdot 358.6HCl \cdot 4585H_2O$. This heat of formation may be obtained from the reactions

(6) ${}^3/_2H_2 + {}^3/_2N_2 + {}^9/_2O_2 + 37.11H_2O \longrightarrow 3HNO_3 \cdot 37.11H_2O$

(7) $3HNO_3 \cdot 37.11H_2O + AlCl_3 \cdot 358.6HCl \cdot 4585H_2O \longrightarrow Al(NO_3)_3 \cdot 361.6HCl \cdot 4622.11H_2O$

(8) $Al(NO_3)_3 \cdot 361.6HCl \cdot 4585H_2O + 37.11H_2O \longrightarrow Al(NO_3)_3 \cdot 361.6HCl \cdot 4622.11H_2O$

The value for the heat of formation of nitric acid in 0.05 *M* solution, −49,234 ± 152 cal., was obtained from the data of Becker and Roth,[8] as explained in a previous paper.[3] The correction for the difference in acid strengths from 0.05 *M* to the present concentration of $3HNO_3 \cdot 37.11H_2O$ was obtained from the heats of dilution given by Becker and Roth.[9] This correction amounted to 56 cal., making $\Delta H_6 = 3(-49{,}178 \pm 152)$ or −147,534 ± 456 cal. The heats of solution of nitric acid, ΔH_7, and the corresponding amount of water, ΔH_8, in the aluminum chloride solution were measured directly as $\Delta H_7 = +53 \pm 5$ cal. and $\Delta H_8 = -2786 \pm 2$ cal. The required ΔH_2 is $\Delta H_6 + \Delta H_7 - \Delta H_8$ or −144,695 ± 456 cal.

Six measurements of the heat of solution of aluminum nitrate enneahydrate, ΔH_3, were made to obtain +11,194 ± 11 cal., the mean of +11,192, +11,173, +11,216, +11,186, +11,196, and +11,201 cal., after application of a +676 ± 1 cal. correction for the measured heat of dilution by the water of hydration.

The heat of formation of 9 moles of water, ΔH_4, was obtained by multiplying Rossini's[10] heat of formation of water by 9: $9(-68{,}318 \pm 10) = -614{,}862 \pm 90$ cal. The heat of formation of aluminum nitrate enneahydrate from the elements, ΔH_5, is −897,590 ± 470 cal. per mole. The heat of formation of this compound from the elements and liquid water, $\Delta H_1 + \Delta H_2 - \Delta H_3$, is −282,720 ± 260 cal. per mole.

The Heat of Formation of Aluminum Nitrate Hexahydrate.—Table II summarizes the reactions used in this work in obtaining the heat of formation of aluminum nitrate hexahydrate.

TABLE II

THE HEAT OF FORMATION OF $Al(NO_3)_3 \cdot 6H_2O$ (CAL. PER MOLE)

Reaction	$\Delta H_{298.16}$	Uncertainty
(9) $Al + 3H^+ \longrightarrow Al^{+++} + {}^3/_2H_2$	−126,834	62

chloric acid gave −543, −531, −550, −539, −550, and −546, with a mean of −543 ± 6 cal. per mole after application of a measured 450 ± 1 cal. correction for the heat of dilution by the water of hydration.

Reaction (12) again involves Rossini's heat of formation of water, −409,908 ± 60 cal. for 6 moles.

The heat of formation of aluminum nitrate hexahydrate from the elements, ΔH_{13}, is −680,890 ± 460 cal. per mole. The heat of formation of this hydrate from the elements and liquid water, $\Delta H_9 + \Delta H_{10} - \Delta H_{11}$, is −270,990 ± 460 cal. per mole.

Whenever a better heat of formation of nitric acid becomes available, the present measurements may be corrected accordingly.

Summary

The heats of formation of aluminum nitrate enneahydrate and aluminum nitrate hexahydrate have been determined by measuring the heats of solution of these compounds and aluminum in 4.000 *N* hydrochloric acid. The heats of formation from the elements are −897,590 ± 470 cal. per mole for aluminum nitrate enneahydrate and −680,890 ± 460 cal. per mole for aluminum nitrate hexahydrate.

The System Acetic Acid–Ammonia

BY ARTHUR W. DAVIDSON, HARRY H. SISLER AND RAYMOND STOENNER

The familiar salt ammonium acetate, $NH_4C_2H_3O_2$, as well as solutions of this salt in acetic acid, may readily be prepared by the direct combination of dry ammonia and anhydrous acetic acid. It is obvious, then, that the entire system acetic acid–ammonium acetate, freezing point data for which have previously been presented,[1] may be regarded as constituting only one-half of the more comprehensive binary system acetic acid–ammonia, in which ammonium acetate assumes the role merely of an especially stable addition compound.[2] Although ammonium acetate has long been known to be readily soluble in liquid ammonia,[3] and a determination of its solubility at a single temperature has indeed been reported,[4] no attempt has thus far been made to study the system throughout the entire range of concentrations.

It will readily be appreciated that the investigation of liquid solutions consisting of ammonium acetate and excess ammonia presents experimental difficulties which are not encountered with solutions of ammonium acetate in acetic acid. Especially is this true at room temperatures and above, since the lowering of the vapor pressure of liquid ammonia produced by ammonium acetate is not nearly so great as might be expected.[5] Other similar systems, consisting of ammonia and ammonium nitrate,[6] ammonium thiocyanate,[7] and the ammonium halides,[8] have been successfully studied, although only in the first two instances was it found possible to cover the entire range of concentrations from ammonia to pure ammonium salt.

The present work consisted mainly of a study of the ammonium acetate–ammonia portion of the system. A part of the earlier work[1] was repeated, also, and somewhat more accurate data were obtained for temperatures above 60°. Three new addition compounds of ammonia and acetic acid, two of them stable at their melting points, have been discovered.

Method

Preparation of Materials.—Anhydrous acetic acid was prepared as described in previous papers from this Laboratory.[1] No sample used had a freezing point of less than 16.60°.

Commercial synthetic anhydrous ammonia, which was stated to be at least 99.95% pure, was found to have a freezing point of −77.5 ± 0.4°, in good agreement with the values of −77.7 to −77.8° found in the literature. Distillation over metallic sodium was found to bring about no change in freezing point; hence this product was used without further purification.

Ammonium acetate was obtained, as described previously,[1] by the passage of dry ammonia over anhydrous acetic acid in a desiccator over calcium oxide. The preparation of pure ammonium acetate (50 mole % of ammonia) by this process is very slow, and requires the use of a large excess of ammonia; furthermore, there is no advantage to be gained by the use of a salt of exactly this composition. Hence, various solid products containing from 38 to 43 mole % of ammonia were used as starting materials, after determination of their compositions by treatment with sodium hydroxide solution and distillation of the ammonia into standard hydrochloric acid.

Determination of Equilibrium.—A few mixtures, containing from 23 to 43 mole % of ammonia, were made up by the addition of acetic acid to the solid starting material, and their freezing points were determined in sealed tubes, as previously described,[1] as a check on the earlier results. For all other mixtures of f. p. higher than −10° (45 to 82 mole % of ammonia), the method used was essentially that of Bradley and Alexander.[7] A small quantity (0.5 to 0.6 g.) of a solid mixture of known composition was introduced into the bend of a U-shaped glass tube of 8 mm. internal diameter and a total length of about 30 cm., and its weight was determined by difference. The lower part of the tube

was then immersed in a bath of solid carbon dioxide, carbon tetrachloride and chloroform, which maintained a temperature of −78°, and dry ammonia was passed through the tube.[9] The quantity of ammonia condensed under these conditions could be readily controlled by maintenance of a constant rate of flow and regulation of the time of absorption, which varied, in different samples, from thirty seconds to three minutes. After a little practice, it was found possible to attain any desired composition by this means. Then, with the bend of the U-tube still in the cold bath, both ends of the tube were sealed in the blast-lamp, and it was allowed to come to room temperature and weighed. After the mixture had completely liquefied, it was again cooled until solidification occurred; the equilibrium temperature was then determined as that at which the last trace of crystals disappeared, while the tube was being slowly heated. Each f. p. was determined at least twice; the temperatures reported are believed to be correct to within 0.5°, except in the range from 67 to 75 mole % of ammonia, where, because of the extremely high rate of change of equilibrium temperature with concentration, the values are accurate only to ±2°.

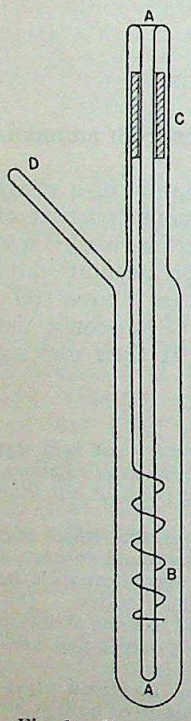

Fig. 1.—Freezing point cell.

At temperatures much below 0°, the mixtures became so viscous and equilibrium was attained so slowly that the procedure just described was no longer satisfactory. The method adopted for solutions of f. p. below −10° was similar to that described by Cady and Jones,[10] except that equilibrium temperatures were determined by means of cooling curves instead of by visual observation. The cells used were as pictured in Fig. 1; their outer dimensions were 35 by 2.5 cm., with a thermocouple well, AA, about 5 mm. in diameter. The stirrer, B, was of stainless steel wire, the upper end of which was attached to a short piece of iron pipe, C, which had been coated with stainless steel. The stirrer was operated by means of a solenoid, which was wired through a motor-driven interrupter making contact approximately 120 times per minute.

Mixtures of the desired composition were made by the following procedure. The weighed cell, surrounded by a weighed test-tube of slightly larger diameter which served as an air jacket, was one-third immersed in liquid air. About 20 cc. of ammonia was introduced by distillation through the side arm D, which was then closed by means of a rubber cap. After the ammonia had solidified, the jacketed cell was removed from the bath, the outer tube was warmed to room temperature, and the weight of the ammonia was determined. The air jacket provided sufficient insulation so that but little of the ammonia melted, and no appreciable amount vaporized, during the weighing. The desired quantity of acetic acid was introduced through the side arm, the end of which was then sealed. The jacket was removed, and the cell was warmed to room temperature and again weighed.

For the determination of equilibrium temperatures, the well, AA, was filled with a mixture of carbon tetrachloride and chloroform, in order to minimize convection effects. A copper–constantan thermocouple was introduced, and the cell was surrounded by several concentric tubes to provide air jackets. It was then immersed in a bath of solid carbon dioxide, or of liquid air, in a Dewar flask, so that cooling took place at a rate not exceeding one degree per minute. The rate of cooling in the neighborhood of the f. p. was kept approximately the same for all the determinations by the expedient of decreasing the number of jackets for mixtures of lower f. p.

The temperature–time curves were recorded directly by means of a Leeds and Northrup Micromax recorder, which had been calibrated at the b. p. of ammonia, the f. p. of pyridine, the sublimation point of carbon dioxide, and the b. p. of oxygen. The level to which the temperature rose immediately after the first break in the cooling curve was taken as the equilibrium temperature.[11] Data so obtained are believed to be correct to ±1.5°.

Analysis of Solid Phases.—Two of the three new compounds encountered in this work exist only under such conditions of temperature and pressure that the obtaining of samples for analysis would have been extremely difficult, if not impossible. Fortunately, however, both of these compounds melt congruently, so that the composition of each is clearly indicated by the position of the corresponding maximum in the f. p. curve. In the case of the third compound, the probable composition is indicated by the course of the curve, but an attempt was made to confirm this by direct analysis. A solution of appropriate composi-

tion was made up in the lower end of a cell consisting of two bulbs, about 8 by 2 cm. each, connected by a vertical tube 10 cm. long and 8 mm. in diameter. The upper end of the cell was then sealed. After equilibrium had been reached at the desired temperature, the cell was inverted and the mother liquor allowed to drain into the lower bulb, both bulbs being maintained at the same temperature throughout the process. After two days, the narrow portion of the cell was sealed and the bulbs separated. The one containing the crystalline solid was weighed, broken under dilute acid, washed out, and weighed again; the amount of ammonium salt formed in the solution was then determined in the usual manner.

Results

In the preceding table, S denotes the mole percentage of ammonia, and T the corresponding equilibrium temperature. These data, together with those of Davidson and McAllister, are presented graphically in Fig. 2, in which, however, a few of the points have been omitted in order to avoid crowding.

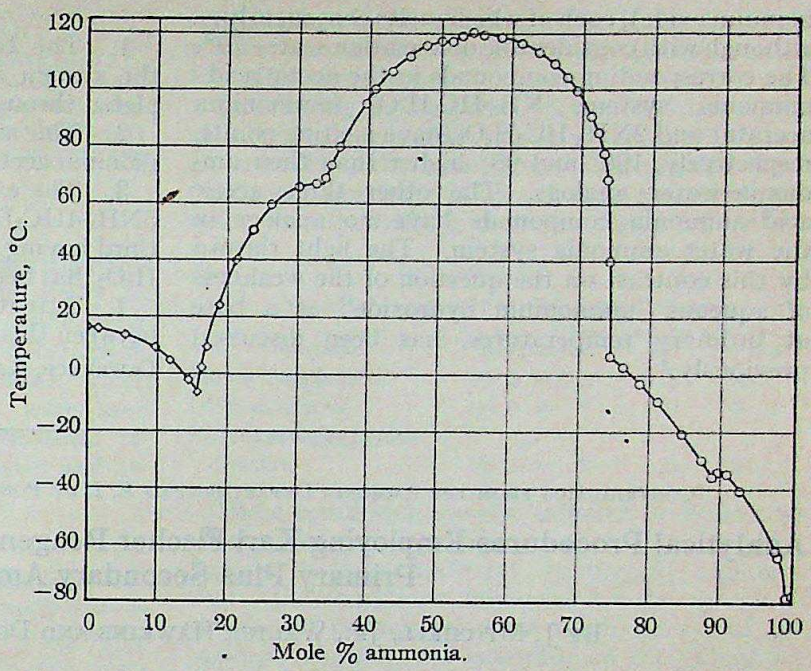

Fig. 2.—System acetic acid–ammonia; the data of Davidson and McAllister (recalculated) are indicated by squares, those of the present work by circles.

The equilibrium temperatures in the range from 25 to 50 mole % of ammonia were found to be a little higher than those previously reported, the difference increasing with increasing ammonia content. Thus, the melting point of the compound $NH_3 \cdot 2HC_2H_3O_2$ (or $NH_4C_2H_3O_2 \cdot HC_2H_3O_2$) was found to be 67.0° instead of 66.5°, and that of ammonium acetate ($NH_3 \cdot HC_2H_3O_2$ or $NH_4C_2H_3O_2$) to be 117° instead of 113°.

Because of the decidedly unexpected course of the curve just beyond the mid-point, this region was studied with special care; the data reported above are representative of a much larger number of determinations. The evidence for the existence of a eutectic point at about 52 mole % of ammonia, and of a surprisingly stable compound of ammonia content but slightly higher than that of ammonium acetate, is unmistakable. The composition of this compound (55.6 mole % of ammonia) corresponds to the formula $5NH_3 \cdot 4HC_2H_3O_2$ (or $4NH_4C_2H_3O_2 \cdot NH_3$), and its melting point is 119.5 ± 0.5°. Its saturated solution in liquid ammonia at 25° is found to contain 25.7 mole % of acetic acid. This figure agrees fairly well with that of 26.4% calculated from the data of Hunt and Boncyk,[4] who, however, do not mention the solvation of ammonium acetate under these conditions.

At about 6.5° this compound undergoes transition to solid phase (d), which is stable in contact with solutions containing from 74.4 to 88.8 mole % of ammonia. Because of the impossibility of freeing the crystals completely from the rather viscous mother liquor, especially since suction could not be applied, accuracy in direct analysis was unattainable; the proportion of ammonia found would inevitably be too high. Three analyses of samples obtained from solutions of different initial concentration gave fairly concordant results averaging 71.9 mole % NH_3. This figure, together with the course of the curve in this region, indicates that the compound is probably $2NH_3 \cdot HC_2H_3O_2$, although the possibility of its having the composition $5NH_3 \cdot 2HC_2H_3O_2$ is not altogether exluded. If the first supposition is correct, the m. p. of the compound, by extrapolation, would appear to be about 16°.

A marked halt in the cooling curves for solutions in the concentration range just mentioned clearly indicated a eutectic point at −35.5°. Beyond 88.8 mole % of ammonia, the stable solid phase is a compound $9NH_3 \cdot HC_2H_3O_2$ (or $NH_4C_2H_3O_2 \cdot 8NH_3$), which melts congruently at −34°. A saturated solution of this compound in liquid ammonia at the f. p. of the latter contains little more than 1 mole % of acetic acid, and the last eutectic temperature is no more than 1° below the f. p. of ammonia.

Discussion

It is of interest to compare the freezing point curve just described with that for the system water–ammonia, first investigated in its entirety by Rupert.[12] Such comparison clearly brings out the enormous difference in stability of the addition compounds in the two cases, which is undoubtedly a consequence of the much greater tendency of acetic acid than of water to act as a proton donor. There are two solid compounds of water and ammonia, $NH_3 \cdot H_2O$ (ammonium hydroxide) and $2NH_3 \cdot H_2O$ ($NH_4OH \cdot NH_3$, or am-

(12) Rupert, THIS JOURNAL, **32**, 748 (1910); *cf.* Postma, *Rec. trav. chim.*, **39**, 515 (1920); and Elliott, *J. Phys. Chem.*, **28**, 887 (1924).

Digitized by Arya Samaj Foundation Chennai and eGangotri

monium oxide), each of which melts congruently—although with considerable dissociation—at −79°. The corresponding compounds in the acetic acid–ammonia system, $NH_3 \cdot HC_2H_3O_2$ (ammonium acetate) and $2NH_3 \cdot HC_2H_3O_2$, have melting points, respectively, 196° and 95° higher than their ammonia–water analogs. The other three acetic acid–ammonia compounds have no analogs in the water–ammonia system. The light thrown by this contrast on the question of the weakness of aqueous "ammonium hydroxide" as a base at ordinary temperatures, has been discussed previously.[2]

Summary

1. The temperature–concentration curve for the system acetic acid–ammonia has been completed throughout the entire concentration range.
2. The melting point of pure anhydrous ammonium acetate has been found to be 117°.
3. The existence of the new solid compounds $5NH_3 \cdot 4HC_2H_3O_2$ and $9NH_3 \cdot HC_2H_3O_2$, and of a third having the probable composition $2NH_3 \cdot HC_2H_3O_2$, has been demonstrated.
4. Attention has been directed to the contrast between this system and that of water–ammonia.

LAWRENCE, KANSAS RECEIVED FEBRUARY 14, 1944

[CONTRIBUTION FROM THE AMMONIA DEPARTMENT OF E. I. DU PONT DE NEMOURS & COMPANY, INC.]

Analytical Procedures Employing Karl Fischer Reagent. XI. The Determination of Primary Plus Secondary Amines[1]

BY J. MITCHELL, JR., WALTER HAWKINS AND DONALD MILTON SMITH

The identification of amines by acylation techniques has been used to some extent,[2,3] but little has been done on their quantitative acetylation. Olson and Feldman[4] modified the acidimetric acetyl chloride procedure of Smith and Bryant[5] so that most amines reacted 90% or better. However, some amides also reacted so that this technique did not differentiate between these classes of compounds. Although acetic anhydride has been used in the determination of tertiary amines,[6,7] it apparently has not been used in the quantitative estimation of primary and secondary amines.

In the present research an acetylation method has been developed which is based on the selective reaction of acetic anhydride with the primary and secondary amines, according to the equations

$$RNH_2 + (CH_3CO)_2O = CH_3CONHR + CH_3COOH$$
$$RNHR' + (CH_3CO)_2O = CH_3CONRR' + CH_3COOH$$
$$(CH_3CO)_2O + H_2O = 2CH_3COOH$$

The new technique, independent of acid–base titrimetry, determines the excess acetic anhydride, after acetylation, by hydrolysis followed by titration of excess water with Karl Fischer reagent under conditions reported in an earlier publication for the determination of anhydrides.[8]

The new procedure is applicable to primary and secondary amines generally including aliphatic, alicyclic, heterocyclic and aromatic types. However, diaryl secondary amines and pyrrole fail to react. Since tertiary amines do not interfere, the method can be used indirectly for the determination of tertiary amine by correcting the total base titer for primary plus secondary amine.

In the presence of primary alcoholic hydroxyl the procedure is modified to effect quantitative acetylation of both the amine and alcohol.

Experimental

Reagents.—The acetylating reagent is prepared by mixing 1.5 moles (142 ml.) of pure acetic anhydride in sufficient dry pyridine to make one liter of solution.[9] The hydrolysis reagent consists of 100 g. of J. T. Baker C. P. or Merck A. R. grade dry sodium iodide and 22 ml. of water in 1 liter of pyridine solution. The preparation of the Karl Fischer reagent has been reported in a previous publication.[10]

Analytical Procedure.—In the absence of hydroxyl the sample, containing up to 10 milliequivalents of primary plus secondary amine, is transferred to a 250-ml. glass-stoppered volumetric flask.[11] To this is added exactly 20 ml. of the acetylating reagent. The flask together with a blank is then stoppered, shaken and allowed to stand for thirty minutes at room temperature.[12] At the end of this time 25 ml. (calibrated pipet) of the hydrolysis reagent is added. The flask is placed in a water-bath at 60 ± 1°, and after momentarily raising the stopper to allow for expansion of the included air, is firmly stoppered and maintained at that temperature for thirty minutes. After cooling spontaneously to room temperature, the contents are titrated directly for water with Karl Fischer reagent.

Ten ml. (calibrated pipet) of the hydrolysis reagent is titrated for water. Free water in the sample is determined by titration of a portion of the sample acidified with glacial acetic acid.

Total anhydride added is equivalent to the net water used up during hydrolysis of the blank. This is found by subtraction of the water found from total water added before hydrolysis. Excess anhydride after acetylation is determined by subtracting water found from total water added to the sample, including free water originally present. The net anhydride is equivalent to the primary plus secondary amine in the sample.

Analytical Results

Thirteen primary amines were analyzed by this method; some were checked acidimetrically by titration to brom phenol blue. The trade products with the exception of hexamethylenediamine, which was sublimed, and *p*-bromoaniline, which was recrystallized from chloroform, were used without further purification. Experimental results are given in Table I. The precision and accuracy are usually within ±0.2%.

TABLE I

ANALYTICAL DATA FOR PRIMARY AMINES

Amine		Found, wt. %: Acidimetric	Acetylation	H_2O	Total
n-Butylamine	(10)[a]	97.7	98.0 ± 0.5	1.7	99.7
Propylenediamine[b]	(2)		84.1 ± .2	13.9	98.0
Hexamethylenediamine[c]	(4)		99.9 ± .1	0.1	100.0

o-Aminodiphenyl[d]	(2)		99.0 ± .2	.0	99.0
2-Aminopyridine[g]	(2)		100.0 ± .3	.0	100.0

[a] Figures in parentheses represent number of indivdual determinations. [b] Carbide & Carbon Chemical, 85%. [c] du Pont. [d] Monsanto. [e] Arthur H. Thomas Co. [f] J. T. Baker. [g] Reilly Tar and Chemical Co.; all others Eastman Kodak Chemicals. [h] Calculated from Kjeldahl nitrogen value.

Analytical data for several secondary amines are given in Table II. Results with diphenylamine, carbazole and phenothiazine were 0.0 ± 0.0%.

TABLE II

ANALYTICAL DATA FOR SECONDARY AMINES

		Found, wt. %: Acidimetric	Acetylation	H_2O	Total
Diethylamine	(2)[a]	99.7	99.7 ± 0.1	0.3	100.0
Di-*n*-butylamine	(10)	98.3	98.4 ± .2	.1	98.5
Di-*s*-butylamine	(4)	99.5	83.5 ± .2	.1	83.6
Di-isobutylamine	(2)	100.1	100.1 ± .1	.0	100.1
Methylaniline	(4)		98.8 ± .1	.0	98.8
Pyrrole	(6)		0.0 ± .1	.0	0.0
Morpholine[b]	(2)		104.1 ± .2	.0	104.1
Piperidine	(2)	99.4	99.8 ± .2	.0	99.8
Piperazine hydrate	(2)		45.8 ± .2	53.8	99.6

[a] Figures in parentheses represent number of determinations. [b] Eastman Kodak Co. practical grade chemical; all others Eastman Kodak.

The low result obtained on di-*s*-butylamine probably indicates the presence of some tertiary amine. It is quite surprising that pyrrole failed to react. Experiments conducted at 60° on the sample as received and on freshly distilled pyrrole gave values of only 0.6% after thirty minutes and 2% after three hours.

Interfering Substances.—Since the above procedure is based on acetylation, alcohols will react. By modifying the technique to include the short additional heating period primary hydroxyl will react quantitatively as shown in Table III.[13]

TABLE III

ANALYTICAL DATA FOR HYDROXYAMINES

Substance	Found, wt. %: Acetylation	H_2O	Total
Monoethanolamine	99.5 ± 0.1	0.2	99.7
Diethanolamine	99.6 ± .1	.0	99.6
Hydroxyethylethylenediamine	99.1 ± .2	.0	99.1

These conditions are not sufficiently drastic to effect quantitative esterification of secondary hydroxyl; tertiary hydroxyl reacts only slightly. Under the conditions employed for the complete reaction of primary alcohols the hydroxyl of diisopropanolamine was esterified to the extent of 80%. By increasing the heating period to one hour at 60° this value was raised to 92%.

The effect of the type of alcohol is given in Table IV. In this case 5 milliequivalents of butanol was analyzed alone and in the presence of an equivalent amount of amine.

TABLE IV

RELATIVE REACTIVITY OF ACETIC ANHYDRIDE WITH *n*-, *s*- AND *t*-BUTANOL

Substances	% OH Esterified
n-Butanol	100
n-Butanol + *n*-butylamine	100[a]
s-Butanol	71
s-Butanol + isobutylamine	72[a]
t-Butanol	6
t-Butanol + isobutylamine	13[a]

[a] Corrected for quantitative amine reaction.

In general the presence of amine had little or no effect on the acetylation of the alcohol.

No interference is encountered from amides, urethans, nitriles or tertiary amines. Acetamide, urea and acetanilide did not react. Acetonitrile and adiponitrile gave 0.7 and 0.4% reaction, respectively. Dimethylaniline reacted to the extent of 1.3 ± 0.1%. This may have been due to secondary amine impurity.

Summary

1. An accurate and precise quantitative procedure for the determination of primary plus secondary amine, based on acetylation with acetic anhydride, has been described. Analytical results for more than twenty-two primary and secondary amines are reported.

(13) When necessary the results may be corrected for primary hydroxyl by the specific esterification procedure described in the preceding paper of this series, Smith, Mitchell and Hawkins, Paper No. X.

Digitized by Arya Samaj Foundation Chennai and eGangotri

2. The interference of alcoholic hydroxyl has been investigated, including the relative reactivity of primary, secondary and tertiary hydroxyl.

3. The method can be used indirectly for the determination of tertiary amine.

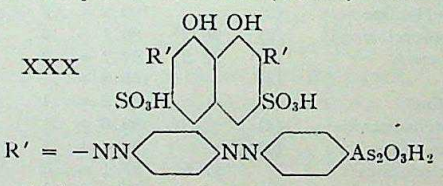
The Serological Properties of Simple Substances. VII. A Quantitative Theory of the Inhibition by Haptens of the Precipitation of Heterogeneous Antisera with Antigens, and Comparison with Experimental Results for Polyhaptenic Simple Substances and for Azoproteins

BY LINUS PAULING, DAVID PRESSMAN, AND ALLAN L. GROSSBERG

In an earlier paper in this series[1] there was developed a simple physicochemical theory of the precipitation of bivalent antibody molecules and bivalent antigen molecules and the inhibition of precipitation by haptens, and it was shown[1,2] that the results of experiments on the precipitation of specific antisera by polyhaptenic substances agree qualitatively but not quantitatively with the theory: in particular, the predicted linear decrease in amount of precipitate with increase in amount of hapten was observed only in the region of small inhibition. The deviation from linearity for larger amounts of hapten was attributed to the heterogeneity of the antisera, which were assumed, as is indicated by many experimental observations, to contain antibody molecules with greatly varying combining powers. We have now developed an extended quantitative theory of hapten inhibition on the assumption of an error-function distribution of antibody molecules with different combining powers in a heterogeneous antiserum, and have found it to be in generally satisfactory quantitative agreement with experiment. The theory permits the evaluation of two constants from each hapten-inhibition experiment, an average bond-strength constant for antibody and hapten (in competition with antigen) and an effective heterogeneity index for the antiserum; values of each of these constants can be interpreted in relation to the molecular structure of the hapten and the antigen.

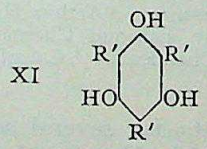
There have previously been reported[2,3] the results of quantitative investigations of the inhibition by haptens of the precipitation of polyhaptenic simple substances by antisera made by inoculating rabbits with sheep serum coupled either with diazotized *p*-arsanilic acid[2] (anti-R sera) or with diazotized *p*-(*p*-aminophenylazo)-phenylarsonic acid[3] (anti-R′ sera). It was found that the relative inhibiting powers of various haptens are essentially the same for different polyhaptenic simple substances precipitated by the same pool of antiserum, but are somewhat different for different pools of anti-R serum or of anti-R′ serum precipitated by the same polyhaptenic substance. Still greater differences are observed between anti-R sera and anti-R′ sera in general. We have now carried out a comparative study of hapten inhibition of the precipitation of a polyhaptenic simple substance (XXX) and an azo

XXX



protein (R′-ovalbumin) by anti-R serum and anti-R′ serum, and of a polyhaptenic substance (XI) by anti-R serum obtained by a single three

XI



weeks' course of inoculations, with the results described below. The data obtained in these and the earlier experiments have been analyzed by use of the new theory, and the results are discussed in relation to the molecular structure of the interacting substances.

Experimental Methods

Materials.—There have been previously described the methods of preparation of the antisera,[3,4] the haptens and antigens,[2,3,4] and the R′-ovalbumin,[3] which contained 2 per cent. arsenic.

The Reaction of Antiserum with Antigen and Hapten.—The reaction mixtures were set up in triplicate, with use in each series of experiments of the amount of antigen giving the largest amount of precipitate in the absence of hapten; borate buffer was used as diluent.[2] The tubes were allowed to stand one hour at room temperature and over two nights in the refrigerator, and the precipitates were then analyzed by our standard method.[5]

The results of the study of the inhibition by each of 24 haptens of the precipitation of antiserum with antigen

[a] The amounts are tabulated as fractions per mille of the amount precipitated in absence of hapten: for antigen XXX this was 715 μg. and for R′-ovalbumin 769 μg. Values for R′-ovalbumin include the precipitated antigen protein. Values are averages for triplicate analyses, with mean deviation ±2%; single analyses are given in brackets. [b] These values are for hapten concentrations one-fifth of those indicated.

XXX and with R′-ovalbumin are given for anti-R serum in Table I and for anti-R′ serum in Table II. These antisera were obtained by successive inoculations and bleedings of several rabbits over a period of several months; for comparison a study was also made of the effect of fifteen haptens on the precipitation by antigen XI of an anti-R serum obtained after a single three-weeks' course of inoculations, with the results given in Table III.

Discussion

In an earlier paper[1] it was shown that in a system containing bivalent antigen, A, homogeneous bivalent antibody, B, and univalent hapten, H, and capable of forming the soluble complexes AB, ABA, HB, HBA, and HBH and the precipitate AB the amount of precipitate, calculated according to the principles of chemical equilibrium with use of reasonable values for the pertinent equilibrium constants, falls off, in the region of the equivalence zone, in linear relation to the amount of hapten present. The slope of the curve for a system containing equivalent amounts of antigen and antibody was found to be given by the equation

$$\frac{dAB\ (pp)}{dH_{total}} = -\frac{1/2 + Ks + (K^2s^2 + Ks)^{1/2}}{1 + Ks + \left(1 + \frac{1}{K's}\right)(K^2s^2 + Ks)^{1/2}} \qquad (1)$$

in which AB (pp) is the amount of precipitate, H_{total} the total amount of hapten present in all forms, K the equilibrium constant for combination of a haptenic group of the antigen and a complementary region of the antibody, K' the corresponding constant for hapten and antibody, and s the solubility of the precipitate. This equation may be rewritten[2] in the form

$$-\frac{dH_{total}}{dAB\ (pp)} = \frac{C}{K'} + C' \qquad (2)$$

with C and C' independent of hapten, and constant for a given antigen–antibody system; and it has been suggested[2] that, as an approximation, the constant C' may be neglected, and the hapten inhibition constants K' for a series of haptens be taken as proportional to the negative slopes $-dAB\ (pp)/dH_{total}$.

It has been found,[1,2,3] however, that the experimental points showing the dependence of the amount of precipitate on the amount of added hapten do not fall on a straight line except in the region of very low hapten concentration—with larger amounts of hapten the inhibition of precipitation is less than predicted by the theory (see Fig. 1 of ref. 2); and this deviation from linearity has been attributed to heterogeneity

o-Aminophenylarsonic	.22	1.5			914	820	686

[a] The amounts are tabulated as fractions per mille of the amount precipitated in absence of hapten, which was 331 μg. Values are averages for triplicate analyses, with mean deviation ±4%; duplicate analyses are given in parentheses. [b] Values of 946 and 867 found for 5 and 10 × 10^{-9} mole of hapten, respectively; the value 2.0 for σ was assumed.

of the antiserum, which appears to contain antibodies of greatly varying combining powers. We have now extended the theory to cover heterogeneous antisera of a particular sort, and have found that the extended theory agrees in a generally satisfactory way with experiment.

Let us assume that the heterogeneity of the antiserum is such that it can be described by a probability distribution function which is an error function in the effective free energy of combination of hapten and antibody (in competition with antigen); that is, in the quantity $\ln(K'/K_0')$, where K' is the effective hapten inhibition constant of the particular antibody molecule under consideration and K_0' is an average effective hapten inhibition constant. The normalized distribution function itself is

$$\frac{1}{\sqrt{\pi}\,\sigma}\, e^{-\{\ln (K'/K_0')\}^2/\sigma^2} \qquad (3)$$

and the fractional number of antibody molecules with given value of K' in a differential region is

$$\frac{dN}{N} = \frac{1}{\sqrt{\pi}\,\sigma} e^{-\{\ln (K'/K_0')\}^2/\sigma^2} d \ln (K'/K_0') \qquad (4)$$

Curves showing the distribution function for several values of the heterogeneity index σ are shown in Fig. 1. For $\sigma = 1$ most of the antibody molecules (84%) have K' values in the range from 0.368 K_0' to 2.718 K_0', for $\sigma = 2$ this range is from 0.135 K_0' to 7.48 K_0', for $\sigma = 3$ from 0.050 K_0' to 20.1 K_0', and for $\sigma = 4$ from 0.018 K_0' to 54.5 K_0'. The corresponding ranges of values of free energy of interaction of antibody and hapten have widths of 1200, 2400, · · ·, cal. per mole for $\sigma = 1, 2, \cdots$.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

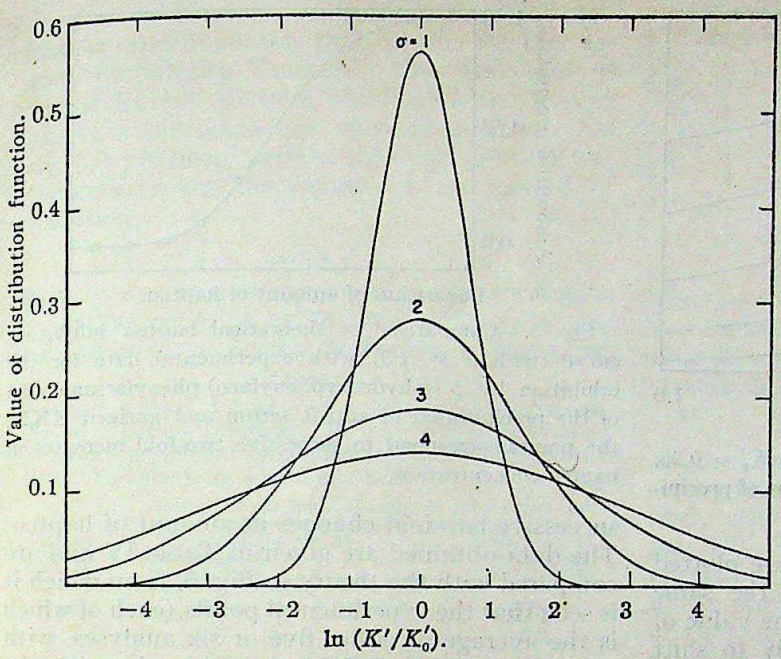

Fig. 1.—Assumed distribution function for values 1, 2, 3, and 4 of the heterogeneity index σ, plotted against ln (K'/K'_0).

This distribution of antibodies would occur in an antiserum if the heterogeneity were the result of a very large number of independent influences, each of which could increase or decrease the free energy of bond formation by an additive contribution. Since this is not unreasonable, in the light of current concepts of the structure of antibodies, we may well expect this distribution to be rather closely approximated by the antiserum from a single animal or by the combined antisera from a large number of animals.[6] On the other hand, the combined antisera from only a few animals or a combination of unlike fractions obtained in the course of fractionation of antibodies might not have an error-function distribution and might not correspond in their properties to the present theory; the theory could, however, easily be extended to cover such special cases.

If we assume that for each kind of antibody the amount of precipitate is linear in the amount of hapten, with slope proportional to K', the amount of precipitate formed by the heterogeneous antiserum is given by the equation

$$P = \frac{AB\ (\text{pp})}{AB\ (\text{pp})_{H_{\text{total}}=0}} = \frac{1}{\sqrt{\pi}\,\sigma}\int_{-\infty}^{\ln (1/H_{\text{total}} K'_0)} (1 - K'H_{\text{total}})\, e^{-\{\ln (K'/K'_0)\}^2/\sigma^2}\, \mathrm{d} \ln (K'/K'_0) \quad (5)$$

The upper limit of the integral represents the value of K' at which the hapten just inhibits completely the precipitation of the corresponding antibody: no precipitate is formed by antibody with larger values of K'. The integral is easily evaluated in terms of the Gaussian probability integral $\mathrm{H}(x)$, for which numerical values are given in tables[7]; the equation then assumes the form

$$P = \frac{1}{2}\{1 + \mathrm{H}(x_1)\} - \frac{1}{2} H_{\text{total}} K_0\, e^{\sigma^2/4}\{1 + \mathrm{H}(x_2)\} \quad (6)$$

with $x_1 = \frac{1}{\sigma} \ln (1/H_{\text{total}} K'_0)$ and $x_2 = x_1 - \sigma/2$. The function $\mathrm{H}(x)$ is to be taken with the same sign as x.

Curves of the calculated amounts of precipitate for $\sigma = 0$, 1, 2, 3, 4, and 5 plotted against H_{total} are shown in Fig. 2. It is seen that with increase in σ there is increasing deviation from the linear relation, which holds for $\sigma = 0$. The similarity in form of the theoretical and experimental curves is evident from a comparison of Fig. 3, which shows calculated curves for $\sigma = 1.5$ and a sequence of values of K'_0, with Fig. 1 of reference 2, in which experimental data for several haptens with the same antigen–antibody system are plotted.

The values of K'_0 for each antigen–antibody system have been normalized by assigning the value 1.00 to an azo hapten or, for some systems, to an average of several haptens.

A very satisfactory way of comparing experiment and theory is to use a logarithmic scale for the amount of hapten. Since K'_0 and H_{total} occur in Equation 6 only as their product, the

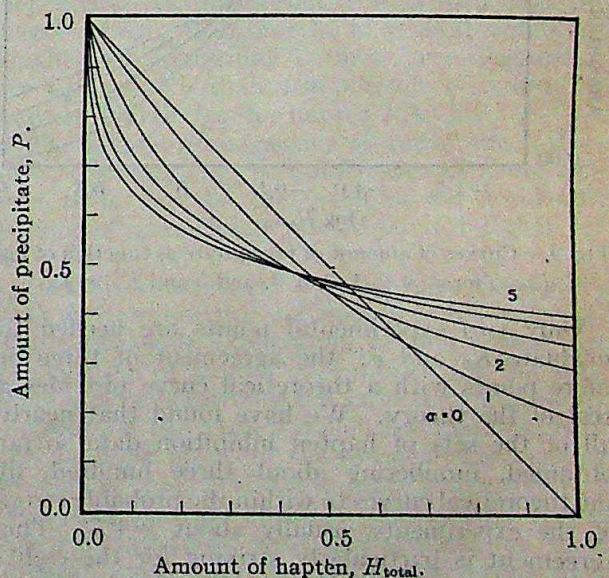

Fig. 2.—Theoretical curves showing dependence of amount of precipitate P on amount of hapten H_{total} for $\sigma = 0$, 1, 2, 3, 4, and 5 and $K'_0 = 1$.

(6) It would not be surprising if the antiserum from a single rabbit inoculated with an azoprotein were to have a different type of distribution. The antibodies produced by the rabbit would be influenced by the nature of the place of attachment of the hapten to the protein (histidine or tyrosine side-chains). The distribution function for such an antiserum might be closely approximated by the sum of two or more error functions.

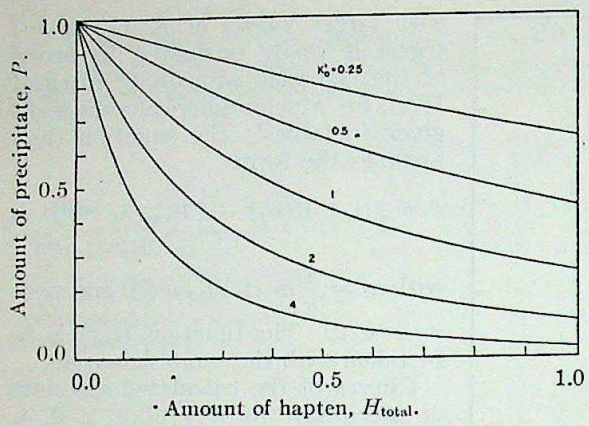

Fig. 3.—Family of curves with $\sigma = 1.5$ and $K_0' = 0.25$, 0.5, 1, 2, and 4, showing dependence of amount of precipitate on K_0' for fixed σ.

curves showing the amount of precipitate plotted against the logarithm of H_{total} have the same shape when they correspond to the same value of σ; the effect of changing K_0' is simply to shift the curve along the log H_{total} axis. Hence only a single family of such curves, covering a range of values of σ, is needed for the evaluation of σ and K_0' from a set of experimental points. Such a set of curves,[8] for $\sigma = 0$, 1, 2, 3, 4, and 5, is shown in Fig. 4.

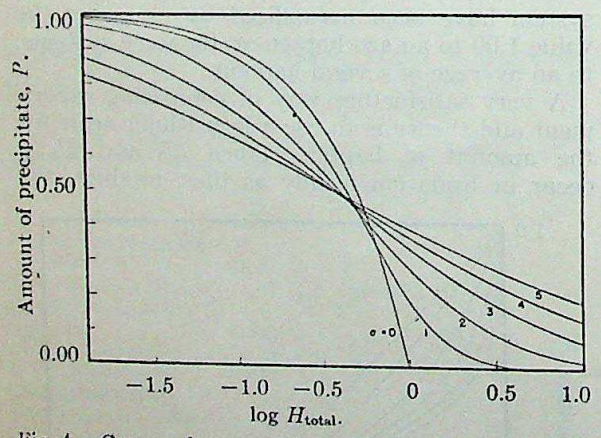

Fig. 4.—Curves of amount of precipitate as function of log H_{total}, for $\sigma = 0$, 1, 2, 3, 4, and 5 and $K_0' = 1$.

Only two experimental points are needed to evaluate K_0' and σ; the agreement of three or more points with a theoretical curve provides a test of the theory. We have found that nearly all of the sets of hapten inhibition data so far obtained, numbering about three hundred, fit the theoretical curves to within the probable errors of the experiments, usually about ±4%. This agreement is particularly striking for the eight-point sets in Tables IV and VI of reference 2. In order to test the theory further a set of analyses was made with special care over a range of ten

(8) In interpreting the experimental data it was found convenient to prepare and use a set of transparent templates, covering the range $\sigma = 0$ to 5 at intervals of 0.5.

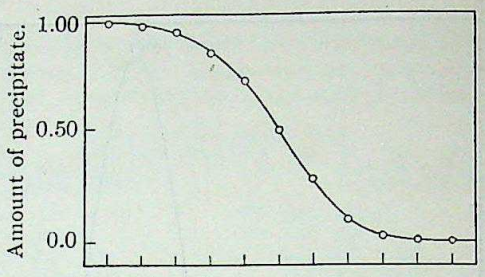

Fig. 5.—Comparison of theoretical hapten inhibition curve (with $\sigma = 1.3$) with experimental data for the inhibition by *p*-(*p*-hydroxyphenylazo)-phenylarsonic acid of the precipitation of anti-R serum and antigen XXX; the points correspond to successive two-fold increases in hapten concentration.

successive two-fold changes in amount of hapten. The data obtained are given in Table IV and are compared with the theory in Fig. 5, from which it is seen that the experimental points (each of which is the average of either five or six analyses, with mean deviation ±1.5%) agree closely with the indicated theoretical curve, which corresponds to $\sigma = 1.3$.

TABLE IV

INHIBITION BY *p*-(*p*-HYDROXYPHENYLAZO)-PHENYLARSONIC ACID OF PRECIPITATION OF ANTI-R SERUM AND ANTIGEN XXX

Antigen solution, 2 ml. (6.7×10^{-8} mole); antiserum, 0.33 ml.; hapten solution, 2.67 ml.; *p*H of supernates, 8.0; amount of precipitate in absence of hapten, 762 μg.; values corrected by 17 μg., the blank for serum and buffer.

[a] Each value is the average of five or six replicate analyses, with mean deviation ±1.5%.

The antiserum used in this experiment was, like most of those which we have used, a pooled serum made by mixing the sera obtained in several bleedings of a number of rabbits (usually about six). Since the mixing of sera would be expected to produce a serum with increased heterogeneity, some experiments were carried out with antisera obtained by single bleedings of individual rabbits, which had been inoculated over a period of months. The results are given in Table V and Fig. 6. It is seen that these antisera are heterogeneous, with $\sigma = 1$ for Rabbit 35 and $\sigma = 1.5$ for Rabbit 43, and that the agreement with the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

theory is satisfactory, indicating that the distribution approximates that given by the assumed probability function. The two sets of data for Rabbit 35 were obtained with antisera from two bleedings on successive days. No study has yet been made of the dependence of the heterogeneity on the length of the period of inoculation.

It is of interest to know how sensitive the parameters of the hapten inhibition function are to change in the amount of antigen in the system—the theory as developed applies only in the region of the equivalence zone, and might be expected not to agree with experiment in the region of excess of antigen and the region of excess of antibody. Several sets of hapten inhibition experiments were carried out with anti-R serum and antigen XXX, the amount of antigen used with 0.33 ml. of antiserum in different sets being 13, 32, 80, and 200 $\times 10^{-9}$ mole; the first corresponds to excess of antibody, the second and third approximately to the equivalence zone, and the fourth to excess of antigen, the amounts of precipitate in absence of hapten being 413, 769, 693, and 323 μg., respectively. A strongly inhibiting hapten, *p*-(*p*-hydroxyphenylazo)-phenylarsonic acid, and a weakly inhibiting hapten, *o*-methylphenylarsonic acid, were used. The results of the experiments, which extended over six two-fold changes in amount of hapten, are shown in Fig. 7, in comparison with the theoretical curves. The agreement with theory is satisfactory for each set of points, and for each hapten the four sets of points lead to the same value of

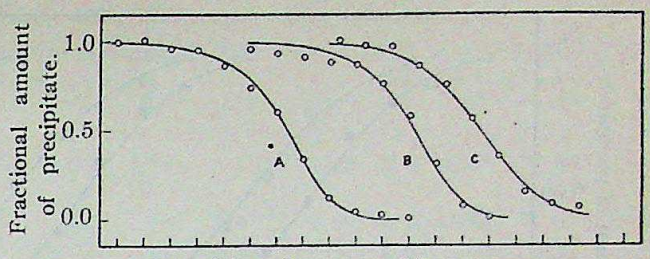

Fig. 6.—Comparison of theoretical hapten inhibition curves (A and B with $\sigma = 1$, C with $\sigma = 1.5$) with experimental data for antisera obtained by single bleedings of individual rabbits: A and B, Rabbit No. 35; C, Rabbit No. 43.

σ, the heterogeneity parameter—1.5 for the strong hapten and 1.8 for the weak one. Moreover, although the amount of hapten required for 50% inhibition increases with increase in amount of antigen (somewhat less rapidly than in linear proportion), the relative inhibiting power of the two haptens remains essentially constant: the four pairs of curves correspond, respectively, to $K_0' = 0.022$, 0.019, 0.023, and 0.026 for *o*-methylphenylarsonic acid relative to the value 1.00 for the other hapten, in excellent agreement with the ratio 0.022:1 given for the two haptens in Table I, for the same antigen–antibody system. We conclude that it is not necessary in comparative hapten inhibition experiments to select the antigen–antibody ratio with extreme care.

Some of the characteristics found for the parameters K_0' and σ may be seen from Table VI, in which there are given values determined from the data in Tables IV and V of reference 2. It is to be noted that the heterogeneity index σ depends on the antiserum, the antigen, and the hapten, being, for example, in general somewhat smaller for antiserum T than for antiserum S, for antigen VI than for antigen III, and for hapten XXIII than for hapten XXVIII.

The greater homogeneity of antiserum T than of S, corresponding to a difference of about one unit in σ, may be the result of the accidental pooling of more closely related sera for T than for S.

Usually σ increases for a sequence of haptens with given antiserum and antigen as K_0' decreases. The presumable explanation of this is that the competition of hapten and antigen for the antibody will be essentially the same for all antibody molecules if the hapten is identical in action with the haptenic group of the antigen—this leading to small σ—whereas if the hapten is much different from the haptenic group of the antigen it will compete favorably with the antigen for those antibody molecules of the heterogeneous antiserum which happen to be more closely complementary in structure to the hapten than to the antigen, and unfavorably for those which are more closely complementary to the antigen than to the hapten, and this variance in nature

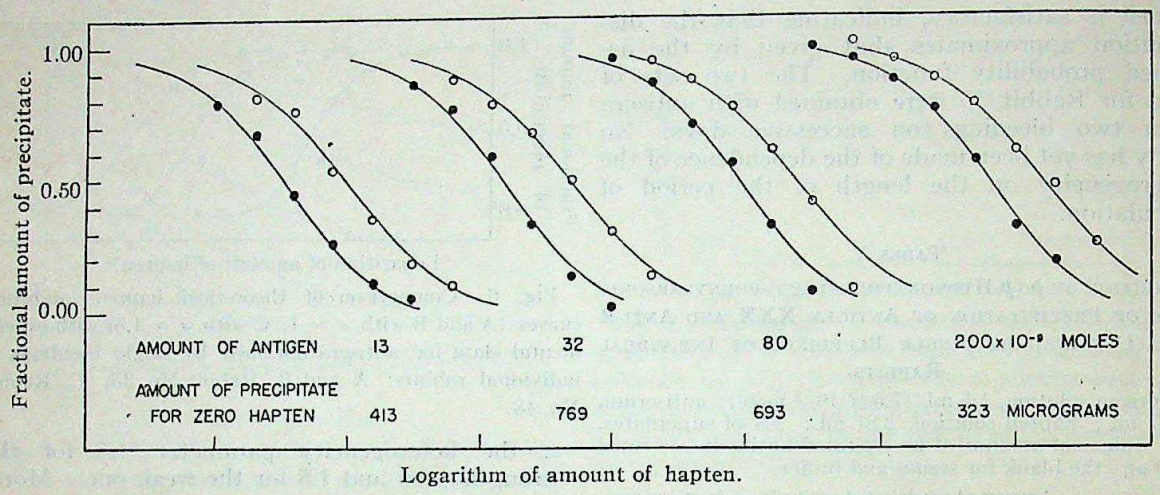

Fig. 7.—Comparison of experimental values of amount of precipitate in presence of hapten with theoretical curves. Fractional amounts of precipitate relative to amount for zero hapten are plotted as ordinates against the logarithm of amount of hapten. The successive curves were obtained with use of different amounts of antigen, as given below the curves. Solution of antigen XXX, 2 ml.; anti-R serum, 0.33 ml.; hapten solution, 2.67 ml.; *p*H of supernates, 8.0; most of the points are averages for triplicate analyses. The point farthest left corresponds to 9.8×10^{-9} mole of hapten in each sequence of points for hapten *p*-(*p*-hydroxyphenylazo)-phenylarsonic acid, represented by solid circles, and to 313×10^{-9} mole of hapten in each sequence for hapten *o*-methylphenylarsonic acid, represented by open circles; the theoretical curves are for $\sigma = 1.5$ and 1.8 for the two haptens, respectively.

of the competition of hapten and antigen for antibody would become evident in a large value of σ. Since a good precipitating antigen is one which combines strongly with most of the antibody molecules in the antiserum, a strong hapten, with large K_0', would be similar in structure to the antigen, and so would have σ small, whereas a weak hapten would have σ large, as observed. It is to be expected from this argument, however, that in the inhibition of precipitation of an antiserum by an antigen with haptenic group different from that of the immunizing antigen used in making the antiserum a hapten similar to the immunizing antigen might have both σ and K_0' larger than a hapten similar to the precipitating antigen.

It is found in practice that, although the theory has been developed only for dihaptenic antigens, it applies equally well also to polyhaptenic antigens, including azoproteins. Values of σ and K_0' determined from the data in Tables I, II, and III are given in these tables, and values determined from the data in Table IV of reference 2 and Table V of reference 3 are included in Table VII. The range of σ values for the twenty-four haptens studied is usually about 2 units

[a] For anti-R serum and antigen VI, Table VI, ref. 2. [b] For anti-R serum and antigen XXX, Table I, this paper. [c] For anti-R serum and R′-ovalbumin, Table I, this paper. [d] For anti-R serum (with short period of inoculation) and antigen XI, Table III, this paper. [e] For anti-R′ serum and antigen XXX, Table VI, ref. 3. [f] For anti-R′ serum and antigen XXX, Table II, this paper. [g] For anti-R′ serum and R′-ovalbumin, Table II, this paper.

(1.0 to 3.0 or 1.5 to 3.5); it is especially small for the anti-R serum of Table I, being only 1.0 to 1.5 for precipitation with R′-ovalbumin and 0.9 to 2.1 for precipitation with antigen XXX.

In our earlier papers[2,3] values were assigned to the hapten inhibition constant K' on the basis of the estimated initial slopes of the hapten inhibition curves. These values, which are given in Table VII for comparison with those of K_0', cover for the series of haptens much smaller ranges than do those of K_0', the range for K' being one-third of that of K_0' for the anti-R serum and one-tenth for the anti-R′ serum. This is as expected: Equation 6 for H_{total} small assumes the form

$$P = 1 - e^{\sigma^2/4} K_0' H_{\text{total}} \qquad (7)$$

which is similar to the equation used to determine K' from the initial slope, with $e^{\sigma^2/4} K_0'$ in place of K'; the effect of the factor $e^{\sigma^2/4}$ would be to increase the range of K_0' over that of K' by the factor 5 for a change in σ from 1.5 to 3.0 (anti-R serum) and by the factor 12 for a change in σ from 1.5 to 3.5 (anti-R′ serum).[9]

(9) The evaluation of K_0' from the data is of course more reliable than that of K' from the estimated initial slopes.

It is of interest to examine the correlations among the K_0' values collected in Table VII. Most striking is the agreement between the values for antigen XXX and those for the greatly different antigen R′-ovalbumin with the same antiserum; this agreement is somewhat better for anti-R′ serum (mean difference 15%) than for anti-R serum (20%). There is similar general agreement between the values for different pools of anti-R serum with simple antigens VI ($K_0'^a$) and XXX ($K_0'^b$) and between the values for two different pools of anti-R′ serum and antigen XXX ($K_0'^e$ and $K_0'^f$).

The most pronounced difference between anti-R sera and anti-R′ sera—the much smaller effect of position of substituents in the benzene ring for the latter than for the former—has been already pointed out[3] in the discussion of the values of K' originally assigned, and a tentative interpretation of the difference as resulting from a greater looseness of fit of the anti-R′ antibody to the larger R′ haptenic group of the immunizing antigen than of the anti-R antibody to the R haptenic group has been proposed. The extent of the difference can be seen from Table VIII, in which the ratios of K_0' values for meta and ortho to

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

those for the corresponding para compounds are presented. It is seen that for the nitro and methyl groups a twenty-fold change in K_0' is caused by changed position in the ring in the precipitation of anti-R serum, and only a two-fold change for anti-R′ serum. The effect of the amino group with anti-R serum is much smaller than that of the nitro group and the methyl group —only about six-fold; but the same two-fold change is shown with anti-R′ serum. The structural significance of these observations is not clear.

TABLE VIII

EFFECT OF POSITION OF SUBSTITUENTS ON HAPTEN INHIBITION CONSTANT

Substituent*	Anti-R sera			Anti-R serum, short inoculation	Anti-R′ sera		
	a	*b*	*c*	*d*	*e*	*f*	*g*

Amino	.16	.14	.19	.36	0.35	.40	.60

* Letters *a* to *g* refer to Table VII.

The effect of the nature of the substituent group is just as pronounced for anti-R′ serum as for anti-R serum; for each antiserum an approximately fifty-fold range of values is covered by K_0' for the twenty-four haptens. The general order of effectiveness of groups is indicated by the order of the para-substituted haptens in the table.

The anti-R serum obtained after a short course of inoculations (*d* in Tables VII and VIII) shows much lower specificity of interaction with haptens than the other antisera, with respect both to the nature of the substituent group and to its position.

This investigation was carried on with the aid of a grant from The Rockefeller Foundation. We are grateful to Professor Dan H. Campbell and Dr. V. Schomaker for assistance.

Summary

A quantitative theory of the inhibition by haptens of the precipitation of heterogeneous antisera by antigens has been developed on the basis of the assumption that the heterogeneity of an antiserum can be described by a distribution function which is an error function of the free energy of interaction of antibody and hapten in competition with the precipitating antigen. The theory has been found to be in satisfactory agreement with experiment. It has been applied to data obtained in previous investigations and to data from new experiments on the inhibition by each of twenty-four haptens of the precipitation of anti-R serum and of anti-R′ serum with a dihaptenic simple antigen and with R′-ovalbumin, yielding values of the average effective inhibition constant of the haptens and of the heterogeneity index of the antisera. A discussion of the structural significance of these quantities is presented.

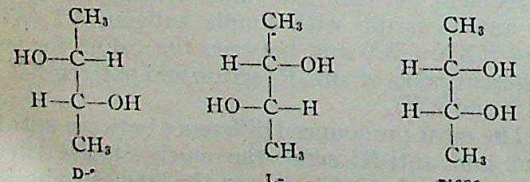
Configuration of the 2,3-Butylene Glycols[1]

BY S. A. MORELL AND A. H. AUERNHEIMER[2]

2,3-Butylene glycol is a symmetrical molecule containing two asymmetric carbon atoms. Like tartaric acid, it can occur in only three stereoisomeric forms, D-, L- and *meso*-, which are formulated configurationally as follows



2,3-Butylene glycols

Previous investigations[3,4,5] on the configuration of the 2,3-butylene glycols have been limited to the distinction between the optically inactive *meso*- and D, L- forms, rather than with relating the active forms to their respective configurational series. In order to accomplish the latter, one of the enantiomorphs must be converted to a compound whose configuration is known.

In studying the conversion of optically active 2,3-butylene glycols to butadiene, by pyrolysis of their diacetates according to the method of Hill and Isaacs,[6] the isolation of several optically active intermediates has made it possible to establish the configuration of the glycols. Both the dextro- and levorotatory glycols were used in the present investigation. From the former, a levorotatory methylvinylcarbinol acetate was obtained which yielded a dextrorotatory methylvinylcarbinol on hydrolysis. From the latter, a levorotatory methylvinylcarbinol was obtained, without isolating its intermediate acetate. The optical purity of the glycols used differed con-

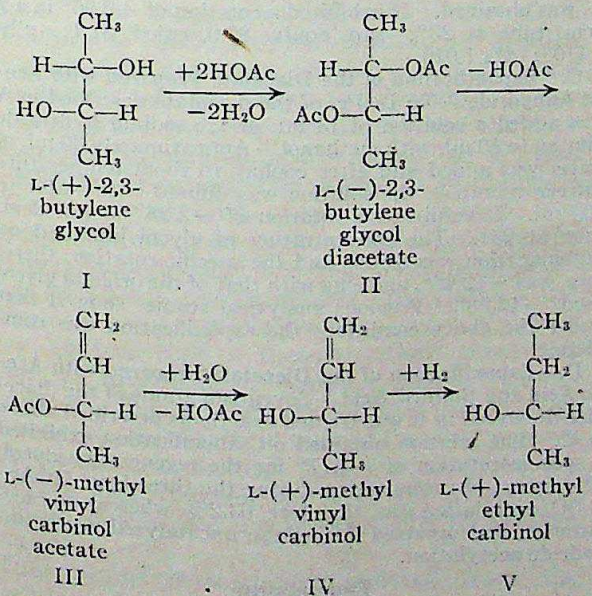
siderably, but it will be evident from the following discussion that the sign of rotation alone, rather than the magnitude of rotation, was sufficient to establish the necessary configurational relationships.

Winstein and Lucas[5] have found that the acetylation of an optically active, 2,3-butylene glycol proceeds with an inversion in the sign of rotation. In confirming this observation, it was found that extensive racemization occurred when the acetylating medium was acetic acid catalyzed by sulfuric acid, whereas with acetic anhydride (uncatalyzed) this reaction proceeded without racemization. Kenyon and Snellgrove[7] also noted an inversion in sign when alkyl vinyl or alkyl ethyl carbinols were converted to their acetates. On the basis of rotatory data, the latter investigators showed that the methyl vinyl and methyl ethyl carbinols of the same sign of rotation are probably related configurationally. In agreement with Kenyon and Snellgrove's[7] rotatory data, hydrogenation of our dextrorotatory methyl vinyl carbinol yielded dextrorotatory methylethylcarbinol.

Levene, Walti and Haller[8] have shown that dextrorotatory methylethylcarbinol possesses the same configuration as dextrorotatory lactic acid, which belongs to the L-series. L-(+)-Methylethylcarbinol is thus related to dextrorotatory 2,3-butylene glycol and the enantiomorphs of the latter are, therefore, L-(+)- and D-(−)- for the dextro- and levorotatory forms, respectively. The following configurational formulas show the reactions which were conducted starting with the L-(+)-glycol



From the above stereochemical formulas, it is evident that L-(−)- methyl vinyl carbinol acetate (III) is the only optically active product possible when one molecule of acetic acid is removed from L-(−)-2,3-butylene glycol diacetate (II). Deacetylation from the 2,3 position produces the isomeric acetate of the 2–3 enol of methyl ethyl ketone, $CH_3—C(OAc)=CH—CH_3$ which contains no asymmetric carbon atom. All of the compounds formulated above can exist in only two optically active forms, D- and L-. For any of them, therefore, the sign of rotation is sufficient to determine which active form is present. In the case of the glycols, or their diacetates, the inactive forms which can also be present are D,L-, *meso-* and a mixture of both. In the deacetylation reaction, the optically active methyl vinyl carbinol acetate formed must have the same configuration as the active glycol originally present, for any D-, L- or *meso*-glycol also present could form only D-, L-methylvinylcarbinol acetate.

Experimental

The glycols were obtained from glucose by the Fermentation Division of this Laboratory. Their isolation from the beers was conducted by the Engineering and Development Division. A complete description of the preparation of the glycols, the acetylation and pyrolysis reactions, and the separation of the bulk of the acetic acid in the pyrolysis liquors, will be included in future communications from this Laboratory on the conversion of 2,3-butylene glycol to butadiene, of which the present investigation is an incidental part.

The physical and analytical values observed for the compounds described below are given in the accompanying table. For convenience in referring to the table, each compound has been assigned a number, starting with the five compounds formulated in the reactions given above for the conversion of dextrorotatory 2,3-butylene glycol (I) to dextrorotatory methyl ethyl carbinol (V). The experiments on racemization, conducted in connection with the possibility of Walden inversion during the acetylation reaction, are treated separately and are not included in the table.

All specific rotations reported refer to the homogeneous liquids, no corrections being made for their densities. In reporting the rotations below, reference to concentration is omitted since this is 100%, unless specified otherwise. A Schmidt and Haensch polarimeter was used, readings reproducible to ±0.01° being readily obtained.

I. Dextrorotatory 2,3-Butylene Glycol.—The glycol was obtained from glucose by the fermentative action of *Aerobacter aerogenes*, as described by Ward, Pettijohn, Lockwood and Coghill,[9] and exhibited a rotation of $[\alpha]^{23}D$ +1.06°. This low value is due to the fact that the organism produces the *meso-* form predominantly, as shown by Fulmer, Underkofler and Bantz.[10] Several attempts to isolate the active enantiomorph, by resolution, have been reported, the highest specific rotations obtained being +5.0° (Böeseken and Cohen[3]) and +6.9° (Chappel[11]). Fulmer, Underkofler and Bantz[10] fermented the dextrorotary glycol ($[\alpha]^{25}D$ +1.0°, produced by the action of *Aerobacter aerogenes*) to acetyl methyl carbinol by means of *Aerobacter suboxydans;* the *meso-* form was preferentially attacked and the unfermented glycol exhibited a specific rotation of +10.15°. Their results indicated that little or none of the levorotatory glycol was produced by *Aerobacter aerogenes*. Since an optically pure isomer of 2,3-butylene glycol has not yet been conclusively obtained, it

is not possible to calculate the concentration of the active form present in the sample used.

II. Levorotatory 2,3-Butylene Glycol Diacetate.—A 10 molar acetylation of I was conducted as described by Hill and Isaacs,[6] using 25 moles of acetic acid, 16.2 g. of sulfuric acid, and benzene as the water entraining agent. In five hours, water removal from the gravity separator had ceased. To the hot solution 45 g. of $NaOAc \cdot 3H_2O$ was added and after cooling, filtering and distilling, the fraction b. r. 190–192° was obtained.

III. Levorotatory Methylvinylcarbinol Acetate.—One hundred and seventy-five grams of II was pyrolyzed at 410° in a 2″ × 36″ Pyrex tube, packed with stainless steel shavings, at the rate of 0.73 g. per minute. The vapors from the tube entered a column where the butadiene gas was stripped from the condensed pyrolysis liquor, 162 g. of the latter, containing 35.5% acetic acid, being obtained. To 121 g. of the liquor was added 300 ml. of ether, and dry ammonia gas was passed into the solution with cooling, until it was neutral to litmus. After filtering, washing with ether and distilling, the main fraction, b. r. 111.5°–113.5°, weighing 15.7 g., was obtained. After saponification, it gave only a trace of a precipitate with 2,4-dinitrophenylhydrazine, thus indicating the absence of the isomeric acetate of 2-butene-2-ol. A determination of its iodine no. (3 min. Wijs method using mercuric acetate) gave a value of 217; theory, 222.

IV. Dextrorotatory Methylvinylcarbinol.—The diacetate of I (2 lb. moles) was prepared by a method similar to that described above for II. The pyrolysis was conducted at 595° in a stainless steel coil and the intermediate unsaturated acetate fraction, mixed with some by-products, was separated from the bulk of the acetic acid in the pyrolysis liquor. The mixture contained 7.2% acetic acid and 21.0% unsaturated acetates as measured by saponification. Two hundred and ninety-four grams of the mixture was saponified with a 10% calculated excess of aqueous sodium hydroxide by stirring (2 layers) under reflux on a steam-bath for eight hours. On distillation, the fraction b. r. 77–100° was collected, which separated into two layers. The upper layer was exhaustively extracted with water and the combined aqueous fractions were redistilled, the fraction b. r. 80–100° being collected. The latter was saturated with sodium chloride and the upper layer so formed was dried over sodium sulfate. On distillation, the fraction b. r. 96.2–96.5°, weighing 19.4 g., was obtained. It exhibited a rotation of +1.36° in a 2-dcm. tube at 23°. Based on Kenyon and Snellgrove's[7] value of $[\alpha]^{25}D$ +33.7° for the pure enantiomorph of methylvinylcarbinol, it contained 2.0% of the active form.

V. Dextrorotatory Methylethylcarbinol.—To 14.6 g. of IV was added 0.2 g. of freshly prepared PtO_2[12] and hydrogenation was conducted in a Parr apparatus[13] at an initial gage pressure of 45 lb. In one hour absorption had ceased, the theoretical quantity of hydrogen being consumed. The catalyst was filtered and washed with 20 ml. of benzyl alcohol, which facilitated the subsequent distillation of the lower boiling methylethylcarbinol, the main fraction having a b. r. of 99–100°. The carbinol weighed 9.3 g. It exhibited a rotation of +0.48° in a 2-dcm. tube at 23°. Based on Kenyon and Snellgrove's[7] value of $[\alpha]^{20}D$ +13.9° for the pure enantiomorph of methylethylcarbinol, it contained 1.7% of the active form, which is in good agreement with the 2.0% concentration of active methylvinylcarbinol in the sample, IV, hydrogenated.

VI. Inactive Methylvinylcarbinol.—In order to compare the physical constants of IV and X (below) under identical conditions, a sample of Shell Development Company methylvinylcarbinol was redistilled, the fraction of b. r. 96.0–96.5° being used.

VII. Inactive Methylethylcarbinol.—In order to compare the physical constants of V under identical conditions, sample VI was hydrogenated and the inactive methylethylcarbinol was isolated exactly as described above for V.

VIII. Levorotatory 2,3-Butylene Glycol.—The glycol was obtained by the fermentative action of *Bacillus polymyxa*, as described by Ward, Pettijohn, Lockwood and Coghill.[9] It exhibited a specific rotation of $[\alpha]^{23}D$ −12.85° and a b. r. of 179–180°. Levorotatory 2,3-butylene glycol, $[\alpha]^{23}D$ −2.4°, had been obtained previously by Neuberg and Nord[14] by the action of fermenting yeast on diacetyl. By a similar biochemical reduction of acetylmethylcarbinol, Neuberg and Kobel[15] obtained the levorotatory glycol $[\alpha]^{25}D$ −5.51°, b. r. 178–181°. As in the case of I, it is not possible to calculate the concentration of the active form present in the sample used.

IX. Dextrorotatory 2,3-Butylene Glycol Diacetate.—The glycol VIII (2 lb. moles) was acetylated as described above for II, except that acetic anhydride was used to complete the esterification. As may be seen from the saponification equivalents in the table, the anhydride readily converted the glycol monoacetate[5,16] to the diacetate.

X. Levorotatory Methylvinylcarbinol.—From the pyrolysis liquor of IX, the levorotatory methylvinylcarbinol was isolated as described above for IV. It exhibited a rotation of −1.28° in a 1-dcm. tube at 23°. Based on Kenyon and Snellgrove's[7] value of $[\alpha]^{25}D$ −33.7° for the pure enantiomorph, it contained 3.8% of the active form.

Effect of Method of Acetylation on the Racemization.—In considering the possibility of Walden inversion, it was of interest to acetylate one of the glycols and saponify the resulting diacetate, in order to learn whether the original glycol would be regenerated.

A. Acetylation with Acetic Anhydride (Uncatalyzed).—To 90 g. (1 mole) of a sample of 2,3-butylene glycol, which exhibited a rotation of −25.98° in a 2-dcm. tube at 23° ($n^{18}D$ 1.4340; d^{25}_4 0.990) was added 225 g. (2.2 moles) of acetic anhydride. The mixture was heated for one hour at 100° and then distilled, the fraction b. r. 193°–193.5°, 156.9 g., being obtained. It exhibited a rotation of +27.46° in a 2-dcm. tube at 23°, sap. equiv., 87.1, calcd. 87.1; $n^{18}D$ 1.4163; D^{30}_4 1.016.

B. Acetylation with Acetic Acid in Presence of Sulfuric Acid.—Ninety grams of the same sample of glycol described in A was acetylated as described above for II, three hours being required before water removal from the gravity separator had ceased. After neutralization with sodium acetate and distillation, the fraction b. r. 190–191°, 85.6 g., was obtained. It exhibited a rotation of +9.96° in a 2 dcm. tube at 23°; sap. equiv. 86.0, calcd. 87.1; $n^{18}D$ 1.4163; d^{30}_4 1.016.

C. Saponification of the Diacetate Prepared with Acetic Anhydride.—To 17.0 g. of the diacetate described in A was added a solution of 13 ml. of 1:1 sodium hydroxide diluted to 50 ml. with methanol. Approximately 30 ml. of water was added and after cooling to room temperature (fifteen minutes), the solution was diluted with water to 100 ml. It exhibited a rotation of −2.28° in a 2 dcm. tube at 23°. The concentration of glycol liberated on saponification was 8.80% and the specific rotation, therefore, was −12.95°, agreeing with that of the original glycol used, −12.98°. Previous analytical studies showed that under the above conditions the saponification was complete.

D. Saponification of the Diacetate Prepared with Acetic Acid and Sulfuric Acid.—Seventeen grams of the diacetate described in B was treated exactly as described above in C. The solution obtained on saponification exhibited a specific rotation of −4.77° for the regenerated glycol. The extent of racemization during the three-hour HOAc–H_2SO_4 acetylation was, therefore, 63.2%, whereas no racemization had occurred during the uncatalyzed acetic anhydride acetylation.

Discussion

In relating the configuration of the active 2,3-butylene glycols to the methyl ethyl carbinols

[a] Conducted by the Analytical and Physical Chemical Division of this Laboratory. [b] Wilson and Lucas[4] report 176.7°$_{742}$ for the D-, L- and 181.7°$_{742}$ for the *meso*- forms. [c] Huntress and Mulliken[17] report $n^{25}D$ 1.4364 for the D-, L- form. [d] Huntress and Mulliken[17] report D^{20}_4 1.0433 for the D-, L- form. [e] Wilson and Lucas[4] report $70_{5.5}$ for the D-, L- and $66_{5.5}$ for the *meso*- forms. [f] Not reported in the literature. [g] Redistilled Shell Development Company methylvinylcarbinol, inactive. [h] From hydrogenation of VI, inactive.

(see reactions I to V above), the possibility of Walden inversion must be considered. Winstein and Lucas[5] observed that in the stepwise transformation of 2,3-butylene glycol to 2,3-dibromobutane, via 3-acetoxy-2-butanol, 2-acetoxy-3-bromobutane and 3-bromo-2-butanol, Walden inversion does not occur in the acetylation and hydrolysis reactions. Since two asymmetric carbon atoms are involved, in order that the configurations formulated above could be vitiated by Walden inversion, the inversion would have had to occur at both asymmetric centers; for inversion at only one center would produce the inactive *meso*-glycol. The regeneration of levorotatory glycol by successive acetylation and hydrolysis (as in racemization experiments above) shows that in *both* of these reactions there was either *no* inversion or *complete double* Walden inversion. The probability of the latter must be extremely small, and in view of the observations of Winstein and Lucas,[5] it is evident that the configurations assigned above to the active 2,3-butylene glycols are not in error due to Walden inversion.

The methylvinylcarbinols isolated from the pyrolysis liquors exhibited $[\alpha]^{23}D$ +0.68° and −1.28°, as obtained from the dextro- and levorotatory glycols, respectively, whereas the pure enantiomorphs of Kenyon and Snellgrove[7] showed $[\alpha]^{25}D$ ±33.7°. Hydrogenation of the dextrorotatory methylvinylcarbinol yielded methylethylcarbinol, $[\alpha]^{23}D$ +0.24°, whereas Kenyon and Snellgrove[7] report $[\alpha]^{25}D$ ±13.9° for the pure enantiomorphs. Since the values of our specific rotations were relatively low (2-dcm. polarimeter tubes were generally used, so that the observed rotations were actually twice as great as reported), the possibility of optically active impurities being present in the original fermentation glycol preparations must also be considered. If present, however, they would have been carried through the acetylation, pyrolysis, hydrolysis, and hydrogenation reactions, and at each step would have contaminated the product isolated. The analytical and physical data for each of the five compounds involved in this series of reactions agreed well with both the literature and theory. The fact that the methylvinylcarbinols isolated exhibited the same sign of rotation as the glycols from which they were prepared would require, furthermore, that any such impurity be dextrorotatory in one case and levorotatory in the other. The probability that the observed rotations were due to impuritities must, therefore, be extremely small.

The proof of the configuration of the 2,3-

butylene glycols herein presented is somewhat unique in that reactions involving extensive racemization, namely, esterification and pyrolysis, were employed and, furthermore, the sign of rotation always indicated which active form was present. The symmetry of the glycol molecule containing two asymmetric centers permits the existence of only two active forms, the D- and L-, and on removing one of these centers by dehydration (or deacetylation of the diacetate), the methylvinylcarbinol (or its acetate) so produced also exists in only two active forms, D- or L-. As pointed out above, the active methylvinylcarbinol (or its acetate) must have the same configuration as the active glycol from which it was prepared.

Summary

In studying the conversion of optically active 2,3-butylene glycols to butadiene, the intermediate methylvinylcarbinols were isolated, each exhibiting the same sign of rotation as the glycol from which it was prepared. Hydrogenation to methylethylcarbinol also proceeded without change in sign. Since the configuration of dextrorotatory methylethylcarbinol had already been related to that of dextrorotatory lactic acid, which belongs to the L-series, the configuration of the active 2,3-butylene glycols was, therefore, established as D-(−)- and L-(+)−.

Orientation in the Biphenyl System. The Preparation of 2- and 4-Aminobiphenyl-4′-sulfonamides[1]

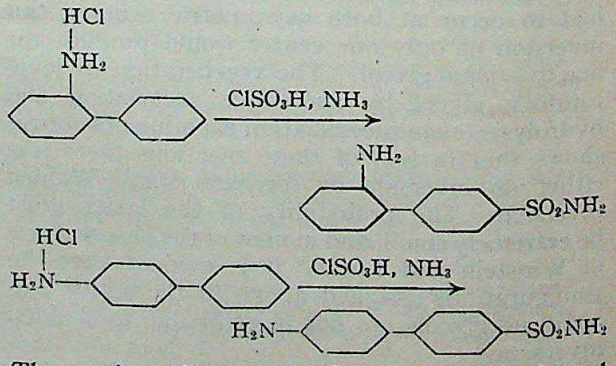
BY A. H. POPKIN AND G. B. MCVEA

Detailed studies[2] on orientation in the biphenyl system have been made in the past and several hypotheses have been proposed to explain the data obtained. These may be summarized as follows: (1) the usual directive influences ascribed to all simple groups when present in the benzene nucleus occur also in the biphenyl group; (2) those groups which normally orient ortho–para usually direct other groups into the same nucleus; conversely, meta-orienting groups direct further substitution into the adjacent ring; (3) the two nuclei of biphenyl act independently of each other.

Certain anomalous behaviors of the acetamido group which normally exhibits an ortho–para-orienting influence have been noted. The nitration of 2-acetamidobiphenyl[3] gave a 50% yield of 2-acetamido-4′-nitrobiphenyl instead of substitution into the five position of the same ring. Also the mononitration of diacetylbenzidine in concentrated sulfuric acid as solvent gave 2-nitrobenzidine instead of the expected 3-nitro-substitution.[4] More recently it was noted that the reaction of 2-acetamidobiphenyl with chlorosulfonic acid also gave substitution in the 4′-position.[5]

Bell[6] explained the anomalous behavior of the acetamido group stating that "this group enters into salt formation with a strong acid thereby being converted into a weakly orienting positive group so that further substitution naturally resembles that of 2-nitrodiphenyl."[7] This conclusion was substantiated by the work of Orton and Bradfield,[8] who showed that the velocity of chlorination of acetanilide was decreased with an increase of the concentration of hydrochloric acid which indicated a gradual shift of the acetamido group from ortho–para-orienting to a meta-orienting characteristic.

The present work confirms further the conclusions arrived at by Bell. The hydrochlorides of 2-aminobiphenyl and 4-aminobiphenyl were each treated with chlorosulfonic acid and ammonia. In each case, substitution was obtained in the 4′-position of the second ring, the products being 2-aminobiphenyl-4′-sulfonamide, 66% yield, and 4-aminobiphenyl-4′-sulfonamide, 88% yield.



The purity of the materials isolated indicated strongly the absence of isomers which might arise from substitution in the five position of the first ring. This proves that the amino group, and by

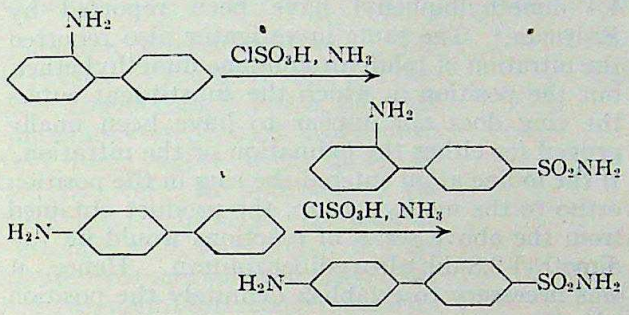
analogy the acetamido group, in combination with a mineral acid as a salt, exhibits a meta-orienting influence.

The reaction of 2-acetamidobiphenyl with chlorosulfonic acid to give 4′-substitution[5] suggested that the corresponding amino compound, being more basic, might react similarly and thereby make available a new and simplified preparation of the sulfonamide. This proved to be true. The reaction of 2-and 4-aminobiphenyls with chlorosulfonic acid and ammonia gave 2-aminobiphenyl-4′-sulfonamide, 55% yield, and 4-aminobiphenyl-4′-sulfonamide, 54% yield.



However, it was surprising to note that the unprotected amino compounds required a more vigorous treatment than either the corresponding acetamido compounds or the hydrochlorides. This was unexpected in the light of the established practice of protecting the amino groups for most substitution reactions.[9]

These reactions are now being applied to aniline, aniline hydrochloride and their various derivatives, and will be reported later.

Experimental

Preparation of 2- and 4-Aminobiphenyl Hydrochlorides.—A solution was made of 200 g. of the corresponding aminobiphenyl in three liters of benzene. Hydrogen chloride gas, generated by dropping concd. sulfuric acid into concd. hydrochloric acid, was bubbled into the solution. The colorless hydrochloride which formed was separated by suction filtration, washed with a liter of benzene and dried at 80°. In this manner, 2- and 4-aminobiphenyl hydrochlorides were prepared in 85–95% yields and substantially free of unconverted amine.

Reaction of 2-Aminobiphenyl Hydrochloride with Chlorosulfonic Acid and Ammonium Hydroxide.—Into a two-liter beaker was placed 1150 g. (650 cc., 9.86 moles) of chlorosulfonic acid. To this was added 410 g., 1.99 moles, of 2-aminobiphenyl hydrochloride during one hour and twenty minutes. The reaction temperature was kept below 10° during the addition. The resulting product was heated during three hours at 60° and then poured slowly and with agitation into 3200 cc. of concd. aqueous ammonium hydroxide. The temperature was kept at 8° during the latter addition. The precipitate was separated by suction filtration, the filter cake reslurried twice with two liters of water and then washed with distilled water until free of chloride and sulfate ions. The solid was dried at 55°; wt. 327 g., 66% yield; m. p. 178–182°. Solution in aqueous alkali and treatment with Norite gave purified 2-aminobiphenyl-4′-sulfonamide, m. p. 186–187°. A mixed m. p. with a sample of known material[5] showed no depression in the m. p.

(9) Smiles and Stewart, "Organic Syntheses," John Wiley and Sons, Inc., New York, N. Y., 1925, Vol. V, p. 3.

Reaction of 4-Aminobiphenyl Hydrochloride with Chlorosulfonic Acid and Ammonium Hydroxide.—This reaction was conducted in the manner just described using 50 g. of 4-aminobiphenyl hydrochloride. A crude product was obtained; wt. 53.7 g., 88% yield; m. p. 230–250°. Purification from methanol gave m. p. 248–250°. No depression in the melting point was obtained when this was mixed with a sample of known 4-aminobiphenyl-4′-sulfonamide.[10]

Reaction of 2-Aminobiphenyl with Chlorosulfonic Acid and Ammonium Hydroxide.—Into a 250-cc. beaker was placed 105 g. (60 cc., 0.9 mole) of chlorosulfonic acid. To this was added 32.3 g., 0.19 mole, of 2-aminobiphenyl (Monsanto Chemical Co.) during fifteen minutes. The reaction temperature was allowed to rise from 25° to 70° during the addition. The resulting product was heated during one and one-half hours at 90° and then poured slowly and with agitation into 300 cc. of concd. aqueous ammonium hydroxide. The temperature was kept below 20° during the latter addition. The precipitate was separated by suction filtration, the press cake reslurried twice with 50 cc. of water and then washed with distilled water until free of chloride and sulfate ions. The solid was dried at 80°; wt. 26.3 g., 55.4% yield; m. p. 176–182°. Crystallization from ethyl alcohol gave purified 2-aminobiphenyl-4′-sulfonamide, m. p. 186–187°. A mixed m. p. with a sample of known material[5] gave no depression in the m. p.

The above conditions were found to give the optimum yield of the sulfonamide. When 2-aminobiphenyl was heated with chlorosulfonic acid at 60° for three hours, unreacted 2-aminobiphenyl was obtained when the reaction product was poured into ammonium hydroxide. When 2-aminobiphenyl was heated with chlorosulfonic acid at 110° for one hour, only 9.3 g. of the sulfonamide was obtained. When heated for one hour at 100° and added to ammonium hydroxide at 25–50°, 8.2 g. of the sulfonamide resulted.

Reaction of 4-Aminobiphenyl with Chlorosulfonic Acid and Ammonium Hydroxide.—This reaction was conducted with the optimum conditions described above and starting with 129.2 g., 0.76 mole, of 4-aminobiphenyl (Monsanto Chemical Co.) and 420 g. (244 cc., 3.7 moles) of chlorosulfonic acid. A crude product was obtained; wt. 103.1 g., 54% yield, m. p. 233–250°. Purification gave m. p. 252–254°. No depression in the m. p. was obtained when this was mixed with a sample of known 4-aminobiphenyl-4′-sulfonamide.

Preparation of 4-Aminobiphenyl-4′-sulfonamide.—This was prepared from 4-acetamidobiphenyl without isolation of the intermediates 4-acetamidobiphenyl-4′-sulfonyl chloride and 4-acetamidobiphenyl-4′-sulfonamide. The reaction product of 4-acetamidobiphenyl and chlorosulfonic acid was poured upon ice water, the resulting solid treated with aqueous ammonium hydroxide and then with boiling hydrochloric acid. Crude 4-aminobiphenyl-4′-sulfonamide was obtained by treating the hydrochloride with ammonium hydroxide and purification effected by washing with boiling water and crystallization from ethyl alcohol; m. p. 255–256° with slight decomposition. Van Meter, Bianculli and Lowy[10] reported m. p. 261° with slight decomposition for a highly purified sample of the same compound.

Acknowledgment.—The authors are indebted to the General Printing Ink Corporation for permission to publish this work.

Summary

2- and 4-aminobiphenyl-4′-sulfonamides were prepared from 2- and 4-aminobiphenyls and their hydrochlorides by the action of chlorosulfonic acid and ammonia. This substantiates the hypothesis that the acetamido group in biphenyl exercises a meta-orienting influence in the presence

Dibenzofuran. XX. 2,3,7,8-Derivatives[1]

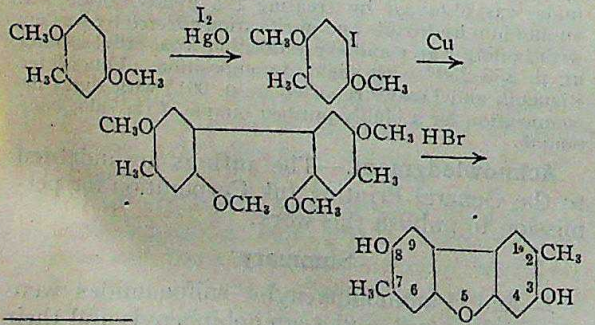
BY HENRY GILMAN, JACK SWISS, H. B. WILLIS AND F. A. YEOMAN

The present work is an extension of studies concerned with the bridging of the 1,9-positions. In an earlier paper,[2] the dibromination of 4,6-dimethoxydibenzofuran was reported. The structure of the resulting dibromo compound has not been definitely established, but it may possibly be 1,9-dibromo-4,6-dimethoxydibenzofuran.

We are now reporting the dibromination of 2,8-dimethoxydibenzofuran. From this reaction there resulted two isomeric dibromodimethoxydibenzofurans, one of m. p. 196–197°, and the other of m. p. 260–261°. The lower-melting isomer has been designated tentatively as 1,9-dibromo-2,8-dimethoxydibenzofuran, since it is known that 1-bromo-2-methoxydibenzofuran has a lower m. p. than the 3-bromo isomer.[3] However, it is possible that the spatial configuration of the dibenzofuran molecule is such that the 1- and 9-positions are in close proximity and simultaneous substitution of both positions by any large group or atom may, consequently, be very difficult. The 1,7-dibromo isomer is, therefore, a possibility not to be excluded from consideration.

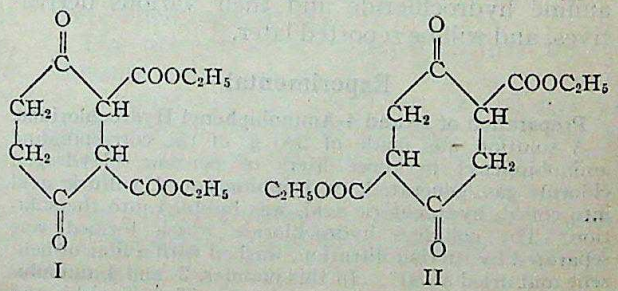
The higher-melting isomer is now shown to be 3,7-dibromo-2,8-dimethoxydibenzofuran. This structure was established by conversion to 3,7-dimethyl-2,8-dihydroxydibenzofuran and comparison of this compound with an authentic sample prepared by a synthesis involving ring closure.

The series of transformations resulting in the formation of 3,7-dimethyl-2,8-dihydroxydibenzofuran through ring closure is schematically represented below.



The iodination of toluhydroquinone dimethyl ether and the Ullmann coupling of the resulting iodo compound to give 2,2′,5,5′-tetramethoxy-4,4′-dimethylbiphenyl have been reported by Erdtman.[4] The same investigator also reported the nitration of toluhydroquinone dimethyl ether, but the position in which the substituent enters the ring does not appear to have been finally proved for either the iodination or the nitration.[5] If the iodine atom entered the ring in the position ortho to the methyl group, the product obtained from the above series of reactions would be 1,9-dimethyl-2,8-dihydroxydibenzofuran. Hence, it was necessary to establish definitely the position of iodination.

Nef[6] has reported the synthesis of 2,5-dimethoxyterephthalic acid and of its diethyl ester from ethyl succinylsuccinate. The latter compound was first prepared by Hermann[7] who believed it to have the structure (I) and oxidized it to the corresponding benzene derivative. Ebert, however, has shown that the symmetrical structure (II) is the correct one.[8]



Accordingly, the iodination product of toluhydroquinone dimethyl ether was converted to 2,5-dimethoxyterephthalic acid by the following series of reactions.

The iodo compound was first converted to the corresponding nitrile by the method of Koelsch.[9]

(4) Erdtman, *Proc. Roy. Soc.* (London), **A143**, 191 (1933).

(5) In a private communication, Dr. Erdtman stated, "I don't think the structure of this compound (5-iodotoluhydroquinone dimethyl ether) has been rigorously proved, but it follows, I believe, conclusively from the analogous reactivity of toluquinol and hydroxyquinol." The present authors have been unable to find any record of an investigation of this type having been carried out on toluhydroquinone or hydroxyhydroquinone. We are grateful to Dr. Erdtman for a sample of the 5-iodotoluhydroquinone dimethyl ether prepared by him. The material proved identical with the iodination product prepared in this Laboratory.

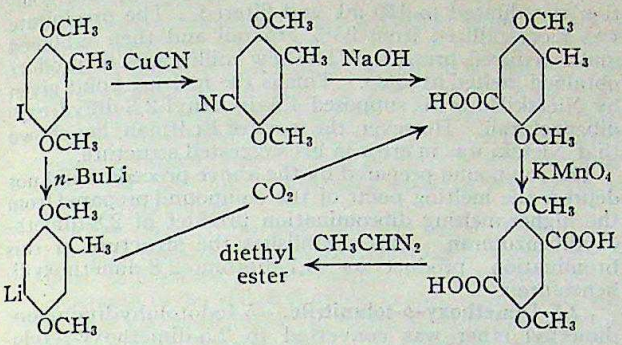
The resulting nitrile was hydrolyzed to give 2,5-dimethoxy-*p*-toluic acid which was oxidized to



2,5-dimethoxyterephthalic acid. The diethyl ester of the final acid was prepared. The melting points of both the 2,5-dimethoxyterephthalic acid and its diethyl ester agree with those reported by Nef. In addition to the method just mentioned, 2,5-dimethoxy-*p*-toluic acid was prepared from 5-iodotoluhydroquinone dimethyl ether by halogen–metal interconversion with *n*-butyllithium followed by carbonation.

Conversion of 3,7-dibromo-2,8-dimethoxydibenzofuran to 3,7-dicarboxy-2,8-dimethoxydibenzofuran and preparation of the dimethyl ester of this acid have already been reported.[10]

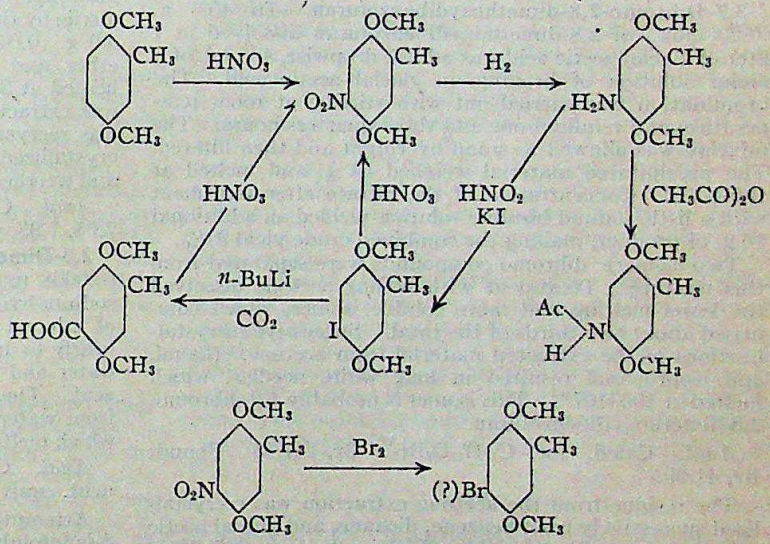
A number of attempts was made to prepare a compound from which 1,9-dimethyl-2,8-dihydroxydibenzofuran might be synthesized by ring closure. Such a compound could be prepared from toluhydroquinone dimethyl ether by introduction of a halogen atom into the 3-position.

First, the structure of the nitration product of toluhydroquinone dimethyl ether was established as being 5-nitrotoluhydroquinone dimethyl ether, in agreement with Erdtman's assumption, by reduction to the amine and conversion to the 5-iodo compound whose structure has been demonstrated.

Since the nitro group is a meta director, halogenation of 5-nitrotoluhydroquinone dimethyl ether might be expected to introduce the halogen atom into the 3-position. The nitro group could then be removed by stannous chloride reduction followed by diazotization. Bromination of the nitro compound proved difficult and the product obtained from the reaction was found to contain bromine, but no nitrogen. This substance has not been further investigated, but it seems likely that the nitro group was replaced by a bromine atom. Attempts at iodination of 5-nitrotoluhydroquinone dimethyl ether were unsuccessful.[11]

An additional substituent introduced into 2,5-dimethoxy-*p*-toluic acid might also be expected to enter the position ortho to the methyl group, since the carboxyl group is a meta directing group. Nitration of 2,5-dimethoxy-*p*-toluic acid, however, resulted in replacement of the carboxyl group by the nitro group. Attempts at iodination of the same acid met with no success.

Nitration of 5-iodotoluhydroquinone dimethyl ether resulted in replacement of the iodine atom by a nitro group. A diagrammatic representation of the work done in attempting to synthesize an intermediate for the preparation of 1,9-dimethyl-2,8-dihydroxydibenzofuran appears below.



A striking feature of this series of reactions is the rather unusual exchange of groups occurring in the 5-position. The marked contrast between the reactivity of this position and that of the other two unsubstituted positions on the ring is difficult to explain on the basis of the normally rather weak directing influence of the methyl group, and yet all three positions bear the same relation to the two methoxyl groups.

Experimental

2,8-Dimethoxydibenzofuran.—An intimate mixture of 100 g. (0.307 mole) of 2,8-dibromodibenzofuran (m. p. 185–189°), 200 g. of technical, flake sodium hydroxide (76% NaOH), and 24 g. of copper–bronze powder was poured onto a mat of 100 g. of copper turnings in a 600 ml. copper beaker, and 100 ml. of copper sulfate solution containing 30 g. of $CuSO_4 \cdot 5H_2O$ was added. The mixture was heated at 235–240° for twelve hours in an electrically heated bomb.[12]

The contents of the beaker were extracted with 300 ml. portions of boiling water until acidification of the filtrate gave no further precipitate. The combined filtrates were made acid to congo red with hydrochloric acid, and the light tan product was filtered. The dried product weighed 67 g. and melted at 230–235°. The theoretical yield is 62 g., but the crude product contained occluded sodium chloride.

To 237.5 g. of crude 2,8-dihydroxydibenzofuran, prepared as described above and dissolved in a liter of water

containing 103 g. of sodium hydroxide, was added 280 ml. of dimethyl sulfate, dropwise with stirring. The mixture was stirred two hours and then stirred and refluxed three hours. Excess dimethyl sulfate was destroyed by addition of 30 g. of sodium hydroxide. The yield of crude 2,8-dimethoxydibenzofuran was 221 g. (81%). This was distilled (b. p., 187° (5 mm.)) to give, after crystallization from 95% ethanol, 89 g. of white plates melting at 88–89°. Concentration of the mother liquor, and extraction of the residue in the Claisen flask yielded an additional 35 g. of impure material which gave on distillation and recrystallization 24 g. of pure product. The total yield of pure 2,8-dimethoxydibenzofuran was 113 g. (45.5% based on the weight of 2,8-dibromodibenzofuran required for its preparation).

Anal. Calcd. for $C_{14}H_{12}O_3$: C, 73.61; H, 5.30. Found: C, 73.65; H, 5.47.

3,7-Dibromo-2,8-dimethoxydibenzofuran.—To 45.6 g. (0.20 mole) of 2,8-dimethoxydibenzofuran dissolved in 1 liter of glacial acetic acid was added, dropwise, 400 ml. of a molar solution of bromine in glacial acetic acid. The bromination was carried out with stirring at room temperature and required one and three-quarters hours. The mixture was allowed to stand overnight and then filtered. The precipitated material weighed 54 g. and melted at 180–220°. Concentration of the filtrate after treatment with a little sodium bisulfite solution yielded an additional 16 g. of product, making the combined crude yield 91%.

Two isomeric dibromo compounds were separated from this mixture. Treatment with boiling acetone dissolved the lower-melting and more soluble isomer, which comprised about two-thirds of the total. Successive recrystallizations of the extracted material from acetone, ethanol, and isopropanol resulted in long white needles, which melted at 196–197°. This isomer is probably 1,9-dibromo-2,8-dimethoxydibenzofuran.

Anal. Calcd. for $C_{14}H_{10}O_3Br_2$: Br, 41.45. Found: Br, 41.90.

The residue from the acetone extraction was recrystallized successively from benzene, dioxane, and glacial acetic acid to give white needles which melted at 260–261°. This compound is 3,7-dibromo-2,8-dimethoxydibenzofuran.

Anal. Calcd. for $C_{14}H_{10}O_3Br_2$: Br, 41.45. Found: Br, 40.90.

Conversion of 3,7-Dibromo-2,8-dimethoxydibenzofuran to 3,7-Dimethyl-2,8-dimethoxydibenzofuran.—*n*-Butyllithium, prepared from 2 g. of lithium and 7 ml. of *n*-butyl bromide in 37 ml. of ether, was added to 4.6 g. (0.0119 mole) of 3,7-dibromo-2,8-dimethoxydibenzofuran in 75 ml. of benzene, and the mixture was refluxed with stirring for 30 minutes. The mixture was cooled for five minutes and 5 ml. of dimethyl sulfate in 10 ml. of ether was added dropwise. Stirring was continued for four hours.

Upon working up the product there was obtained 1.5 g. (49%) of a compound which melted at 140° after recrystallization from ethanol. A second recrystallization from the same solvent raised the melting point to 144–144.5°.

Preparation of 3,7-Dimethyl-2,8-dihydroxydibenzofuran.—To 0.1 g. (0.00039 mole) of 3,7-dimethyl-2,8-dimethoxydibenzofuran was added 2 ml. of glacial acetic acid and 2.5 ml. of constant boiling hydrobromic acid. The mixture was refluxed for seventeen hours in an apparatus fitted with ground-glass joints and then poured into 45 ml. of water. The crude dihydroxy compound which precipitated melted at 225–227°. This material was treated with Norite in boiling alcohol and then recrystallized from dilute alcohol. Light yellow plates, which sintered at 228° and melted at 231–232°, were obtained.

2,2′,5,5′-Tetramethoxy-4,4′-dimethylbiphenyl.—This compound was prepared in essential accordance with the procedure of Erdtman[4] from 3 g. of copper and 3 g. (0.0108 mole) of 5-iodotoluhydroquinone dimethyl ether. The yield was 50% of white crystals that melted at 134°. In a second, larger run the yield was raised to 84%.

Demethylation of 2,2′,5,5′-tetramethoxy-4,4′-dimethylbiphenyl.—A mixture of 4.5 g. (0.0149 mole) of 2,2′,5,5′-tetramethoxy-4,4′-dimethylbiphenyl, 20 ml. of glacial acetic acid, and 25 ml. of 42% hydrobromic acid was refluxed twenty hours in an all-glass apparatus. The solution was diluted to 450 ml. and filtered. The precipitate was recrystallized from 95% ethanol and then sublimed under reduced pressure. The few milligrams of product obtained melted at 232°. This is the melting point given by Nietzki[13] for his supposed 4,6-dimethyl-2,8-dihydroxydibenzofuran. However, the work of Erdtman[4] has shown that Nietzki was in error in his suggested structure.

The compound prepared by the above procedure did not depress the melting point of the compound prepared from the higher-melting dibromination product of 2,8-dimethoxydibenzofuran. This establishes the structure of this bromination product as 3,7-dibromo-2,8-dimethoxydibenzofuran.

2,5-Dimethoxy-*p*-tolunitrile.—5-Iodotoluhydroquinone dimethyl ether was converted to 2,5-dimethoxy-*p*-tolunitrile by the method of Koelsch.[9] An intimate mixture of 3.0 g. (0.0108 mole) of 5-iodotoluhydroquinone dimethyl ether and 2.12 g. of anhydrous cuprous cyanide was heated at 240° for four hours. The solid mass remaining was extracted with acetone and the yellow solid obtained was recrystallized from dilute ethanol. The pure nitrile crystallized in yellow needles which melted at 130–131° and weighed 1.4 g. (73%).

Anal. Calcd. for $C_{10}H_{11}O_2N$: N, 7.91. Found: N, 7.95, 7.98.

2,5-Dimethoxy-*p*-toluic Acid.—A solution of 1.2 g. (0.0068 mole) of 2,5-dimethoxy-*p*-tolunitrile in 5.8 g. of sodium hydroxide in a mixture of 5 ml. of water and 35 ml. of ethanol was refluxed ten hours and then evaporated nearly to dryness. The residue was extracted with boiling water and the cooled extract acidified with hydrochloric acid. The precipitate was filtered off and recrystallized from water. The pure acid crystallized in white needles which melted at 125–126° and weighed 0.55 g. (41%).

Anal. Calcd. for $C_{10}H_{12}O_4$: neut. equiv., 196. Found: neut. equiv., 197, 195.

Attempts at preparation of the Grignard reagent from 5-iodotoluhydroquinone dimethyl ether were unsuccessful.

A halogen–metal interconversion on the iodo compound using *n*-butyllithium was successful. To the *n*-butyllithium prepared from 0.20 g. (0.0285 mole) of lithium and 1.52 ml. (0.0144 mole) of *n*-butyl bromide in 30 ml. of ether was added with stirring a solution of 2.0 g. (0.0072 mole) of 5-iodotoluhydroquinone dimethyl ether in 20 ml. of ether. The mixture was stirred five minutes at room temperature and then carbonated. The crude acid obtained melted at 124–125° and weighed 0.57 g. Upon recrystallization from water, 0.50 g. of acid melting at 125–126° was obtained, representing a yield of 35%. The acid thus prepared did not depress the melting point of the acid prepared by hydrolysis of the nitrile.

Oxidation of 2,5-Dimethoxy-*p*-toluic Acid.—To a boiling solution of 1.0 g. (0.0051 mole) of 2,5-dimethoxy-*p*-toluic acid in 80 ml. of water was added a solution of 1.6 g. of potassium permanganate in 40 ml. of water. The permanganate was reduced almost instantaneously. A further 0.5 g. of potassium permanganate was added and the solution refluxed for fifteen minutes, at which time decolorization of the permanganate was again complete. The mixture was filtered hot, concentrated to 50 ml., and acidified with hydrochloric acid. The crude product resulting melted at 210–239°, and weighed 0.47 g., a crude yield of 40%.

Purification was difficult, but finally crystallization from a large volume of water yielded 30 mg. of pure 2,5-dimethoxyterephthalic acid of m. p. 265–265.5° in agreement with the melting point reported by Nef.[6]

Anal. Calcd. for $C_{10}H_{10}O_6$: neut. equiv., 113. Found: neut. equiv., 114.

A small amount (about 8 mg.) of 2,5-dimethoxyterephthalic acid was esterified by treatment with diazoethane in ether solution. The crude diethyl ester melted

(13) Nietzki, *Ber.*, **11**, 1278 (1878).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

at 91–96°. Two recrystallizations from ethanol raised the melting point to 101–102° in agreement with that reported by Nef.

5-Aminotoluhydroquinone Dimethyl Ether.—In a glass hydrogenation vessel was placed a solution of 9.0 g. (0.0456 mole) of 5-nitrotoluhydroquinone dimethyl ether in the minimum amount of hot ethanol. One gram of activated Raney nickel catalyst was added. The mixture was hydrogenated at a hydrogen pressure maintained between 30 and 45 pounds gage pressure at a temperature of 100° for one hour. Constant shaking was maintained during this period.

After the mixture had been thoroughly cooled and the pressure released, it was filtered quickly to remove catalyst. A colorless filtrate resulted. The solution was concentrated under reduced pressure and, when nearly all the alcohol had been removed, white needles which melted at 108.5–109.5° precipitated. The amine darkened very rapidly upon exposure to air and, consequently, no attempt was made to purify it for analysis.

To the flask containing the crude 5-aminotoluhydroquinone dimethyl ether was added 10 ml. of acetic anhydride. The light yellow solution which resulted upon gentle heating was transferred to a small Erlenmeyer flask and refluxed one hour. Dilution and cooling resulted in a white, granular precipitate which was filtered off and recrystallized several times from an ethanol–water mixture. The pure 5-acetaminotoluhydroquinone dimethyl ether, which crystallized in white needles, weighed 5.1 g., and melted at 160–162°. This is a yield of 53% based upon the amount of 5-nitrotoluhydroquinone dimethyl ether originally reduced.

Anal. Calcd. for $C_{11}H_{15}O_3N$: N, 6.69. Found: N, 6.72, 6.75.

Conversion of 5-Aminotoluhydroquinone Dimethyl Ether to 5-Iodotoluhydroquinone Dimethyl Ether.—The 5-aminotoluhydroquinone dimethyl ether resulting from the reduction of 10.0 g. (0.0507 mole) of 5-nitrotoluhydroquinone dimethyl ether was transferred quickly to a one liter Erlenmeyer flask flushed out with nitrogen. A solution of 11 ml. of concentrated hydrochloric acid in 38 ml. of water was added and the resulting solution was cooled to 0°. To the chilled amine hydrochloride solution was added slowly with stirring a solution of 2.6 g. of sodium nitrite in 11 ml. of water. On slow addition of a solution of 6.4 g. of potassium iodide in 12 ml. of water to the above mixture, a yellow precipitate formed. Upon boiling, the color of the precipitate darkened through red to black. Attempts at crystallization of this material were unsuccessful, but sublimation at reduced pressure yielded a light tan solid which melted at 79–81°. Recrystallization from alcohol raised the melting point to 84–85° and removed virtually all the color. The pure product did not depress the melting point of an authentic sample of 5-iodotoluhydroquinone dimethyl ether.

Bromination of 5-Nitrotoluhydroquinone Dimethyl Ether.—To a solution of 3.94 g. (0.02 mole) of 5-nitrotoluhydroquinone dimethyl ether in 25 ml. of carbon tetrachloride was added 3.2 g. (0.02 mole) of bromine. A trace of iron was added as a catalyst and the solution was refluxed for several hours. When all the bromine had reacted, the mixture was washed with sodium thiosulfate solution and the carbon tetrachloride was distilled off. The yield was 2.4 g. of crude product. Recrystallization from ethanol gave 1.5 g. of pure product which melted at 168°. This compound contained bromine but no nitrogen.

The corresponding diacetoxy compound was prepared by hydrolysis of the above compound with hydrobromic acid in glacial acetic acid followed by acetylization with acetic anhydride. The diacetoxy derivative melted at 253–254°. These compounds were not analyzed or further investigated.

Nitration of 2,5-Dimethoxy-*p*-toluic Acid.—To a solution of 3.0 g. (0.0153 mole) of 2,5-dimethoxy-*p*-toluic acid in 25 ml. of glacial acetic acid was added slowly with stirring 5.0 ml. of concentrated nitric acid. The mixture was warmed to 45° for ten minutes and then cooled and diluted with water. An amorphous yellow precipitate which melted at 114–117° formed. Two recrystallizations from alcohol produced 2.5 g. (83%) of yellow plates melting at 118–119°. A mixed melting point with an authentic sample of 5-nitrotoluhydroquinone dimethyl ether showed no depression.

Nitration of 5-Iodotoluhydroquinone Dimethyl Ether.—A nitration was carried out on 3.0 g. (0.0107 mole) of 5-iodotoluhydroquinone dimethyl ether by the same procedure as that applied to 2,5-dimethoxy-*p*-toluic acid. Iodine vapors were given off during the course of the reaction. When the mixture was worked up, 1.7 g. (80%) of pure 5-nitrotoluhydroquinone dimethyl ether was obtained, as shown by a mixed m. p. with an authentic sample.

Summary

Several 2,3,7,8-substituted derivatives of dibenzofuran have been prepared. Their structures have been demonstrated through a biphenyl ring closure.

The structures of the 5-iodotoluhydroquinone dimethyl ether and the 5-nitrotoluhydroquinone dimethyl ether reported by Erdtman have been established.

An unusual series of reactions involving exchange of groups substituted in the 5-position of toluhydroquinone dimethyl ether is reported.

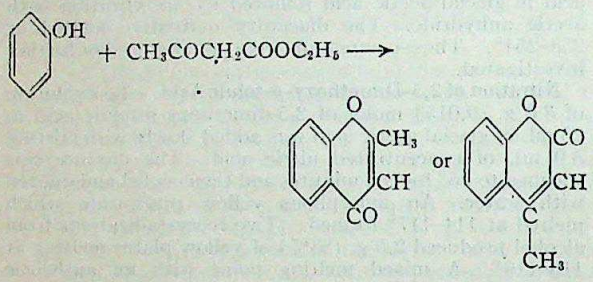
The Formation of a Chromone by the von Pechmann Condensation of Ethyl Acetoacetate with 4-Chloro-3,5-dimethylphenol

BY ROGER ADAMS AND J. W. MECORNEY

The condensation of ethyl acetoacetate or its substitution products with phenols proceeds under the influence of various reagents to give either chromones or coumarins.



Experience has shown that the von Pechmann[1] reaction, namely, that which involves the use of concentrated sulfuric acid as a condensing agent, leads almost invariably to the coumarin. The report of Jacobson and Ghosh[2] that chromones had been synthesized by the von Pechmann procedure was shown to be incorrect by later investigators[3] who demonstrated that coumarins actually had been obtained. Dey and Laksminarayanan[4] isolated merely the coumarin from the crude condensation product of ethyl acetoacetate and β-naphthol. From the same crude reaction product they were able by the action of benzaldehyde and sodium ethoxide to isolate a small yield of a styryl derivative of 1,4-β,α-naphthopyrone, indicating that some chromone was present. Chakravarti[5] states that with this exception there is no other case in which the presence of a chromone has even been detected when sulfuric acid was used as a condensing agent.

The requirements in another research of a coumarin derived from 4-chloro-3,5-dimethylphenol led to experiments on the application of the von Pechmann reaction first to 3,5-dimethylphenol as a type compound and then to 4-chloro-3,5-dimethylphenol. The synthesis with 3,5-dimethylphenol proceeded smoothly to a coumarin as previously reported,[6] but the chloro derivative yielded a pure product which was not a coumarin and was, therefore, assumed to be a chromone. Investigation has confirmed these facts. It does appear therefore that the von Pechmann condensation may lead to coumarins when the phenols are properly substituted.

The proof of the structure of the chromone (I) from 4-chloro-3,5-dimethylphenol, ethyl acetoacetate and sulfuric acid was established by (1) hydrolysis to a 1,3-diketone (II) which was synthesized by the unequivocal method of condensation of 5-chloro-4,6-dimethyl-2-hydroxyacetophenone (III) with ethyl acetate and which by the action of acid reverts to the chromone; (2) condensation with benzaldehyde to a styryl derivative (IV); (3) hydrolysis to a hydroxy ketone (III) or hy-

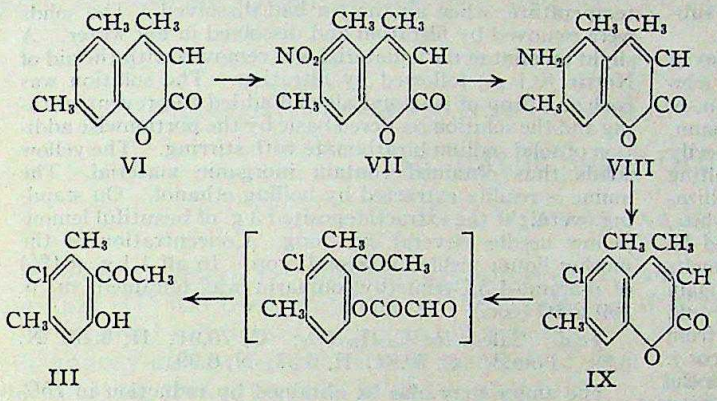
drolysis followed by methylation to a methoxy ketone (V).

In order to obtain the desired chlorinated coumarin, the coumarin (VI) from 3,5-dimethylphenol and ethyl acetoacetate was nitrated to a mononitro compound (VII) which was reduced to the amine (VIII) and this was diazotized and treated with hydrochloric acid to replace the amino group with chlorine (IX).



The structure of the coumarin was confirmed by ozonization followed by treatment with alkali. 5 - Chloro - 4,6 - dimethyl - 2 - hydroxyacetophenone was obtained, which serves to identify the original compound as a coumarin and at the same time to establish the position of the chlorine atom.

Experimental

6-Chloro-2,5,7-trimethylchromone (I).—To a mixture of 50 g. of 4-chloro-3,5-dimethylphenol (1 mol. equiv.) and 42 g. of freshly distilled ethyl acetoacetate (1 mol. equiv.), was added 300 cc. of concentrated sulfuric acid. The solution was warmed on a steam-bath for one-half hour and then allowed to stand at room temperature for one week. Fine needles separated from the reaction mixture on cooling and were redissolved by occasional warming. A large quantity of solid material was obtained by adding the solution to 3 kg. of crushed ice and allowing to warm to room temperature. The crude solid was removed by filtration, thoroughly washed with water, and after two crystallizations from aqueous ethanol, 25 g. (35%) of flat white rods 1–2 cm. long was obtained; m. p. 145–146° (cor.). The mother liquors contained considerable amounts of oily material which was not investigated further. Previous runs with a twenty-four hour reaction time gave lower yields (7–20%).

Anal. Calcd. for $C_{12}H_{11}ClO_2$: C, 64.73; H, 4.98; Cl, 15.92. Found: C, 64.96 (64.97); H, 4.81; Cl, 15.80.

6-Chloro-5,7-dimethyl-2-β-styrylchromone (IV).—This styryl derivative is readily formed by the condensation of the chromone with benzaldehyde in the presence of alcoholic sodium ethoxide following the general procedure of Heilbron, Barnes and Morton[7]; fluffy, flocculent crystals from absolute ethanol; m. p. 186–186.5° (cor.); yield, quantitative.

Anal. Calcd. for $C_{19}H_{15}ClO_2$: C, 73.43; H, 4.87; Cl, 11.41. Found: C, 73.61; H, 4.74; Cl, 11.56.

4-Chloro-3,5-dimethyl-6-acetylacetophenol (II).—A solution of 5 g. of 6-chloro-2,5,7-trimethylchromone and 5 g. of potassium hydroxide pellets in 50 cc. of absolute ethanol was refluxed with stirring for one-half hour. The solution which had turned a claret red, was added to crushed ice and gave a clear solution. Cold, dilute hydrochloric acid was added dropwise and a yellow oil separated which solidified slowly. The crude solid was dissolved in 5% aqueous sodium hydroxide and warmed on the steam-bath for one minute. Norite (0.1 g.) was added and the solution was filtered. Upon careful addition of cold, dilute hydrochloric acid a solid was obtained which could be crystallized from toluene as fine, white needles, m. p. 148–150° (cor.), yield 2.5 g. (45%).

Anal. Calcd. for $C_{12}H_{13}ClO_3$: C, 59.88; H, 5.44; Cl, 14.73. Found: C, 60.06; H, 5.59; Cl, 14.70.

It is insoluble in 5% sodium bicarbonate solution, but readily soluble in 5% aqueous sodium hydroxide solution. Aqueous suspensions, as well as ethanolic and acetonic solutions, gave no color with ferric chloride. A transient coloration could be obtained in the following way. Five cubic centimeters of glacial acetic acid is heated to boiling and a drop of 3% ferric chloride solution added. Upon addition of 50 mg. of the 1,3-diketone, an intense red color is obtained which disappears rapidly upon stirring.

The 1,3-diketone could be readily converted to the chromone by warming 0.2 g. in glacial acetic acid to which a drop of dilute hydrochloric acid had been added.[8] Water is added to the reaction mixture and the crystals removed by filtration, m. p. 145–146° (cor.); yield, quantitative. A mixed m. p. with 6-chloro-2,5,7-trimethylchromone (I) prepared above showed no depression

5-Chloro-4,6-dimethyl-2-hydroxyacetophenone (III).—A mixture of 2 g. of the chromone, 1.2 g. of sodium hydroxide and 13 cc. of water was refluxed vigorously for five hours. The reaction mixture was added to crushed ice and acidified with concentrated sulfuric acid. The solid was collected by filtration and crystallized from dilute aqueous methanol; long white needles, m. p. 89.5–90° (cor.).

Anal. Calcd. for $C_{10}H_{11}ClO_2$: C, 60.46; H, 5.58. Found: C, 60.39; H, 5.76.

It is insoluble in 5% aqueous sodium bicarbonate but readily soluble in 5% aqueous sodium hydroxide.

5-Chloro-4,6-dimethyl-2-methoxyacetophenone (V).—A mixture of 10 g. of the chromone, 6 g. of sodium hydroxide and 65 cc. of water was refluxed with stirring for five hours, the chromone dissolving in about two hours. In the course of one hour, 26 cc. of dimethyl sulfate was added dropwise, the solution kept basic by portionwise addition of 20% aqueous sodium hydroxide. In all, 50 cc. of alkali was added. An insoluble oil soon separated from the reaction mixture. A further 50 cc. of 20% alkali was added and the heating and stirring continued for one hour. The solution was added to crushed ice and the oil which separated solidified readily. The solid was taken up in hot methanol and the solution was concentrated. Upon standing overnight at room temperature, large white rhombohedral crystals were obtained, m. p. 76–77° (cor.); yield, 5 g. (52%). von Auwers, Muerbe and Sauerwein[9] report m. p. 76–77°. The melting point of a mixture with authentic material showed no depression.

Anal. Calcd. for $C_{11}H_{13}ClO_2$: C, 62.12; H, 6.16. Found: C, 62.53; H, 6.32.

4-Chloro-3,5-dimethylphenyl Acetate.—A mixture of 15 g. of 4-chloro-3,5-dimethylphenol, 16 cc. of acetic anhydride and two drops of concentrated sulfuric acid was warmed on the steam-bath for five hours, then poured onto crushed ice. The acetate separated as an oil which solidified on standing. The crude acetate is suitable for the Fries rearrangement without further purification. It can be crystallized from petroleum ether (b. p. 60–110°), m. p. 48° (cor.); yield 19 g. (93%).[10]

5-Chloro-4,6-dimethyl-2-hydroxyacetophenone (III).—To a well-stirred melt of 4-chloro-3,5-dimethylphenyl acetate warmed to 50°, was added 12.5 g. of anhydrous aluminum chloride. The mixture became quite viscous and stirring had to be discontinued. The temperature of the bath was raised to and held at 155° for forty-five minutes. After cooling, the solids were decomposed and triturated with ice and dilute hydrochloric acid. The compound can be purified by steam distillation. The solids thus collected contained some unchanged acetate and were freed by washing with cold dilute alkali. Upon acidification, the solid was collected and crystallized from petroleum ether (b. p. 60–110°). It is a white, flaky substance, m. p. 106–110° (cor.), yield 7 g. (41%).[9,10]

The substance was found to show the characteristics of dimorphs. von Auwers, Muerbe and Sauerwein,[9] who prepared this compound by a different route, report m. p. 106–109° crystallizing from petroleum ether. Klarmann, Shternov and Gates[10] report m. p. 89.7° but do not specify the solvent used for crystallization. The higher-melting form could be converted to the lower by two crystallizations from aqueous ethanol or methanol: long, white, well defined needles, m. p. 89–90° (cor.). It should be pointed out that although the lower modification melts quite sharply at 89–90° (cor.) the liquid does not remain clear until 110° (cor.). The lower-melting form could also be converted to the higher, by one crystallization from petroleum ether (b. p. 60–110°), m. p. 106–110° (cor.). That no unexpected migration of groups took place in the course of the Fries rearrangement was shown by conversion to the methyl ether with dimethyl sulfate, m. p. 76–77° (cor.).[9] The possibility that the lower form might be a hydrate was excluded on the basis of the fact that its melting point remained 89–90° (cor.) both before and after drying for analysis.

4-Chloro-3,5-dimethyl-6-acetylacetophenol (II).—To 3 g. of 5-chloro-4,6-dimethyl-2-hydroxyacetophenone, m. p. 106–110° (cor.) in 16 g. of ethyl acetate, was added 1.2 g. of clean finely-chopped sodium.[8] An immediate reaction took place with the liberation of hydrogen and the insoluble sodium phenolate precipitated. Upon gentle warming a lively reaction set in and the mixture was allowed to stand overnight. The reddish-brown solution was decanted from a small amount of tarry matter and added to water acidified with dilute acetic acid. An orange oil separated which solidified when scratched with a stirring rod. After two crystallizations from toluene, small white needles were obtained, m. p. 148–150° (cor.). A mixed m. p. with the 1,3-diketone isolated by the mild alcoholic hydrolysis of the chromone was not depressed; yield, 2 g. (55%).

6-Chloro-2,5,7-trimethylchromone (I).—The 1,3-diketone thus prepared could also be converted to the chromone by warming in glacial acetic acid to which a drop of dilute hydrochloric acid had been added, m. p. 145–146° (cor.). The mixed m. p. of this material with the chromone prepared by the von Pechmann reaction gave no depression.

4,5,7-Trimethylcoumarin (VI).—Following the procedure described by Clayton,[6] 50 g. of 3,5-dimethylphenol and 55 g. of freshly distilled ethyl acetoacetate were condensed in the presence of 300 cc. of concentrated sulfuric acid; yield, 25 g. (32%) of 4,5,7-trimethylcoumarin, m. p. 181° (cor.). Clayton[6] reports m. p. 175–176°.

6-Nitro-4,5,7-trimethylcoumarin (VII).—This substance was prepared by the method of Jordan and Thorpe.[11] To 30 g. of 4,5,7-trimethylcoumarin dissolved in 300 cc. of concentrated sulfuric acid cooled to −10° by means of a salt–ice-bath, was added with stirring 46 cc. of a nitrating mixture comprised of three parts by volume of sulfuric acid to one part of nitric acid (sp. gr. 1.42) in the course of nine hours. If at any time the temperature reached −5° the addition was interrupted and the reaction mixture was cooled. After an additional hour the solution was allowed to warm to room temperature in the course of forty-five minutes, and added to crushed ice. The solid was collected, washed with water and crystallized from glacial acetic acid. The first crop of fine, white needles weighed 21 g. The mother liquor can be worked up by further crystallization to yield additional material. In all 26 g. (80%) of nitrocoumarin, m. p. 209–211° (cor.) was obtained. Jordan and Thorpe[11] report m. p. 208°. If the rate of addition is increased materially or the temperature allowed to exceed 0°, the yield is much lower.

6-Amino-4,5,7-trimethylcoumarin (VIII).—To 7.5 g. of 6-nitro-4,5,7-trimethylcoumarin was added 8 g. of tin, 7.5 g. of stannous chloride, 75 cc. of concentrated hydrochloric acid and 20 cc. of ethanol. After standing overnight the contents were shaken mechanically for six hours at room temperature, when all the tin had dissolved. The solids were removed by filtration and dissolved in hot water. A slight amount of dark material was removed with the aid of Norite (0.1 g.) followed by filtration. The solution was cooled, a drop of iso-amyl alcohol added to prevent frothing and the solution rendered basic by the portionwise addition of solid sodium bicarbonate with stirring. The yellow solids thus obtained contain inorganic material. The amine is readily extracted by boiling ethanol. On standing overnight the extract deposited 3 g. of beautiful lemon-yellow needles several cm. long. Concentration of the mother liquor yielded a second crop. In all 4.1 g. (64%) of 6-amino-4,5,7-trimethylcoumarin was obtained, m. p. 199–200° (cor.).

Anal. Calcd. for $C_{12}H_{13}NO_2$: C, 70.91; H, 6.45; N, 6.89. Found: C, 70.84; H, 6.57; N, 6.99.

The amine may also be obtained by reduction in 75% acetic acid with iron powder. The method is somewhat more laborious and the yield unreliable (25–70%).

6-Chloro-4,5,7-trimethylcoumarin (IX).—To 300 cc. of water and 35 cc. of concentrated hydrochloric acid heated to boiling was added 9.5 g. of 6-amino-4,5,7-trimethylcoumarin. The clear solution was then cooled rapidly to 0° with vigorous stirring, whereupon the amine hydrochloride separated as a light lavender solid in a finely divided state. In the course of one hour and fifteen minutes, 3.52 g. of reagent quality sodium nitrite dissolved in 45 cc. of water was added from a dropping funnel until the diazotized solution gave an immediate blue color with starch iodide paper. The clear, cold diazonium solution was then added to 15 g. of freshly prepared cuprous chloride dissolved in 60 cc. of concentrated hydrochloric acid cooled to 5° with vigorous stirring. Immediate evolution of nitrogen took place and a white solid separated. After one hour the stirring was discontinued and the contents were allowed to stand overnight. Crystallization from ethanol gave 8.7 g. (83%) of the chlorocoumarin. The material thus obtained has a light orange hue. Repeated crystallization from ethanol gave a colorless product, m. p. 194–195.5° (cor.).

Anal. Calcd. for $C_{12}H_{11}ClO_2$: C, 64.73; H, 4.98; Cl, 15.92. Found: C, 64.81; H, 5.15; Cl, 15.73.

Ozonization of 6-Chloro-4,5,7-trimethylcoumarin (IX).—A solution of 0.5 g. of 6-chloro-4,5,7-trimethylcoumarin in 75 cc. of ethyl acetate–methanol mixture 1:1, was subjected to a stream of ozone, 2.5% by volume, at the rate of 100 cc. per minute for three hours. The ozonide was decomposed with 20 cc. of water and the solvent removed on the steam-bath with an air blast. The intermediate glyoxalate was not isolated. The resulting oil was taken up in aqueous methanol, 0.5 g. of sodium hydroxide added and the solution refluxed for two hours. Upon acidification a dark oil separated and was removed by extraction with ether. The ethereal solution was extracted with dilute aqueous sodium hydroxide, acidified and reëxtracted with ether. Upon removal of the ether with an air blast, an oil resulted that was extracted twice with 10 cc. of petroleum ether (b. p. 60–110°). The extract was concentrated and upon standing overnight at 0° deposited about 50 mg. of 5-chloro-4,6-dimethyl-2-hydroxyacetophenone. The higher melting modification, m. p. 106–110°, was obtained.

Pechmann condensation of ethyl acetoacetate and phenols does not always yield coumarins as previously reported.

2. Although sulfuric acid causes the condensation of 3,5-dimethylphenol and ethyl acetoacetate to a coumarin, this same reagent results in the formation of a chromone from 4-chloro-3,5-dimethylphenol and ethyl acetoacetate.

3. The structure of the chromone was established by various hydrolytic reactions and by condensation with benzaldehyde.

4. The coumarin expected in the initial condensation was synthesized by nitration of 4,5,7-trimethylcoumarin, followed by reduction and replacement of the amino group by chlorine. The proof that the product was a coumarin and that the chlorine was in the 6-position was determined by ozonolysis to 5-chloro-4,6-dimethyl-2-hydroxyacetophenone.

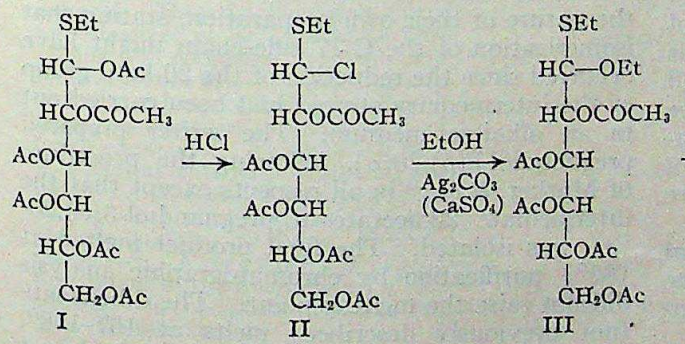
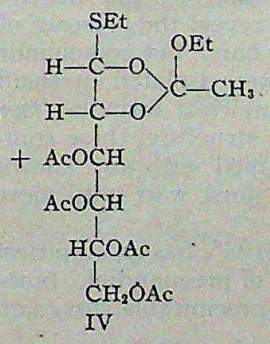
An Acyclic Sugar Orthoacetate

BY M. L. WOLFROM AND D. I. WEISBLAT

1-Chloro-1-thioethoxy-*aldehydo*-D-galactose pentaacetate (II) has been prepared by the action of a dry ethereal solution of hydrogen chloride upon 1-thioethoxy-*aldehydo*-D-galactose hexaacetate (I).[1] On repeating this procedure in larger quantities, a crude preparation of II was treated with ethanol and silver carbonate. The main reaction product was III, designated D-galactose diethyl monothioacetal pentaacetate and previously synthesized[2] in a similar manner from pure II, prepared by the action of a mixture of acetyl chloride and phosphorus oxychloride upon D-galactose diethyl mercaptal pentaacetate. In addition there was obtained in low yield a product IV, to which is assigned an orthoacetate structure.





The orthoacetate structure of IV, designated 1-thioethoxy-*aldehydo*-D-galactose ethyl 1,2-orthoacetate tetraacetate, is based upon the fact that one acetyl group in the compound was resistant to alkaline hydrolysis but was removable by acid hydrolysis. This fact, among others, has been employed in establishing the orthoacetate structure[3] in the cyclic sugar derivatives. In formula IV, the placement of the sulfur atom and the size of the ring are probable but arbitrary. To our knowledge, this is the first recorded occurrence of an orthoacetate structure in an acyclic sugar derivative.

Experimental

1-Thioethoxy-*aldehydo*-D-galactose Ethyl 1,2-Orthoacetate Tetraacetate.—Crude unrecrystallized 1-chloro-1-thioethoxy-*aldehydo*-D-galactose pentaacetate (m. p. 95–98°, 45 g.), prepared from 1-thioethoxy-*aldehydo*-D-galactose hexaacetate as previously described[1] and thoroughly washed with an ether–petroleum ether (1:1) mixture, was added to a suspension of 25 g. of Drierite (anhydrous calcium sulfate) and 60 g. of silver carbonate in 250 cc. of absolute ethanol. The reaction was then allowed to run at room temperature, under mechanical stirring and protection from atmospheric moisture, for approximately sixteen hours. The inorganic salts were removed by filtration through a bed of Super-cel (Johns-Manville) and the clear filtrate was made just opalescent with water. One crop of crystals was deposited on cooling to ice-box temperature; a second and third crop of crystals were obtained by treating the successive filtrates in a like manner. The first two crops (15–16 g.) were recrystallized from six parts of hot absolute ethanol; m. p. 103–105°, spec. rot. +50° (25°, *c* 4, abs. $CHCl_3$, D line). This product was therefore identified (mixed m. p. with an authentic sample unchanged) as D-galactose diethyl monothioacetal pentaacetate for which the following constants are recorded:[2] m. p. 104–105°, spec. rot. +50° (20°, *c* 3.5, abs. $CHCl_3$, D line). The third crop (6–8 g.) had a melting point of 85–95°. Pure material was obtained after five recrystallizations from four parts of hot methanol; yield 1.5–2.0 g., m. p. 125–126° (mixed m. p. with D-galactose diethyl monothioacetal pentaacetate of m. p. 104–105°, 93°), spec. rot. +54° (24°, *c* 4, abs. $CHCl_3$, D line).

The substance crystallized in transparent, elongated prisms and exhibited properties and solubilities similar to the isomeric D-galactose diethyl monothioacetal pentaacetate, except that it was more sensitive to acidity.

Anal. Calcd. for $C_{10}H_{17}O_6S(CH_3CO)_5$: C, 49.99; H, 6.71; S, 6.67; CH_3CO (4 equiv.), 8.33 cc. 0.1 *N* NaOH per 100 mg.; CH_3CO (5 equiv.), 10.41 cc. Found: C, 49.92; H, 6.73; S, 6.86; CH_3CO (alkaline hydrolysis, Kunz and Hudson[4] method), 8.39 cc.; CH_3CO (acid

A Study of the Neutral, Non-Saponifiable Fraction of Ox Bile[1]

BY W. H. PEARLMAN[1a]

A theory[2] postulating a biological conversion of cholesterol to the bile acids has recently received experimental support in an investigation[3] carried out with the aid of deuterium. One might expect to find metabolic products intermediate between cholesterol and the bile acids in bile since it contains these steroids in large amount. Studies of the comparative biochemistry of the bile have already furnished clues as to the nature of the hypothetical intermediates. The bile of elasmobranchs[2] contains a polyhydric alcohol, scymnol ($C_{27}H_{46}O_5$) which is related to cholesterol; it can be readily degraded in the laboratory to cholic acid.[4,5] Other alcohols of an alleged steroid nature have been isolated from the bile of frogs[6] and toads[7,8]; of these, pentahydroxybufostane ($C_{28}H_{50}O_5$) can be oxidized *in vitro* to cholic acid.[7] A mechanism for the biological oxidation of the side-chain of steroids with 27 and 28 carbon atoms has been suggested by Kazuno.[7]

An exploratory examination of the neutral fraction of ox bile failed to reveal the presence of scymnol, etc. On the other hand, five compounds (other than cholesterol[9]) were isolated in small amount. Although the empirical formulas (see Table I) point to a steroid structure, these compounds could not be identified with any known steroids. Structural proof must wait until more material is available.

Compound B, m. p. 192–193°, has an empirical formula identical with that of pregnandiol. Since Compound B is digitonin-precipitable, pregnandiol-3(β),20(α) was suspected to be the isomer in question. This steroid had been prepared by Butenandt and Müller[14] and they reported a melting point of 189–190.5° uncor. Marker, *et al.*,[15] had previously prepared the isomer from pregnandiol but their preparation melted at 182°. This discrepancy in melting points was noted by Butenandt and Müller; they raised a doubt regarding the nature of their own preparation, stating that isomerization of the C-17 side-chain might have occurred since the reduction of the 20-keto group of the intermediary steroid had been carried out in an alkaline medium. The writer prepared pregnandiol-3(β),20(α), following the procedure of Marker, *et al.*,[15] in all respects except that the intermediate 20-acetate of pregnandiol-3(α),20(α), was isolated. The final product melted at 182°; purification by chromatographic analysis did not raise the melting point. The dibenzoate (not previously described) melts at 167–168°. Since the dibenzoate of Compound B melts at 234–235°, it is clear that Compound B cannot be identical with pregnandiol-3(β),20(α). Compound B thus remains unidentified for the time being; it is probably an (*allo*) pregnane derivative containing a 3(β)-hydroxyl group.

TABLE I

COMPOUNDS (OTHER THAN CHOLESTEROL) ISOLATED FROM THE NEUTRAL, NON-SAPONIFIABLE FRACTION OF OX BILE

Compd.	M. p.,[12] °C.	Tentative empirical formula	Derivatives: Type	Derivatives: M. p.,[12] °C.

steroid structure of Compounds A-E is not yet established, any discussion as to the possible origin of these from either cholesterol or the bile acids during the course of isolation would be altogether premature.

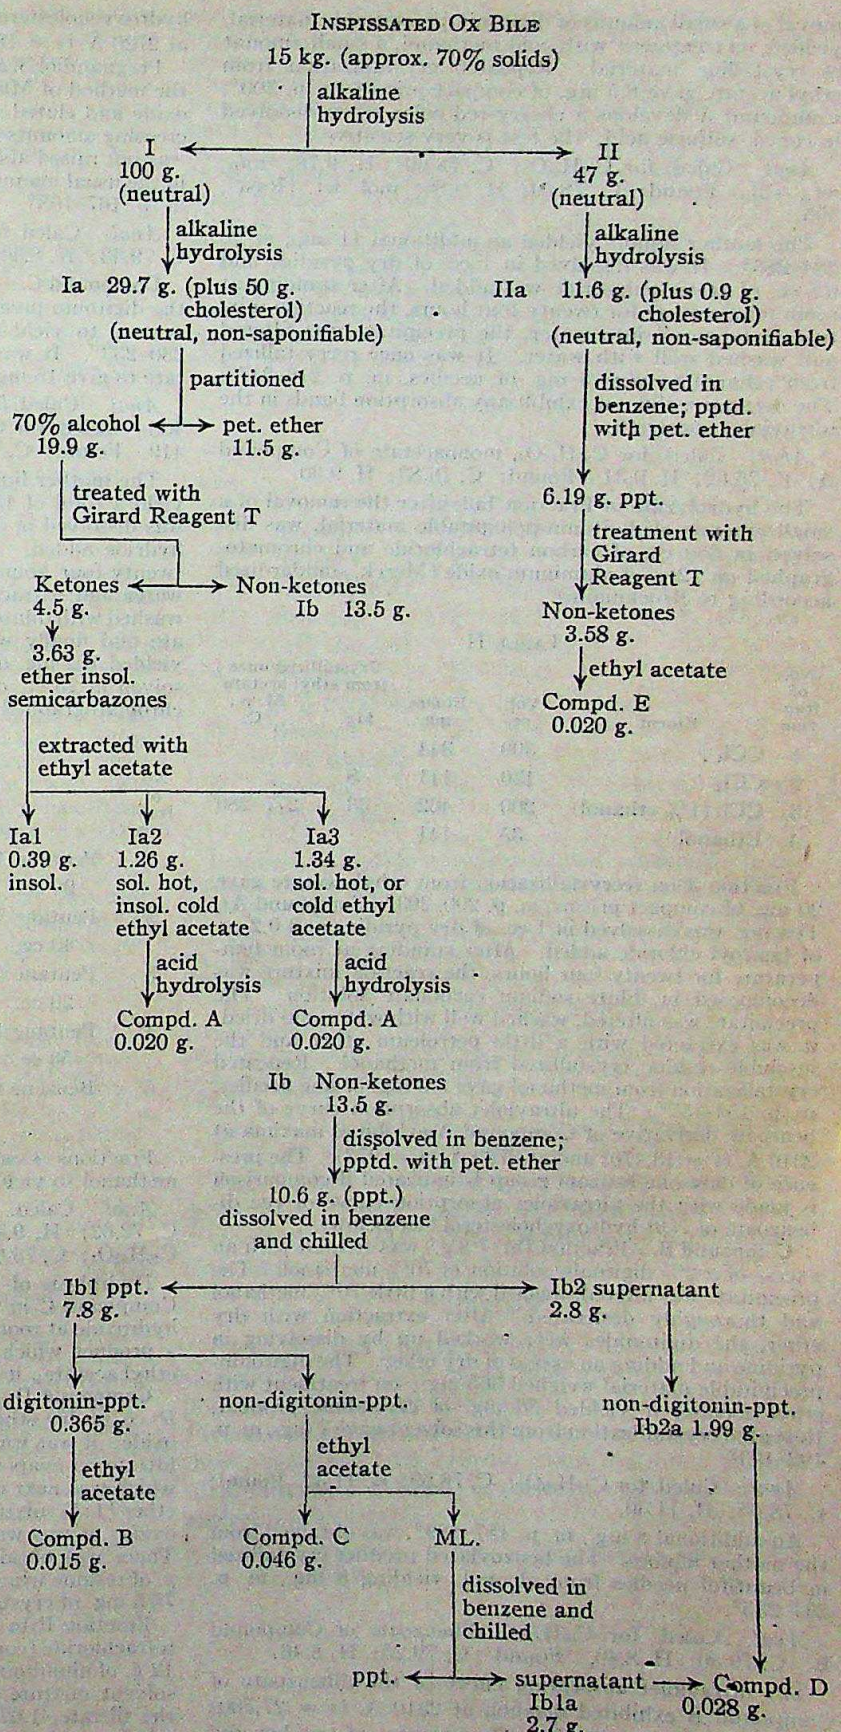
This investigation was undertaken at the kind invitation of Professor Gregory Pincus. The author is grateful to Miss Mary Ruth Jones for technical assistance.

Experimental

The Non-saponifiable Fraction of Ox Bile.—Fifteen kilograms of inspissated ox bile, containing approximately 70% solids, was hydrolyzed for eighteen to twenty hours at 104° in 27% solution with 6% sodium hydroxide. Addition of hydrochloric acid to the hydrolyzate gave a precipitate of crude bile acids which was extracted with ethyl acetate. The extract was evaporated, the residue dissolved in dilute alkali and extracted with ether. The ether extract on evaporation weighed 100 g. (Fraction I). The crude bile acids were crystallized from alcohol. The mother liquor was evaporated and the residue crystallized from 55% acetic acid. The mother liquor was evaporated, the residue dissolved in dilute alkali, and extracted with ether. The ether extract on evaporation weighed 47 g. (Fraction II).[16]

Fractions I and II still contained considerable amounts of saponifiable material. These fractions were therefore dissolved in 90% methanol containing 5% potassium hydroxide and refluxed for one hour. The hydrolyzate of Fraction I crystallized on cooling to room temperature, yielding 50 g. of crude cholesterol; an additional 29.7 g. of neutral material (Fraction Ia) was obtained. Fraction II likewise yielded 11.6 g. of neutral material (Fraction IIa) in addition to 0.9 g. of crude cholesterol. A very much abbreviated description of the fractionation of the neutral, non-saponifiable material follows (see flow sheet).

Compound A.—Fraction Ia (29.7 g.) was partitioned between 70% alcohol and low boiling petroleum ether (30–60°). The 70% alcohol fraction (19.9 g.) was treated with Girard reagent T[19] to give 4.5 g. of ketones, from which was obtained 3.63 g. of ether-insoluble semicarbazones. Treatment of the latter with boiling ethyl acetate yielded three fractions. Fraction Ia1 (0.39 g.) was insoluble in hot or cold ethyl acetate. Fraction Ia2 (1.26 g.) was soluble in hot ethyl acetate but insoluble in the cold and Fraction Ia3 (1.34 g.) was soluble in hot or cold ethyl acetate. These fractions were hydrolyzed with acid under mild conditions. The hydrolyzate of Fraction Ia1 failed to yield any crystalline products. The hydrolyzate of Fraction Ia2, after the re-



(16) The processing was carried out in the laboratories of G. D. Searle and Company; the author is especially indebted to Dr. R. T. Dillon.

moval of a small amount of digitonin-precipitable material, yielded, on treatment with cold methanol, a small amount of crystalline material. Repeated crystallization from ethyl acetate gave 8.5 mg. of compact prisms, m. p. 300°. Compound A develops a cherry-red color when dissolved in concd. sulfuric acid; the test is very sensitive.

Anal. Calcd. for $C_{27}H_{40}O_3$: C, 78.60; H, 9.78; mol. wt., 413. Found: C, 78.64; H, 9.86; mol. wt. (Rast), 395.

The mother liquors yielded an additional 11 mg., m. p. 284–286°. It was dissolved in 1 cc. of dry pyridine and 0.5 cc. of acetic anhydride was added. After standing at room temperature for twenty-four hours, the reaction mixture was poured into water, the precipitate was filtered and washed well with water. It was once recrystallized from ethanol to give 5 mg. of needles, m. p. 216–217°. The derivative did not exhibit any absorption bands in the ultraviolet spectrum.

Anal. Calcd. for $C_{29}H_{42}O_4$, monoacetate of Compound A: C, 76.62; H, 9.31. Found: C, 76.83; H, 9.30.

The hydrolyzate of Fraction Ia3, after the removal of a small amount of digitonin-precipitable material, was dissolved in 250 cc. of carbon tetrachloride and chromatographed on 12 g. of aluminum oxide (Merck, standardized according to Brockmann).

TABLE II

No. of fraction	Eluent	Vol., cc.	Eluate, mg.	Crystallized once from ethyl acetate Mg.	Crystallized once from ethyl acetate M. p., °C.
1	CCl_4	300	344		
2	CCl_4	130	111	8	
3	CCl_4 (1% ethanol)	200	462	33	277–280
4	Ethanol	35	141		

Fraction 3 on recrystallization from ethyl acetate gave 20 mg. of compact prisms, m. p. 290–293° (Compound A). Ten mg. was dissolved in 1 cc. of dry pyridine and 0.2 cc. of benzoyl chloride added. After standing at room temperature for twenty-four hours, the reaction mixture was decomposed in dilute sodium carbonate solution. The precipitate was filtered, washed well with water and dried; it was extracted with a little petroleum ether and the insoluble residue crystallized from methanol. Repeated crystallization from methanol gave 3.5 mg. of fine needles, m. p. 155–157°. The ultraviolet absorption curve of the benzoate derivative of Compound A exhibited maxima at 2310 A. (ϵ = 13,470) and at 2720 Å. (ϵ = 973). The presence of only one benzoyl group is indicated if comparison is made with the ultraviolet absorption curve of the dibenzoate of 7(β)-hydroxycholesterol (see below).

Compound B.—Fraction Ibl (7.8 g.) was treated with an excess of a 2% digitonin solution in 70% methanol. The precipitate was filtered, washed with a little 70% methanol and thoroughly desiccated. After extraction with dry ether, the digitonides were worked up by dissolving in pyridine and adding an excess of dry ether. The digitonin-precipitable material weighed 365 mg.; on treatment with ethyl acetate, it yielded 56 mg. of crystalline product. Repeated crystallization from this solvent gave 7 mg., m. p. 192–193°.

Anal. Calcd. for $C_{21}H_{36}O_2$: C, 78.69; H, 11.33. Found: C, 78.65; H, 11.30.

An additional 8 mg., m. p. 187–189°, was obtained from the mother liquors. The benzoylated product crystallized in beautiful needles from alcohol, yielding 8 mg., m. p. 234–235°.

Anal. Calcd. for $C_{35}H_{44}O_4$, dibenzoate of Compound B: C, 79.50; H, 8.40. Found: C, 79.25; H, 8.46.

The ultraviolet absorption curve of the dibenzoate of Compound B exhibited maxima at 2310 A. (ϵ = 27,700) and at 2720 Å. (ϵ = 1985). The presence of two benzoyl groups is thus indicated if comparison is made with the ultraviolet absorption curve of the dibenzoate of 7(β)-hydroxycholesterol[17] [maxima at 2310 Å. (ϵ = 30,000) and at 2720 Å. (ϵ = 1857)].

Pregnandiol-3(β),20(α) which had been prepared by the method of Marker, *et al.*,[15] was adsorbed on aluminum oxide and eluted with carbon tetrachloride containing increasing amounts of ethanol. The m. p. of the preparation was not raised above 182°. The product was benzoylated in the usual manner. It crystallized from alcohol as plates, m. p. 167–168°.

Anal. Calcd. for $C_{35}H_{44}O_4$: C, 79.50; H, 8.40. Found: C, 79.43; H, 8.30.

Compound C.—Fraction Ibl (7.8 g.), after the removal of the digitonin-precipitable material, was treated with ethyl acetate to yield 65 mg. of a crystalline product, m. p. 230–233°. It was crystallized repeatedly from ethyl acetate to give 15 mg. of long white needles, m. p. 255–257°.

Anal. Calcd. for $C_{25}H_{40}O_4$: C, 74.21; H, 9.96; mol. wt., 405. Calcd. for $C_{26}H_{42}O_4$: C, 74.61; H, 10.11; mol. wt., 419. Found: C, 74.47; H, 10.18; mol. wt. (Rast), 386.

The mother liquors of Compound C were worked up to yield a total of 151 mg. of crude crystalline material. It was dissolved in 5 cc. of pyridine and 2.5 cc. of acetic anhydride added. After standing at room temperature for twenty-four hours, the reaction mixture was poured into water and extracted with ether. The ether extract was washed with dilute hydrochloric acid, dilute sodium carbonate and finally with water; evaporation of the extract yielded 102 mg. of a colorless glassy product. It was dissolved in 25 cc. of a pentane:benzene (4:1) mixture and chromatographed on 7 g. of aluminum oxide.

TABLE III

No. of fraction	Eluent	Eluate, mg.	Crystallized once from methanol Mg.	Crystallized once from methanol M. p., °C.
1	Pentane:benzene (4:1) 90 cc.	2.7 (oil)		
2	Pentane:benzene (1:1) 40 cc.	25.5 (oil)	5.6	225–228
3	Pentane:benzene (1:1) 20 cc.	14.9 (oil)	5.9	176–178
4	Pentane:benzene (1:1) 50 cc.	23.8 (cryst.)	9.5	185–186
5	Benzene 95 cc.	38.2 (cryst.)	33.2	181–183

Fractions 4 and 5 were repeatedly crystallized from methanol to yield, in all, 31 mg. of needles, m. p. 187°.

Anal. Calcd. for $C_{27}H_{42}O_5$, monoacetate of $C_{25}H_{40}O_4$: C, 72.62; H, 9.47. Calcd. for $C_{28}H_{44}O_5$, monoacetate of $C_{26}H_{42}O_4$: C, 73.00; H, 9.64. Found: C, 72.69; H, 9.70.

Hydrolysis of a specimen of the acetate derivative of Compound C in 90% methanol containing 5% potassium hydroxide at room temperature for twenty-four hours gave a product which crystallized in long white needles from ethyl acetate; it melted at 260°.

Compound D.—Fraction Ib2a (1.99 g.) was dissolved in 50 cc. of dry ether and filtered through 12 g. of aluminum oxide; it was washed with 20 cc. of dry ether. The ether filtrate on evaporation gave 1.23 g. of a glass-like residue which was next dissolved in 35 cc. of an ether–petroleum ether (1:1) mixture and filtered through 12 g. of aluminum oxide; it was washed with 65 cc. of the solvent mixture. There was obtained on evaporation of the filtrate, 0.94 g. of residue which on treatment with ethyl acetate yielded 75.5 mg. of crystalline material, m. p. 198–217°.

Fraction Ib1a (2.7 g.) was dissolved in 40 cc. of carbon tetrachloride (containing 3% ethanol) and filtered through 12 g. of aluminum oxide; it was washed with 10 cc. of the solvent mixture. There was obtained on evaporation of the filtrate, 1.67 g. of residue which on treatment with ethyl acetate gave 155 mg. of crystalline material, m. p.

180–185°. It was recrystallized twice from ethyl acetate to give 70 mg., m. p. 190–195°; this product appeared to be a complex crystalline mixture. It was combined with the 75.5 mg. from Fraction Ib2a, which appeared to be of a similar nature and acetylated in the usual manner. There was obtained in all 166 mg. of acetylated material which was dissolved in 50 cc. of carbon tetrachloride and chromatographed over 12 g. of aluminum oxide.

TABLE IV

No. of fraction	Eluent	Vol., cc.	Eluate, mg.	Crystallized once from methanol Mg.	M. p., °C.
1	CCl_4	60	7		
2	CCl_4	40	64	45	110–111
3	CCl_4	40	10	5	180–185
4	CCl_4	40	3		
5	Ethanol	40	80	38	150–160

Fraction 5 was a crystalline mixture which could not be resolved. Fraction 2, on repeated crystallization from methanol, yielded 28 mg. of needles, m. p. 111°; $[\alpha]^{18}D$ +72° (*c* 0.806 in absolute ethanol).

Anal. Calcd. for $C_{26}H_{42}O_4$: C, 74.61; H, 10.11; mol. wt., 419. Found: C, 74.36; H, 10.09; mol. wt., 408 (by titration of acetyl groups).

To 16.1 mg. (0.0385 ml.) of the acetate derivative, there was added 15 cc. of methanol and an excess of aqueous standard alkali. The solution was refluxed for four hours and then permitted to stand for forty-eight hours at room temperature. Back titration with standard acid solution indicated that 0.0394 milliequivalent of alkali had been neutralized, after deducting the value of the blank. Refluxing for an additional three hours did not cause any further neutralization of alkali. The hydrolyzate yielded a product which on crystallization from methanol gave 7 mg. of plates, m. p. 229–231°. Recrystallization from the same solvent gave 2 mg., melting sharply at 232–233° (Compound D). The empirical formula of Compound D is assumed to be $C_{24}H_{40}O_3$ since its acetate derivative appears to contain but one acetyl group.

TABLE V

No. of fraction	Eluent	Eluate, mg.	Hydrolyzate[18] mg.	Crystallized once from aqueous methanol Mg.	M. p., °C.
1	Pentane: benzene (3:1) 105 cc.	293	263	6 (prisms)	202–207
2	Pentane: benzene (3:1) 25 cc.				
	Pentane: benzene (1:1) 90 cc.	79.7	70	29.5 (needles)	184–191
3	Benzene 50 cc.	79.6	68	24 (needles)	188–190

Compound E.—Fraction IIa (11.6 g.) was taken up in a little benzene and an excess of petroleum ether added. The precipitate (6.19 g.) was treated with Girard reagent T[19] to yield 3.58 g. of non-ketones. Treatment with ethyl acetate gave 448 mg. of crystals, m. p. 192–200°; these were difficultly soluble in ethyl acetate, acetone, benzene and chloroform but moderately soluble in ethanol. Recrystallization twice from ethanol gave 99 mg. of compact prisms, m. p. 204–206°; $[\alpha]^{26}D$ +37° (*c* 0.979 in ethanol). The material was recovered and crystallized repeatedly from alcohol but the melting point of each new crop rose until 11 mg. was obtained which melted at 216–218°. The original crystalline fraction was obviously a mixture. It was recovered (total, 433 mg.) and acetylated in the usual manner. The acetates (569 mg.) were dissolved in 40 cc. of a pentane: benzene (3:1) mixture and chromatographed over 10 g. of aluminum oxide (Table V).

The hydrolyzates of Fractions 2 and 3 were combined (total-138 mg.) and extracted with small portions of hot benzene, using in all 35 cc. of benzene. A residue of 51.5 mg. remained. The benzene extract was chromatographed over 7.5 g. of aluminum oxide.

TABLE VI

No. of fraction	Eluent	Vol., cc.	Eluate, mg.	Crystallized once from aqueous methanol Mg.	M. p., °C.
1	Benzene	175	trace		
2	Benzene (4% ethanol)	25	34.4 (semicryst.)	14.0	195–196

4	Benzene (4% ethanol)	25	4.4 (oil)		
5	Benzene (4% ethanol)	25	0.8		
6	Benzene (8% ethanol)	50	21	10.7	210–215

Fractions 2 and 3 were crystallized repeatedly from aqueous methanol to give 8.5 mg. of needles, m. p. 202° (Compound E).

Anal. Calcd. for $C_{24}H_{42}O_4$: C, 73.04; H, 10.72; mol. wt., 395. Found: C, 72.66; H, 10.51; mol. wt. (Rast), 380, 395.

The mother liquors of Compound E were worked up to give an additional 11.6 mg., m. p. 199–200°. It was acetylated in the usual manner to give on repeated crystallization from aqueous methanol, 4.7 mg. of needles, m. p. 142.5°.

Anal. Calcd. for $C_{28}H_{46}O_6$, diacetate of Compound E: C, 70.25; H, 9.69. Found: C, 70.36; H, 9.56.

The carbon and hydrogen analyses and the molecular weight (Rast) determinations were performed by Mr. Wm. Saschek at Columbia University.

Summary

An exploratory examination of the neutral, non-saponifiable fraction of ox bile yielded five compounds (other than cholesterol) in small amount. Tentative empirical formulas were established for these, pointing to a steroid constitution. Structural elucidation must, however, wait until more material is available.

The Reaction of Diazomethane with α-Cyanocrotonic Acid[1]

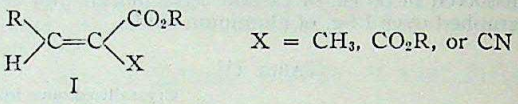
BY WILLIAM G. YOUNG, LAWRENCE J. ANDREWS, SEYMOUR L. LINDENBAUM AND STANLEY J. CRISTOL

Among several methods considered for the preparation of the methyl ester of α-cyanocrotonic acid was the reaction of the acid with diazomethane. It was hoped that the diazomethane would methylate the carboxyl group much faster than it would attack the ethylenic linkage.[2] However, the product isolated had considerably different properties from those of methyl α-cyanocrotonate prepared by treatment of the silver salt of α-cyanocrotonic acid with methyl iodide or by the acid catalyzed esterification with methanol.

An investigation of the structure of the product of the reaction with diazomethane indicated that the compound isolated was methyl isopropylidenecyanoacetate. The presence of the isopropylidene linkage was demonstrated by the fact that the compound liberated acetone on heating with aqueous sodium hydroxide. This unsaturated compound, like others of its type,[3] was resistant to ozonization; and no acetone could be isolated when the product of its reaction with ozone was hydrolyzed. On the other hand, methyl α-cyanocrotonate gave small amounts of acetaldehyde both when it was ozonized and when it was heated with dilute alkali. The structure of the diazomethane reaction product was definitely established by a comparison of its absorption spectrum and melting point with those of a sample of methyl isopropylidenecyanoacetate prepared by condensing acetone with methyl cyanoacetate.[4]

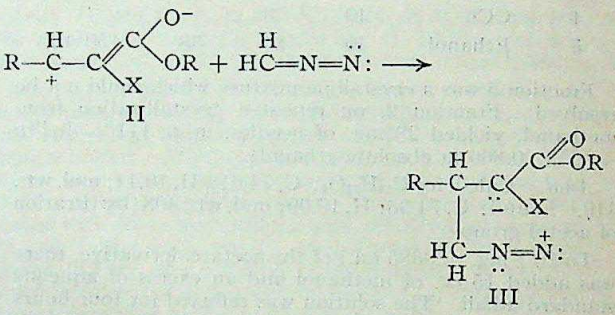
It previously has been shown that diazomethane reacts with the olefin bond of α,β-unsaturated esters[5] or ketones[6] producing a pyrazoline which loses nitrogen on heating, usually to form a mixture of a substituted cyclopropane and the β-methyl analog of the original olefin. Presumably the reaction of diazomethane with α-cyanocrotonic acid first gives a methyl ester which then reacts with a second molecule of diazomethane forming a pyrazoline. An attempt was made to isolate this pyrazoline intermediate by treatment of methyl α-cyanocrotonate with an ether solution of diazomethane, but the mixture gave off nitrogen at room temperature, and the only product isolated was methyl isopropylidenecyanoacetate.

It is interesting to note that in reactions of diazomethane with compounds of the type I the carbon atom of diazomethane attaches to the β-carbon of the ethylenic linkage. This is no doubt associated with the existence of resonance forms



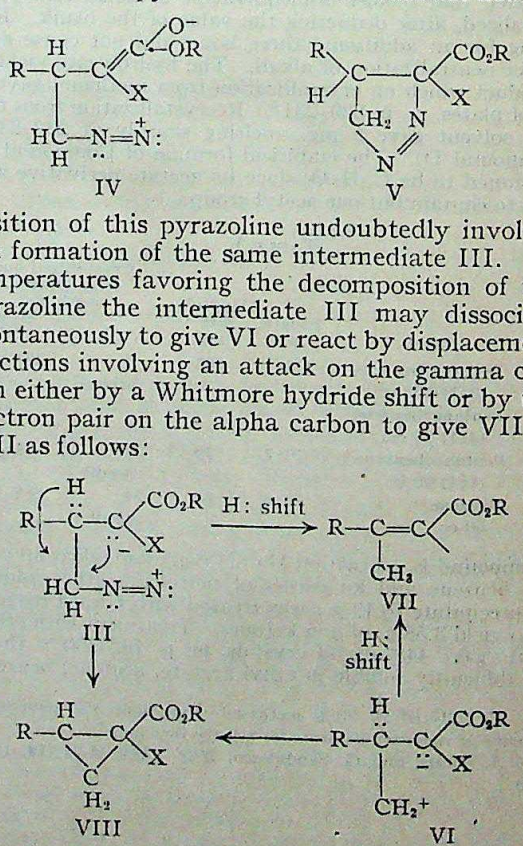
I

of the type II which may allow the β-carbon atom to enter into an electrophilic attack on the carbon–nitrogen double bond of diazomethane to give the intermediate III which is stabilized by resonance



II III

with the form IV. This normally leads to the production of the pyrazoline V. The thermal decomposition of this pyrazoline undoubtedly involves the formation of the same intermediate III. At temperatures favoring the decomposition of the pyrazoline the intermediate III may dissociate spontaneously to give VI or react by displacement reactions involving an attack on the gamma carbon either by a Whitmore hydride shift or by the electron pair on the alpha carbon to give VII or VIII as follows:



IV V III VII VIII VI

If X is a cyano or carboalkoxy[5] group, the only product isolated is VII; while if X is a methyl[5] group both VII and VIII are obtained. When X is a cyano or carboalkoxy group the intermediates III and VI have a decreased electron density on

the α-carbon atom due to increased resonance involving these groups. Consequently the hydride shift should be favored.

Experimental Part

α-Cyanocrotonic Acid.—Fifty grams (0.58 mole) of cyanoacetic acid,[7] 34 g. (0.77 mole) of acetaldehyde and 1.4 ml. of piperidine were placed in that order in a 125-ml. pressure bottle and the mixture was heated at 60–70° for ten hours. The product was cooled and excess acetaldehyde was removed under reduced pressure. The hygroscopic crude yellow crystalline product was filtered under a rubber dam. The weight of crude product was 36 g. For ordinary synthetic work the acid was purified by two recrystallizations from a carbon tetrachloride–ether solution using decolorizing carbon. To obtain an analytically pure sample a small quantity of the crude acid was recrystallized several times from carbon tetrachloride until the product no longer oiled out but crystallized from the solvent. The properties of a pure sample were: m. p. 96–99°.[8] *Anal.* Calcd. for $C_5H_5O_2N$: C, 54.06; H, 4.54; neut. eq., 111.1. Found: C, 53.84; H, 4.69; neut. eq., 113.2.

Methyl α-Cyanocrotonate.—The dried silver salt prepared from 11.1 g. (0.1 mole) of α-cyanocrotonic acid was refluxed and stirred for twenty-four hours with a solution of 21.3 g. (0.15 mole) of methyl iodide in 100 ml. of ether. The ether solution of the product was filtered from the silver residue. After removal of the ether the product was distilled under reduced pressure. Six grams of methyl α-cyanocrotonate having the following properties was obtained: b. p. 75.5–76.8° (4–5 mm.); m. p. 20.0–22.0°; $n^{25}D$ 1.4571; d^{25}_4 1.0687; M_D calcd. 30.85; M_D obs. 31.89; exalt., +1.04; absorption maximum in 95% ethanol 220 mμ (ε 8400). *Anal.* Calcd. for $C_6H_7O_2N$: C, 57.59; H, 5.64. Found: C, 57.71; H, 6.04.

This ester was also prepared by heating (80–95°) a mixture of 11 g. (0.1 mole) of α-cyanocrotonic acid, 80 ml. of anhydrous methanol and 0.4 ml. of concentrated sulfuric acid in a pressure bottle for ten hours. Excess methanol was removed under reduced pressure, and 150 ml. of water was added to the residue. The mixture was extracted several times with ether. The ether solution was washed with water and aqueous sodium carbonate, dried and distilled. The properties of the methyl α-cyanocrotonate (3.3 g.) thus obtained were essentially those given for the ester prepared from the silver salt of the acid.

The Reaction of α-Cyanocrotonic Acid with Diazomethane.—Seven hundred ml. of an ether solution containing about 5 g. of diazomethane, prepared from 25 ml. of ethyl N-nitroso-N-methylcarbamate,[9] was treated with 11.6 g. of α-cyanocrotonic acid. Vigorous evolution of nitrogen took place, and the solution lost its yellow color. After the solution had stood for several hours, the ether was removed and the residue distilled under reduced pressure. The distillate (6.7 g.) had properties which were within experimental error identical with those of methyl isopropylidenecyanoacetate prepared according to Cope.[4] These properties and those of the sample prepared by the method of Cope (in parentheses) were: b. p. 90–91° (5 mm.) (88–90° (5 mm.)); m. p. 19.5–21.0° (21.5–22°) (mixed m. p. of the two samples 21.0–22.0°); $n^{25}D$ 1.4728 (1.4726); d^{25}_4 1.0605 (1.0632); M_D calcd. 35.45; M_D obs. 36.89; exalt., +1.44; absorption maximum in 95% ethanol 230 mμ, ε 11100 ($\lambda_{max.}$ 230 mμ, ε 10900). *Anal.* (diazomethane reaction product) Calcd. for $C_7H_9O_2N$: C, 60.42; H, 6.52. Found: C, 60.16, 59.74; H, 7.02, 6.57.

The Reaction of Methyl α-Cyanocrotonate with Diazomethane.—To an ice-cold solution of 1.9 g. of diazomethane in 500 ml. of ether was added a solution of 5 g. (0.04 mole) of methyl α-cyanocrotonate in 25 ml. of ether. The yellow color of the diazomethane immediately decreased in intensity. As the ether solution warmed to room temperature, nitrogen bubbled off vigorously and the solution became almost colorless. Three grams of methyl isopropylidenecyanoacetate, having the same physical properties as those previously given, was obtained after removing the ether and distilling the product.

The Reaction of Methyl α-Cyanocrotonate and Methyl Isopropylidenecyanoacetate with Dilute Aqueous Alkali.—Each ester (0.75 g.) was heated at 90° in a modified Claisen flask with 10 ml. of 3 *N* sodium hydroxide solution until the ester had completely dissolved. The bath temperature was then raised, and 2 ml. of distillate was collected in an ice-cooled receiver. A few drops of the distillate was tested for acetone by the use of sodium nitroprusside.[10] The product from methyl α-cyanocrotonate gave a negative test, while those from the methyl isopropylidenecyanoacetate samples gave a positive test. The remainder of the distillate was treated with a solution of 2,4-dinitrophenylhydrazine in acidified ethanol. The isopropylidene type ester gave 0.12 g. of acetone 2,4-dinitrophenylhydrazone (m. p. after one recrystallization from ethanol and mixed m. p. with an authentic sample 125.5–127.5°). The ethylidene type ester gave 0.038 g. of acetaldehyde 2,4-dinitrophenylhydrazone which after two recrystallizations from ethanol melted from 160.5–162.5° (mixed m. p. with an authentic sample 160.5–164.5°) with some softening below these temperatures.

Ozonization of Methyl α-Cyanocrotonate.—A solution of 1.0 g. (0.008 mole) of the ester in 6 ml. of methylene chloride was ozonized at dry-ice temperature for one hour. After removal of the solvent the ozonide was decomposed under reducing conditions,[11] and the aqueous solution of the product was tested with methone reagent for formaldehyde and acetaldehyde.[12] No formaldehyde derivative was obtained, but a small quantity of the methone derivative of acetaldehyde was isolated. After one recrystallization from ethanol this gave a m. p. and mixed m. p. with an authentic sample of 142–144°.

When methyl isopropylidenecyanoacetate was submitted to this ozonization procedure, no aldehyde or acetone could be detected after reductive decomposition procedures were applied.

The authors are indebted to Mr. J. W. Ralls for the combustion analyses reported.

Summary

The reaction of diazomethane with α-cyanocrotonic acid produces methyl isopropylidenecyanoacetate rather than methyl α-cyanocrotonate. The reaction is presumed to occur through the formation of a pyrazoline as an intermediate, and a mechanism for the decomposition of this pyrazoline has been proposed.

The Debromination of Pentaerythrityl Bromide by Zinc. Isolation of Spiropentane[1]

BY M. J. MURRAY AND EUGENE H. STEVENSON

When Gustavson[2] first debrominated pentaerythrityl bromide he assigned to the reduction product the structure vinyltrimethylene. Zelinsky,[3] however, concluded that the spirocyclane (spiropentane) configuration would more nearly account for the chemical reactions and for the synthesis of the compound. Shortly thereafter Philipov[4] was convinced that the reduction product was a mixture of methylenecyclobutane and methylcyclobutene. In 1923 Ingold[5] stated that "the simplest possible *spiro*-compound has never yet been isolated or even transiently formed as an unstable intermediate product." Rogowski,[6] however, in 1939, interpreted the results of an electron diffraction study on the reduction product as proving spiropentane to be the correct formula. Whitmore and Williams[7] painstakingly fractionated a large quantity of the reduction product and proved by ozonolysis that it consisted of a mixture of 2-methyl-1-butene and methylenecyclobutane. The ratio found was about one of the former to eleven of the latter. No evidence could be obtained for the presence of any other compound. Bauer and Beach[7] made an electron diffraction study of the high-boiling fraction obtained by Whitmore and Williams and concluded that it could not possibly be spiropentane and that the methylenecyclobutane structure was the correct one.[8]

The present work began with a Raman spectroscopic investigation of the product obtained when pentaerythrityl bromide was reduced by zinc in aqueous methanol. Two Raman lines which could be assigned neither to the main product, methylenecyclobutane (I), nor to 2-methyl-1-butene (II) showed that a third compound (III) was present. Modified conditions of reduction resulted in the formation of a much larger proportion of the third component and made possible its isolation. A preliminary study of the compound lends considerable support to the opinion that it is the long-sought spiropentane.

Discussion

The spectroscopic results obtained in this work are listed in Table I. For purposes of comparison the spectra of 2-methyl-1-butene and cyclobutanone were taken from the literature.

The high-boiling fraction (41.6–41.9°) of the product obtained from the reduction in aqueous methanol shows a strong, polarized Raman line near 960 cm.$^{-1}$. This line is present also in the spectra of cyclobutanone and methylcyclobutane and is characteristic of the cyclobutane ring. Cyclobutanone has very nearly the same symmetry, mass, and force constants as would be present in methylenecyclobutane, and there is excellent correspondence in a majority of the lines of this ketone with those of the high-boiling fraction of the reduction product.

In ordinary, unconjugated ketones the carbonyl frequency is near 1720 cm.$^{-1}$. The value of 1774 cm.$^{-1}$ found by Kohlrausch and Skrabal for cyclobutanone indicates that the carbonyl is attached to a ring that is not strain free. Similarly, the spectrum of the high-boiling fraction has an olefinic frequency at 1679 cm.$^{-1}$, an unusually high value for an unsymmetrical disubstituted ethylene which normally has this vibration near 1650 cm.$^{-1}$. This is excellent evidence that the olefin is exocyclic. Furthermore, if the olefinic linkage were within the strained ring itself (methylcyclobutene), it would be expected to exhibit a much lower frequency—probably near 1600 cm.$^{-1}$.[9] On the basis of these considerations the authors feel that the spectrum of the high-boiling fraction is thoroughly consistent with the methylenecyclobutane structure.

After eliminating the lines due to methylenecyclobutane from the spectrum obtained for the low-boiling fraction, the remaining lines, with two exceptions, are found to be the more prominent lines in the spectrum of 2-methyl-1-butene. This gives spectroscopic confirmation to the chemical evidence of Whitmore and Williams on the occurrence of this compound. The absence of any trace of line at 1338 cm.$^{-1}$ precludes the possibility that any significant amount of 2-methyl-2-butene exists in the mixture. The appearance of the substantial line at 1033 cm.$^{-1}$ and of the somewhat weaker line at 581 cm.$^{-1}$, however, proves that a third component is present. The quantity of the third compound cannot be estimated with any degree of certainty until the scattering ability of the substance is known, but it seems rather likely that the crude reduction product may contain between 1 and 5% of the compound.

A careful study of the Raman spectra of the crude reduction product and of various fractions obtained in its distillation revealed that the com-

[a] Thompson and Sherrill, THIS JOURNAL, **58**, 746 (1936). [b] Intensity measured on a Gaertner microdensitometer. Values of ρ for methylene cyclobutane were also measured on this instrument. Lines listed as w were too weak for intensity measurements. [c] Kohlrausch and Skrabal, *Z. Elekt.*, **43**, 282 (1937). [d] The sample used was not fractionated. It contained some III, hence lines known to belong to that compound have been deleted.

pound responsible for the 1033 and 581 cm.$^{-1}$ lines should boil within a few degrees of 37°. This observation sharply narrowed the list of compounds to be considered. A number of other compounds were eliminated because of the absence of Raman lines in certain positions. For example, the lack of a line in the 2100–2200 cm.$^{-1}$ region proved that the compound was not an acetylene. Still other substances were eliminated because they were known not to exhibit Raman lines at 1033 and 581 cm.$^{-1}$. In this way it was possible tentatively to conclude that III was no compound whose properties were known to the authors. (Methylcyclobutane was eliminated only after its spectrum was obtained—see Table I.)

At this point the authors were convinced that there was excellent chance that III was spiropentane.

In the isolation of the new compound there appeared to be two possible procedures. One was the tedious concentration, either by chemical means or by fractional distillation, of the small amount of the substance in the crude reduction product which was obtained when aqueous methanol was employed as solvent. The other was the use of different conditions for the debromination. Fortunately the latter method proved successful and the authors were able, by carrying out the reduction by zinc in molten acetamide[10,11,12] containing sodium iodide and sodium carbonate, to obtain a product consisting of about 40% of the new compound.

Spectroscopically this method of reduction was

shown to yield the same volatile products as did the debromination in aqueous methanol.

While separation of the components of the crude mixture by fractionation should be possible in an efficient column, the amount of hydrocarbon mixture available at the moment (18 g.) was not sufficient for this purpose.

Distinct enrichment of III was accomplished easily by repeated extraction with cool, almost saturated, aqueous silver nitrate. The hydrocarbon recovered by heating the separated silver nitrate layer showed spectroscopically that practically no III was absorbed in the extraction. Further purification was carried out by extraction with almost saturated silver perchlorate.

There are certain definite advantages to the use of silver ions for the separation of an olefin from other organic compounds, whenever the extraction is a possible one. The coördinating action of silver ion on olefins is so mild as to cause no detectable rearrangement,[13] a fact which is in direct contrast to the results often obtained with sulfuric acid. Bromine and alkaline permanganate give new products that require separation, and in the latter case the solid manganese dioxide creates experimental difficulties. Finally the silver nitrate method of extraction allows one to recover the olefin merely by warming the solution for low molecular weight substances or by diluting for high-boiling compounds.

On the other hand, the formation of the silver ion-olefin complex is an equilibrium process[13] which makes it increasingly difficult to extract the olefin as its concentration in the organic layer becomes smaller. Furthermore, the ease of coördination differs markedly with various olefins. In the present case it was found to be much easier to extract from III a larger amount of methylenecyclobutane than the somewhat smaller amount of 2-methyl-1-butene. It was necessary to complete the purification process by reaction of the olefin with bromine. Analysis showed the compound to be C_5H_8. The Raman spectrum of the final sample is listed in Table I.

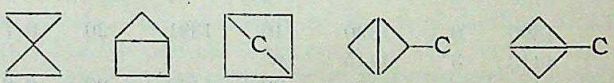
Throughout the early stages of purification of III the hydrocarbon mixture always had the sharp, characteristic odor of low molecular weight, unsaturated compounds. The odor remained practically unchanged until the final extractions with concentrated silver perchlorate solution. The organic layer then had an odor similar to that of chloroform.

It was felt at first that the observed boiling point of the new compound, 38.3–38.5°, was too high for spiropentane. However, Dr. H. I. Bernstein called the authors' attention to the fact that the boiling point of 1,1-dimethylcyclopropane is about 10° higher than that of neopentane. Closure of the second ring would undoubtedly increase the boiling point considerably.

(13) Winstein and Lucas (THIS JOURNAL, 60, 836 (1938)) found that neither *cis*- nor *trans*-2-butene underwent isomerization in the aqueous solution.

The value of the highly polarized frequency, 1033 cm.$^{-1}$, is nearer to that for a cyclobutane ring (960 cm.$^{-1}$) than that for a cyclopropane ring (1200 cm.$^{-1}$). That spiropentane should show an abnormal cyclopropane ring frequency is definitely not out of order. First, the addition of a second ring in the gem position would give rings with strain characteristics quite different from the one ring system; and, second, the almost pure inner vibration obtained for those hydrocarbons with one ring would probably be replaced by a more highly coupled vibration involving both rings more intimately. This may be considered similar to an effect observed in the Raman spectra of olefins. The C=C vibration is always represented in the spectrum by a prominent line near 1600 cm.$^{-1}$ except when another double bond carbon is attached to the first to form an allene. The interaction of the two double bonds in this type of compound is sufficient to move the vibration completely out of the 1600 cm.$^{-1}$ region.

Raman spectra considerations and the nonreactivity with bromine eliminate acetylenes, diolefins and monocyclic olefins and leave of the C_5H_8 isomers only the dicyclic compounds



IV V VI VII VIII

as structural possibilities.

There are at present two reasons why the authors believe structure IV to be the most plausible:

1. In the presence of sodium iodide and sodium carbonate the reduction of 1,3-dihalides in molten acetamide has been found to produce good yields of the normally expected compounds (cyclopropane and derivatives) when the starting products were 1,3-dichloropropane,[10] 1,3-dichlorobutane[11] and 1,3-dibromo-2,2-dimethylpropane.[12] The formation from pentaerythrityl bromide of any condensed ring system other than spiropentane could occur only through an extensive series of rearrangements—a phenomenon which would be expected to occur *less* in acetamide than in aqueous methanol.

2. The carbon–hydrogen Raman lines between 2800 and 3100 cm.$^{-1}$ can be cited as favoring structure IV. Both compounds V and VI have hydrogen attached to cyclobutane rings, whereas IV has the hydrogen combined only with cyclopropane groups. Kohlrausch and Skrabal,[14] who have made a comprehensive study of cyclobutyl and cyclopropyl compounds by means of the Raman effect, found that hydrogen atoms attached to cyclobutane rings produced several intense frequencies near those of aliphatic hydrocarbons; *i. e.*, between 2850 and 3000 cm.$^{-1}$. On the other hand, cyclopropane and those derivatives with hydrogens attached only to three-membered rings (carbocyclic) produce no intense Raman lines in

(14) Kohlrausch and Skrabal, *Monatsh.*, 70, 44, 377 (1937).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

this region much below 3000 cm.$^{-1}$. In the new compound the only intense Raman lines between 2800 and 3100 cm.$^{-1}$ occur at 2991 and 3065 cm.$^{-1}$. Although 2991 cm.$^{-1}$ might belong to a substance having either a cyclobutane or a cyclopropane ring, the former structure would show several intense lines below this figure, whereas only the latter structure could give rise to the 3065 cm.$^{-1}$ frequency. This appears to the authors to be quite conclusive as to the absence of a cyclobutyl and as to the presence of a cyclopropyl compound. The weak lines at 2836 and 2891 cm.$^{-1}$ in the spectrum of the sample studied may be due to a trace of impurity or they may actually belong to the pure compound. Their occurrence, since they are so weak, appears to the authors to be beside the point as far as structural arguments are concerned. Structures VII and VIII are ruled out because each has a methyl group and hence would exhibit strong carbon–hydrogen vibrations between 2850 and 2980 cm.$^{-1}$.

The chemical stability of the new compound is remarkable. Its reaction with bromine at 25° in the dark is negligible. It is not hydrogenated over Raney nickel at room temperature. It appears not to be isomerized at 300° when passed over aluminum oxide. With alkaline permanganate the reaction is very slow, and what reaction there is may be caused by a small amount of impurity.

The Raman effect is a method *par excellence* for the study of a problem of this nature and throughout the investigation close check was kept on the changing composition caused by varying factors. One difficulty, however, should be mentioned. Because of the very great differences in scattering ability of various compounds, error is likely to be made in estimations of the composition of mixtures when unknown compounds are concerned. For example, the scattering power of III is high while that of 2-methyl-1-butene is quite low. Consequently there is a tendency for one to estimate the amounts of the former as too high and of the latter as too low until the spectra of the pure compounds have been obtained under similar conditions.

Experimental

Pentaerythrityl Bromide.[15]—The pentaerythritol used was an Eastman Kodak Company product, m. p. 254°. The only modification made in the procedure given in "Organic Syntheses" for the preparation of the bromide was the substitution of acetone for ethyl alcohol in the extraction of the impure reaction product. When acetone was used it was found that the extraction went at a much faster rate and with a smaller volume of solvent, and yielded a product having a m. p. 160° (not recrystallized) which is the same as that obtained by the use of ethyl alcohol. Furthermore, samples extracted by the two methods upon reduction gave products with identical spectra.

Reduction of Pentaerythrityl Bromide in Aqueous Methanol.—Five hundred sixty grams of the pentaerythrityl bromide was mixed with 380 g. of zinc dust, and 1200 ml. of 50% methyl alcohol was poured over the mixture. The volatile product, 57 g., was caught in a dry-ice trap and then dried over calcium chloride. It was fractionated using an 85-cm. Ewell column. Several fractions were obtained and examined spectroscopically. The only one showing Raman lines for a single compound was the high-boiling fraction, b. p. 41.6–41.9° at 752 mm., d^{20}_4 0.7326, $n^{25}D$ 1.4158.

Reduction of Pentaerythrityl Bromide in Acetamide.—Into a 500-ml. three-necked flask was placed 190 g. of Eastman Kodak Company practical grade acetamide, 10 g. of sodium iodide, 30 g. of sodium carbonate and 90 g. (1.4 mole) of zinc dust. The flask was provided with a mercury-seal mechanical stirrer, a reflux condenser from the top of which a tube led to a dry-ice trap, and a device for slowly adding 90 g. (0.23 mole) of solid pentaerythrityl bromide. The flask was heated in an oil-bath at 170–180°. Each addition of the bromide resulted in the evolution of fumes. Carbon dioxide, which formed in the reaction from the sodium carbonate, escaped from the exit tube of the trap. Nine grams of crude material was caught in the dry-ice trap. The Raman spectrum of this material after straight distillation showed the 1033 line to be more intense than the 957 cm.$^{-1}$ line of the methylenecyclobutane. Several lines of 2-methyl-1-butene were also present.

Purification of the Non-olefinic Constituent.—The separation of the olefinic constituents of the mixture from the compound showing the 1033 cm.$^{-1}$ Raman line was accomplished largely by the use of silver salts. Loss of the highly volatile hydrocarbon during extraction was avoided by use of a cylindrical separatory funnel constructed of 18 mm. glass tubing and having a stopcock attached to each end. The positions of the aqueous and hydrocarbon layers were noted for each extraction in order to determine when the process had reached the point of diminishing returns. The contents of the tube were cooled under the tap.

In this apparatus 18 g. of the hydrocarbon mixture was extracted ten times with 5-ml. portions of nearly saturated aqueous silver nitrate. The volume of the hydrocarbon layer decreased 47%. Then followed four extractions with 5-ml. portions of almost saturated aqueous silver perchlorate. Precautions were, of course, taken in the use of the perchlorate solutions, but no vigorous reaction was noted in any case. In the first and second extractions with perchlorate three layers were obtained. The top was the hydrocarbon, the middle probably contained the greater amount of the olefin, and the bottom contained most of the water. The middle layer showed some slight discoloration, but the other two layers remained water-white. The third and fourth extractions gave only two layers each. In spite of several transfers of material, two fractionations for determining constancy of boiling point, and the removal of samples for chemical and spectroscopic tests, the amount of hydrocarbon remaining at this point was 5 g. It appeared by bromination to contain about 6% olefins.

The hydrocarbon layer was then washed thoroughly with water and dried over calcium chloride. It was cooled in an ice–hydrochloric acid-bath, and bromine was added dropwise with stirring until a very faint color of bromine persisted. This color did not noticeably decrease in half an hour. The slight excess of bromine was removed by blowing a trace of olefin vapor from a capillary pipet into the solution. Distillation was through a six inch (length) column packed with glass helices. The main fraction, 38.3–38.5°, was collected at 750 mm.; $n^{20}D$ 1.4117; d^{20}_4 0.755; mol. ref. calcd. for spiropentane, 22.32; found, 22.43. *Anal.*[16] Calcd. for C_5H_8: C, 88.17; H, 11.83. Found: C, 87.91; H, 11.53. The amount finally isolated was only about 1 g. but this was partly because a number of preliminary tests were made with small amounts of the sample before final purification with bromine and partly because of loss in the column which was not equipped with control of reflux ratio.

Stability of the Hydrocarbon.—The method of purification indicates the stability of the product toward bromine. In another experiment several drops (capillary) of the

Digitized by Arya Samaj Foundation Chennai and eGangotri

hydrocarbon were added to carbon tetrachloride containing a little bromine. In three days at room temperature in the dark there was but little change in the color of the solution.

A few drops (capillary) of the hydrocarbon when shaken with a very dilute aqueous permanganate solution caused no noticeable color change in fifteen minutes. When alkali was added a very slow reaction took place. At the present time it is not certain whether this might be caused by a small amount of impurity or whether it represented a *bona fide* oxidation of the hydrocarbon.

A mixture of methylenecyclobutane, 2-methyl-1-butene and the compound in question was added to cold concentrated sulfuric acid. After dilution and distillation the Raman spectrum showed the presence of both the 1033 and the 581 cm.$^{-1}$ lines.

Passage of a mixture of methylenecyclobutane and the compound thought to be spiropentane over aluminum oxide at 300° resulted in isomerization of almost all of the methylenecyclobutane to isoprene but did not noticeably affect the intensity of the 1033 cm.$^{-1}$ Raman line in the treated sample.

Methylcyclobutane.—Five grams of methylenecyclobutane (containing a small amount of the compound having a Raman line at 1033 cm.$^{-1}$) was hydrogenated over Raney nickel at atmospheric pressure and at room temperature. The Raman spectrum of the material was taken after a straight distillation into the Raman tube without any attempt at fractionation.

Recovery of Olefins.—The combined silver nitrate layers were heated on a water-bath and the olefins collected in a dry-ice trap. A Raman spectrum of the sample showed only lines for methylenecyclobutane and for 2-methyl-1-butene. There was no more than a faint trace of line at 1033 cm.$^{-1}$, the position of the strong Raman-active frequency of III. This, coupled with the fact that treatment of the hydrocarbon layer with silver salts failed after several extractions to dissolve appreciable material from the organic layer, showed that III was practically unaffected by this reagent.

Hg 4358 Å. was used for exciting the Raman spectra. Exposure times were of the order of four hours and the slit width was 0.08 mm. The experimental details of obtaining the spectra are given elsewhere.[17]

Summary

1. Reduction of pentaerythrityl bromide by zinc in aqueous methanol yields a mixture of methylenecyclobutane, 2-methyl-1-butene and a small amount of a third component with Raman lines at 1033 and 581 cm.$^{-1}$.

2. Reduction of pentaerythrityl bromide by zinc in molten acetamide in the presence of sodium carbonate and sodium iodide yields a mixture containing a relatively large amount of the new compound, together with methylenecyclobutane and 2-methyl-1-butene.

3. The new compound was isolated by removal of the olefins with aqueous solutions of silver salts and with bromine.

4. The method of synthesis as well as the Raman spectrum of the substance leads to the belief that the compound is spiropentane.

Reaction of Benzene with Butadiene in the Presence of Sulfuric Acid and Hydrogen Fluoride Catalysts

BY V. N. IPATIEFF, HERMAN PINES AND R. E. SCHAAD

The large number of theoretically possible reaction products, some of which may have important applications in the synthesis of valuable materials, prompted us to study the reaction between benzene and butadiene.

We have found that benzene reacts with butadiene in the presence of sulfuric acid or hydrogen fluoride. In order to favor reaction with benzene and to decrease polymerization of butadiene, it was considered advisable to use a large excess of benzene. Under these conditions one mole of butadiene reacted with an average of approximately 1.5 moles of benzene in the presence of sulfuric acid and with 1.2 moles of benzene in the presence of hydrogen fluoride.

The hydrocarbon of lowest boiling point obtained from this reaction was 1,2-diphenylbutane, which was formed by the interaction of two molecules of benzene with one molecule of butadiene. The proof of the structure of this compound was based on the comparison of its physical constants, infrared absorption spectrum, and the melting points and mixed melting points of the acetamino derivative with those of synthetically prepared (liquid) 1,1-, 1,2- and 1,3-diphenylbutanes. The primary product of the reaction was probably 1-phenylbutene-2 formed by the 1,4-addition of benzene to butadiene-1,3 in the presence of the investigated catalysts. Under these conditions phenylbutene then reacted with another molecule of benzene to form the diphenylbutane obtained.

Experimental Part

Reaction of Benzene with Butadiene in the Presence of Sulfuric Acid.—Benzene (156 g.) and 96% sulfuric acid (50.2 g.) were stirred at 0–5° in a 500-cc. flask of the type described[1] by us and 20.0 g. of butadiene (98% pure) was introduced to the stirred mixture as gas from a weighed aluminum bomb during 1.25 hours. The butadiene was added through an opening in the reflux condenser in order that it would be diluted before coming in contact with the sulfuric acid. After the addition of butadiene was completed, the stirring was continued for 0.25 hour while the temperature of the reaction mixture was maintained at 0–5°.

The dark brown product of the reaction consisted of 178 g. of an upper hydrocarbon layer and 46 g. of a lower acid layer. The upper layer, neutralized by sodium hydroxide solution, was steam-distilled to remove the excess of benzene (82 g.). The higher boiling material when distilled

under reduced pressure yielded 13 g. of a hydrocarbon fraction boiling at 152–154° at 16 mm. pressure, and a remainder (81 g.) of higher boiling products. The lower boiling product, after redistillation over sodium, had the properties compared in Table I with the same properties determined on a similar product formed in the presence of hydrogen fluoride and on three synthetically prepared liquid diphenylbutanes.

[a] Calculated: C, 91.37; H, 8.63. [b] Infrared absorption indicates that the product is only 90% pure. [c] Calculated: N_2, 8.64. [d] Infrared absorption spectra agreed with that of 1,2-diphenylbutane.

Reaction of Benzene with Butadiene in the Presence of Hydrogen Fluoride.—This reaction was carried out in a stainless steel autoclave provided with a motor-driven stirrer. The autoclave was charged with 408 g. of benzene (5.25 moles) and 311 grams of hydrogen fluoride (15.5 moles) and cooled to 5°. The contents of the autoclave were stirred and a mixture consisting of 312 g. (4 moles) of benzene and 135 g. (2.5 moles) of butadiene was added from a pressure charger during 3.75 hours. The temperature during the reaction rose to 20° and the pressure was the vapor pressure of the mixture. After all the mixture of butadiene and benzene had been added to the reaction mixture, the hydrogen fluoride was released to a potassium hydroxide scrubber, and the autoclave was heated to 50° to remove the greater part of the hydrogen fluoride dissolved in the hydrocarbons. The autoclave was then cooled, and the reaction mixture removed and treated with potassium hydroxide solution. The reaction product formed an emulsion from which the excess of benzene was removed by steam distillation. High boiling products which remained were separated from the alkaline aqueous layer by extraction with *n*-pentane. The extracted material was washed with water, dried, and vacuum distilled. The fractions so separated had the boiling points and refractive indices shown in Fig. 1.

All of the butadiene entered into reaction. The molar ratio of benzene to butadiene which reacted was 1.2:1. About 50% by weight of the reaction product was diphenylbutane. The higher boiling fraction consisted of a complex mixture among which were products of the interaction of 2 moles of benzene with 2 or 3 moles of butadiene as evidenced by the carbon and hydrogen analyses shown in Table II.

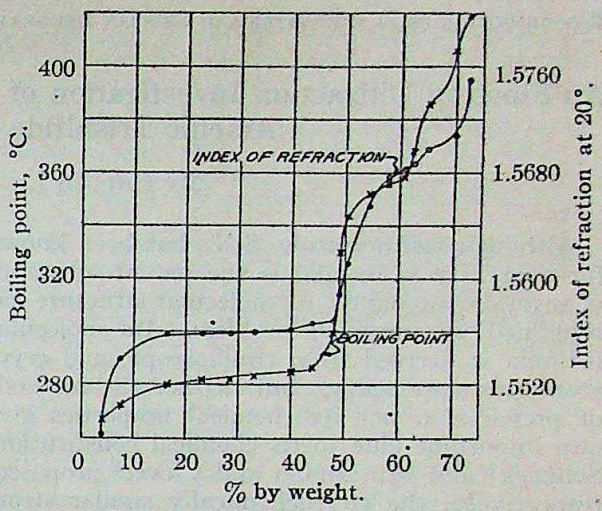

Fig. 1.—Boiling range and index of refraction of the reaction products from benzene and butadiene in the presence of hydrogen fluoride.

Synthesis of Normally Liquid Diphenylbutanes.—The method used for the preparation of diphenylbutanes, illustrated in Table III, consisted in coupling a ketone with a Grignard reagent to form a carbinol which was dehydrated to an olefin by passage over activated alumina at 350°. The olefin was diluted with an equal volume of pentane and hydrogenated at 50° in an Ipatieff rotating autoclave in the presence of a nickel catalyst under 100 atmospheres initial pressure of hydrogen. By this procedure only the olefinic double bond was hydrogenated while the aromatic ring remained unchanged.

Summary

Reaction of butadiene with benzene in the presence of sulfuric acid and hydrogen fluoride catalysts was studied.

1,2-Diphenylbutane was identified as one of the products of the reaction.

The respective yields of 1,2-diphenylbutane obtained from the reaction of butadiene with benzene catalyzed by sulfuric acid and hydrogen fluoride were 14% and 59% on the basis of the benzene which reacted.

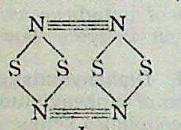
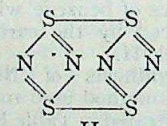
An Electron Diffraction Investigation of Sulfur Nitride, Arsenic Disulfide (Realgar), Arsenic Trisulfide (Orpiment) and Sulfur

BY CHIA-SI LU AND JERRY DONOHUE

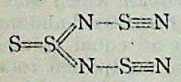
Although sulfur nitride, S_4N_4, has been known for over fifty years and is the parent substance of several compounds, its molecular structure has remained an unsolved problem. Its molecular formula is derived from ebullioscopic and cryoscopic measurements; but neither the methods of preparation nor its chemical properties give any important clue to its chemical constitution. Schenck[1] and Muthmann and Clever[2] proposed, respectively, the stereochemically similar structural formulas I and II, which are rather improbable because of the four rings and the small distances. Later Ruff and Geisel[3] proposed the formulas III and IV. They gave preference to the latter formula, which was also supported by



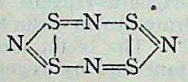
I



II

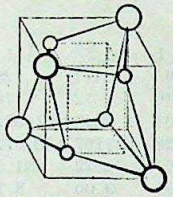


III

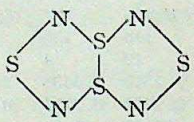


IV

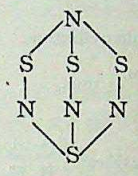
Meuwsen.[4] None of these formulas seems to account for the chemical properties of sulfur nitride satisfactorily. In 1931 Jaeger and Zanstra,[5] on the basis of their x-ray investigation of the crystals of sulfur nitride, reported that the molecules had the configuration of two interpenetrating concentric bisphenoids (tetragonal bisphenoids) of sulfur and nitrogen atoms (formula V). The N-S bond length of their model was only about 1.2 Å., which seems to be far too short. Their results are rendered more doubtful, inasmuch as they regarded the crystals as being orthorhombic, by the fact that the crystals have been shown to possess only monoclinic symmetry by means of both goniometric and x-ray methods[6,7] but usually twin themselves to exhibit orthorhombic symmetry. In 1936 Arnold, Hugill and Hutson[8] proposed formula VI, which would involve resonance among several bond structures. They also considered formula VII, which would easily



V



VI



VII

account for the formation of the thiotrithiazyl ion[9] $(N_3S_4)^+$ from sulfur nitride but would not readily account for the other reactions. Formula VI was supported by Phalnikar and Bhide,[10] although their argument on the basis of their dipole moment measurements is not at all convincing.

The molecular structure of arsenic disulfide (realgar) has been another unsolved problem in structural chemistry. The possibility of isomorphous structures of sulfur nitride and realgar was first suggested by Szarvasy and Messinger.[11] They determined the vapor densities of realgar at several temperatures, and found that the measured vapor density would correspond to As_4S_4 at temperatures below 550° but dissociation into As_2S_2 molecules became appreciable at higher temperatures. They proposed a structure similar to I for the As_4S_4 molecule except with single bonds between the arsenic atoms instead of the triple bonds. Recently Buerger[12] determined the dimensions of the unit cell in the realgar crystal and compared them with those in the crystal of sulfur nitride,[7] and suggested that the difference in the length of the monoclinic *b*-axis might be attributed to the difference in the sizes of the arsenic and nitrogen atoms. However, no complete structure investigation for either substance has been reported in the literature.

Burt[13] reported in 1910 that sulfur nitride can be sublimed readily *in vacuo* at as low a temperature as 100°. Realgar also sublimes readily *in vacuo* at temperatures below its melting point (307°); and excellent realgar crystals can be grown in this way.[14] We have therefore undertaken an electron diffraction investigation of these

two substances in the vapor state. In the course of our investigation we began to feel the desirability of examining arsenic trisulfide (orpiment) and sulfur by means of similar experimental techniques. In the case of orpiment, which exhibits rather large birefringence in the crystal, it might be expected that the crystal structure would be different from that of arsenolite,[15] which consists of As_4O_6 molecules. However, orpiment can be distilled unchanged,[16] although it does not sublime as readily as realgar.[14] It is thus of interest to find out whether it could have the As_4O_6 structure in the vapor state.[17] In the case of sulfur a puckered ring structure has been established in the rhombic crystals[18] as well as in the vapor.[19] Since the electron diffraction photographs of Howe and Lark-Horovitz[19] apparently were not taken to show features beyond $q = 30$ ($q = 40/\lambda \sin \theta/2$), their patterns are not capable of giving as complete information with regard to the size, configuration, and rigidity of the ring as we have been able to obtain.

We have accidentally taken some excellent photographs of arsenic trioxide, which apparently contaminated a sample of stockroom-grade "pure" arsenic trisulfide. Five more features could be seen and measured than those reported by Hampson and Stosick.[20] Our final parameters are as follows: As—O = 1.78 ± 0.02 Å., As—As = 3.20 ± 0.02 Å. and ∠ As—O—As = 128 ± 2° (∠O—As—O = 99 ± 2°). These agree very well with the values of Hampson and Stosick:[20] namely, As—O = 1.80 ± 0.02 Å., As—As = 3.20 ± 0.03 Å. and ∠ As—O—As = 126 ± 3°. It should be noted that both the As—O bond length and the oxygen bond angle indicate large amounts of double bond character in the As—O bonds arising from the unshared electrons on the oxygen atoms.

Experimental.—The sample of sulfur nitride used in this investigation was prepared by the method described by Arnold, Hugill and Hutson.[8] The sample was recrystallized twice from chloroform. It burned quietly in air and left no residue on sublimation *in vacuo*. The samples of realgar and orpiment were purchased from a mineralogical supply service in Pasadena. According to Mr. Grieger of this supply service, the sources of these mineral specimens are: realgar, White Caps mine, Manhattan, Nevada; orpiment, Mercur, Utah. Both specimens are of very high quality. The realgar was purified by sublimation *in vacuo* at a temperature of *ca.* 300°. Orpiment would not sublime so readily; hence it was fused *in vacuo* to a glassy mass at a temperature of 300–400° to remove both arsenic trioxide and realgar, and was then pulverized. The powdered sample had a dark yellow color. Another sample of arsenic trisulfide was prepared artificially by precipitation by hydrogen sulfide from a solution of arsenic trichloride in hydrochloric acid. The sample of sulfur was obtained from the chemical stockroom. It was apparently of very high purity, and it left practically no residue on sublimation *in vacuo*.

The electron diffraction apparatus used for this investigation has been described by Brockway.[21] The camera distance used was about 11 cm. The wave length of the electrons (*ca.* 0.06 Å.) was determined against zinc oxide smoke[22] ($a_0 = 3.2426$ Å., $c_0 = 5.1948$ Å.) with a camera of about 40 cm. distance.

The metal high-temperature nozzle of Brockway and Palmer[23] was found to be unsuitable for sulfur nitride and realgar. With this nozzle no photographs could be obtained below a certain heating current; while at higher heating current only photographs of decomposition or reaction products resulted. A glass high-temperature nozzle of very simple design was made to meet this difficulty and was used throughout this investigation. It consists of a small sample tube (diameter 6 mm.; length 2.5 cm.) with a male ground joint, and a capillary chimney (O. D. 6 mm.; I. D. 2 mm.; length 2.5 cm.) with a female ground joint on one end and a constricted bore of 0.5 mm. diameter on the other. Each of these two parts is wound with a few turns of no. 26 nichrome wire. Of the four substances studied (aside from arsenic trioxide), sulfur nitride required the lowest heating current and orpiment the highest. No attempt was made to measure the temperature of the vapor in the nozzle; evidently it was never as high as the softening point of Pyrex glass. A diagram of the nozzle is shown in Fig. 1.

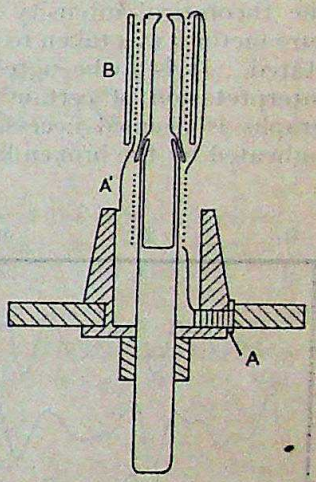

Fig. 1.—Diagram of the high temperature nozzle: A,A', leads for heating coil; B, glass shield for upper part of chimney. In actual practice the entire chimney was wrapped in asbestos.

The photographs were examined on a viewing box, and, for the outer rings, two or more good, heavy photographs were superimposed and examined on a Triplett and Barton viewing lamp of adjustable illumination aperture and intensity. Measurements of the diffraction features were made on a comparator in the usual manner. All the intensity patterns could be observed up to or beyond $q = 80$. The photographs were all corrected for film expansion by measuring two fiducial distances on the film.

Interpretation.—Both the radial distribution method[24] and the correlation method[25] were used in interpreting the photographs. The radial distribution functions were calculated from the visual intensity curves by means of the following equation

$$rD(r) = \sum_{q=1}^{q_{max}} I(q)e^{-aq^2} \sin\left(\frac{\pi}{10} qr\right)$$

where a was so determined that e^{-aq^2} was 1/10 or 1/20 at $q = 90$. The unobservable first feature of the visual curve (dotted part) was introduced arbitrarily. (In the case of sulfur, this first feature was taken from the theoretical intensity curves, *cf.* Fig. 2.) On the other hand, for the correlation treatment the simplified theoretical scattering formula,[24] was used to calculate

$$I^{\circ}(q) = \sum_{i,j}{}' \frac{Z_i Z_j}{r_{ij}} e^{-b_{ij}q^2} \sin\left(\frac{\pi}{10} r_{ij}q\right)$$

the theoretical intensity curves. The temperature factor b was taken to be zero unless otherwise stated. It is to be noted that sometimes a reinterpretation of certain features of the photographs is deemed necessary. Such a change is indicated by the broken lines on the visual curve.

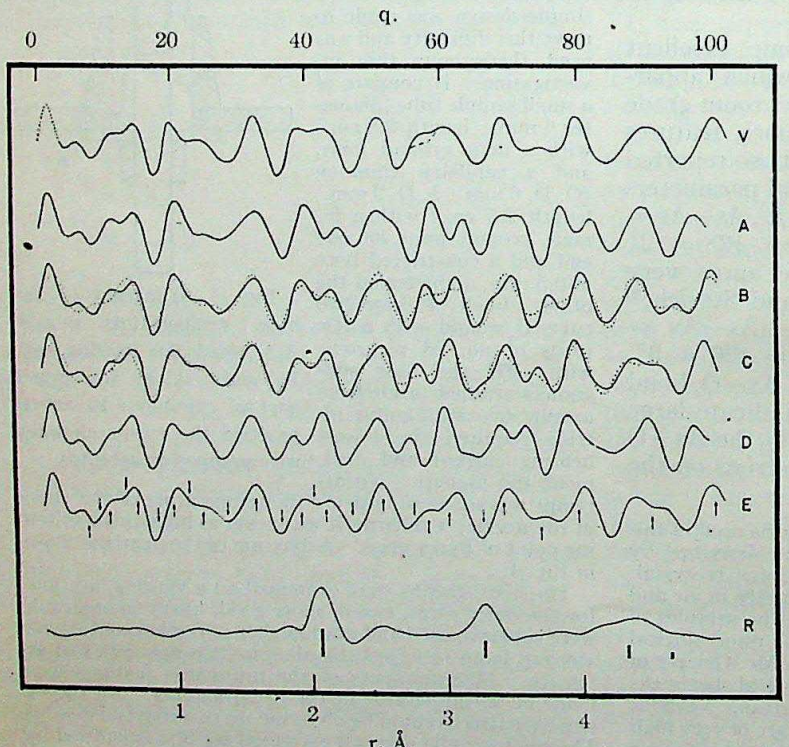

Fig. 2.—Electron diffraction curves for sulfur, S_8

	S.S, Å.	<S.S.S	Remarks
A	2.07	100°	
B	2.07	103°	
C	2.07	106°	
D	2.07	109°	
E	2.07	104°50′	Temperature factor (b = 0.0009) for two longer terms

We shall describe our results obtained in this investigation in the following order: sulfur, orpiment, sulfur nitride and realgar.

Sulfur.—The electron diffraction pattern of the sulfur molecule S_8 is depicted in curve V of Fig. 2. The radial distribution function R calculated for this visual curve gives two sharp peaks at 2.07 and 3.28 Å. and a broad peak at 4.3–4.4 Å. From these we obtain S.S = 2.07 ± 0.02 Å. and ∠ S–S–S = 105 ± 2°. The broad peak should then arise from the longer S–S terms, which, for a regular puckered eight-ring, would be 4.34 and 4.67 Å., with weights *ca.* 2:1. Several configurations derivable from a regular puckered ring by systematic distortions, such as the "tub" form, the "chair" form, the "cradle" form and the "butterfly" form (Fig. 3), have been shown to be incompatible with the radial distribution peak at 4.3–4.4 Å. Therefore the fraction of sulfur molecules having these configurations in the vapor phase must be small.

Four theoretical intensity curves A–D were calculated for regular puckered ring models with S–S = 2.07 Å. and ∠ S–S–S = 100°, 103°, 106° and 109°, respectively. In order to estimate the thermal vibration of the ring two more theoretical curves (dotted curves) including only the two shortest terms were calculated for the models B and C. Qualitative comparison reveals at once that there is a rather large thermal vibration associated with the puckered ring structure. (We estimate from the curves B and C that $\sqrt{\overline{\delta r^2}} \cong 0.15$ Å. for the two longer S–S terms. Curve E calculated with S–S = 2.07 Å., ∠S–S–S = 104°50′, and this amplitude of vibration (corresponding to b = 0.0009) for the two long terms is seen to agree very well with the visual curve.) Quantitative comparison of the observed and the calculated features is given in Table I.

Both the electron diffraction values of Howe and Lark-Horovitz[19] (S–S = 2.08 ± 0.02 Å.) and the x-ray values of Warren and Burwell[18] (S–S = 2.12 Å., ∠ S–S–S = 105°) for the sulfur molecule agree satisfactorily with our present results.

Orpiment.—The fused orpiment and the precipitated arsenic trisulfide gave identical electron diffraction patterns, which are depicted in curve V of Fig. 4. The radial distribution function R calculated for this visual intensity curve gives a sharp peak at 2.25 Å. and a peak at 3.46 Å. with a broad shoulder on the outside. The first peak (2.25 ± 0.02 Å.) corresponds to a single-bond As–S distance.[26] No

plausible model, however, can be constructed for As_2S_3 such that the As—S bonds would be expected to be essentially single bonds and such that the peaks in the radial distribution function are satisfactorily accounted for. Hence, it is likely that the orpiment molecule in the vapor phase is As_4S_6 and has the As_4O_6 structure. For As_4S_6 with this structure, with As—S = 2.25 Å. and ∠ As—S—As = 100°, we would expect a large As—As peak at 3.45 Å., a small S—S peak at 3.77 Å. (which possibly falls in the shoulder of the As—As peak), a large As—S peak at 4.25 Å., and a negligibly small S—S peak at 5.33 Å. Theoretical intensity curves calculated for this model with As—S = 2.25 Å. and ∠ As—S—As = 97°, 100°, and 103°, respectively, are shown in curves A—C of Fig. 4. In order to estimate the thermal effect on such a rigid model, we calculated two more theoretical curves (dotted curves) including only the three shorter terms for the models B and C. From a qualitative comparison of the curves B and C with the visual curve it is easily seen that if As_4S_6 molecules do exist in the vapor phase they cannot be as rigid as the As_4O_6 molecules. This loss of rigidity is probably due to the high temperature used in our investigation.

Curve D was calculated for an As_4S_6 model with

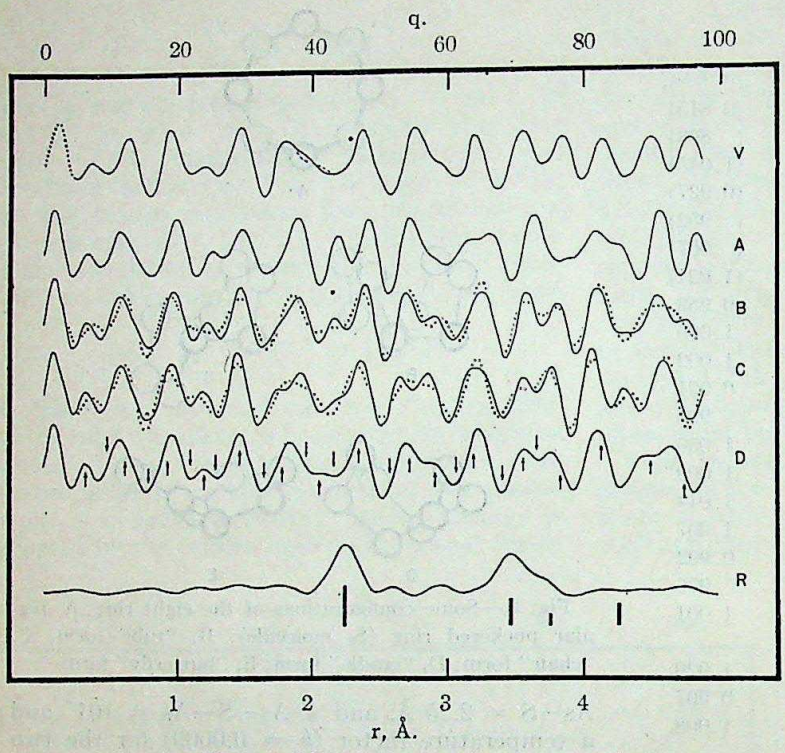

Fig. 4.—Electron diffraction curves for orpiment, As_4S_6:

	As-S, Å	<As-S-As	Remarks
A	2.25	97°	
B	2.25	100°	
C	2.25	103°	
D	2.25	101°	Temperature factor (b = 0.0009) for two longest terms

observed and the calculated features is given in Table II. Our final parameters are as follows: As−S = 2.25 ± 0.02 Å., ∠ As−S−As = 100 ± 2° (∠ S−As−S = 114 ± 2°). The As_4S_6 molecules exhibit large thermal vibration under our experimental conditions.

The orpiment crystal probably bears a similar relationship to As_4S_6 molecules as orthorhombic antimony trioxide (valentinite)[27] does to Sb_4O_6, and possibly even as monoclinic arsenic trioxide (claudetite) does to As_4O_6, although the crystal structure of claudetite is not yet known.

It is interesting to note that Medlin[28] obtained for orpiment the following interatomic distance peaks: 2.24 Å. (somewhat asymmetric), 3.46 Å., and 4.39 Å., from the radial distribution treatment of x-ray powder photographs. Although the close agreement with our radial distribution function is apparently coincidental, this tends to indicate that the bond lengths and bond angles in the orpiment crystal are not subject to severe deformation during the process of volatilization.

Sulfur Nitride.—The electron diffraction pattern of the sulfur nitride molecule S_4N_4 is represented by curve V of Fig. 5. The radial distribution function R calculated for this visual intensity curve gives a sharp peak at 1.62 Å., another equally sharp but somewhat stronger peak at 2.69 Å. with a slight asymmetry on the inside, followed by a small shouldering peak at about 3.1 Å., a small peak at 3.78 Å., and possibly another small but broad peak at about 4.2 Å. The first peak at 1.62 Å. undoubtedly arises from the N−S bonds in the sulfur nitride molecule. Since the length of a single S−N bond is expected to be *ca.* 1.74 Å. while that of a double bond is *ca.* 1.54 Å.,[26] it seems that practically all the S−N bonds in the sulfur nitride molecule would have considerable amounts of double bond character. The second peak at 2.69 Å. might be interpreted as due mostly to the S−S intractions; if this is the case, the bond angle ∠ S−N−S would be close to 112°. Meanwhile, the relative sizes of the first two peaks might have some significance which must be taken into consideration. At any rate, our radial distribution function indicates that the sulfur nitride molecule is rather compact, since no important long distance in the molecule is shown by it.

The height of the first peak and its shape would exclude all models involving either more than one direct bond between the sulfur atoms or more than two N−N bonds. Hence the structural formulas II and IV are very improbable. Formula III, on the other hand, is not likely to be correct since the radial distribution function indicates that there is no important distance longer than 3.1 Å. in the molecule. Jaeger and Zanstra's model (V) is also not acceptable, because even if the N−S bond length and the size of the nitrogen bisphenoid should be made more reasonable, the interatomic distance spectrum of the radial distribution function could not be fitted at all. As a matter of fact, we have not been able to find any satisfactory models consisting of two interpenetrating concentric bisphenoids of nitrogen and sulfur atoms.

Formula VI represents a limiting case of one of the several plausible configurations which can be derived from a regular puckered eight-ring of alternate sulfur and nitrogen atoms by systematic distortions. Calculations were made for two planar models of formula VI with N−S = 1.62 Å. and S−S = 2.08 Å. and 1.88 Å., respectively. The theoretical curves A_1 and A_2 are shown in Fig. 5; and the corresponding interatomic distance spectra are shown under R. Since the

inter-ring distances contribute less than one-fifth of the total molecular scattering, the analysis of these two planar models suffices to show that such a configuration, suggested by Arnold, Hugill and Hutson,[8] is not likely, insofar as it is impossible to get a sufficiently important term at about 3.1 Å. The counterpart of such a configuration obtained by the exchange of the sulfur and nitrogen atoms is equally unsatisfactory.

A regular puckered ring model was also investigated. With N−S = 1.62 Å. and ∠S−N−S = 112°, and the angle ∠ N−S−N taken as a variable parameter, satisfactory agreement with the radial distribution function can be obtained (although the relative heights of the peaks are not correct), but only with the unreasonably small value 70° for the sulfur bond angle.

Two other simple "cradle" models, one the counterpart of the other, can be derived from the puckered ring configuration. One consisting of a bisphenoid of nitrogen atoms and a square of sulfur atoms was found to be unlikely by comparison with the radial distribution function and by calculation of a theoretical curve for a model (curve B, Fig. 5) of this type which most nearly agrees with the radial distribution function. The limiting form of this structure, obtained by reducing the N−N distance across the "cradle" to 1.47 Å., the N−N single bond distance,[29] cannot be made to fit the radial distribution function and at best demands unreasonably small nonbonded N−N distances and sulfur bond angles. Essentially the same difficulties are encountered with the less symmetrical model analogous to this which would be taken as the modern realization of formula I. The counterpart of this "cradle" configuration, consisting of a bisphenoid of sulfur atoms and a square of nitrogen atoms, is, on the other hand, a promising configuration. A model with N−S = 1.62 Å., ∠ S−N−S = 112°, and ∠ N−S−N = 106° (the distribution of the sulfur atoms is tetrahedral in this model) gives curve C of Fig. 5; the corresponding interatomic distance spectrum is shown under R. Quantitative comparison of the observed features and those calculated for this model is given in Table III.

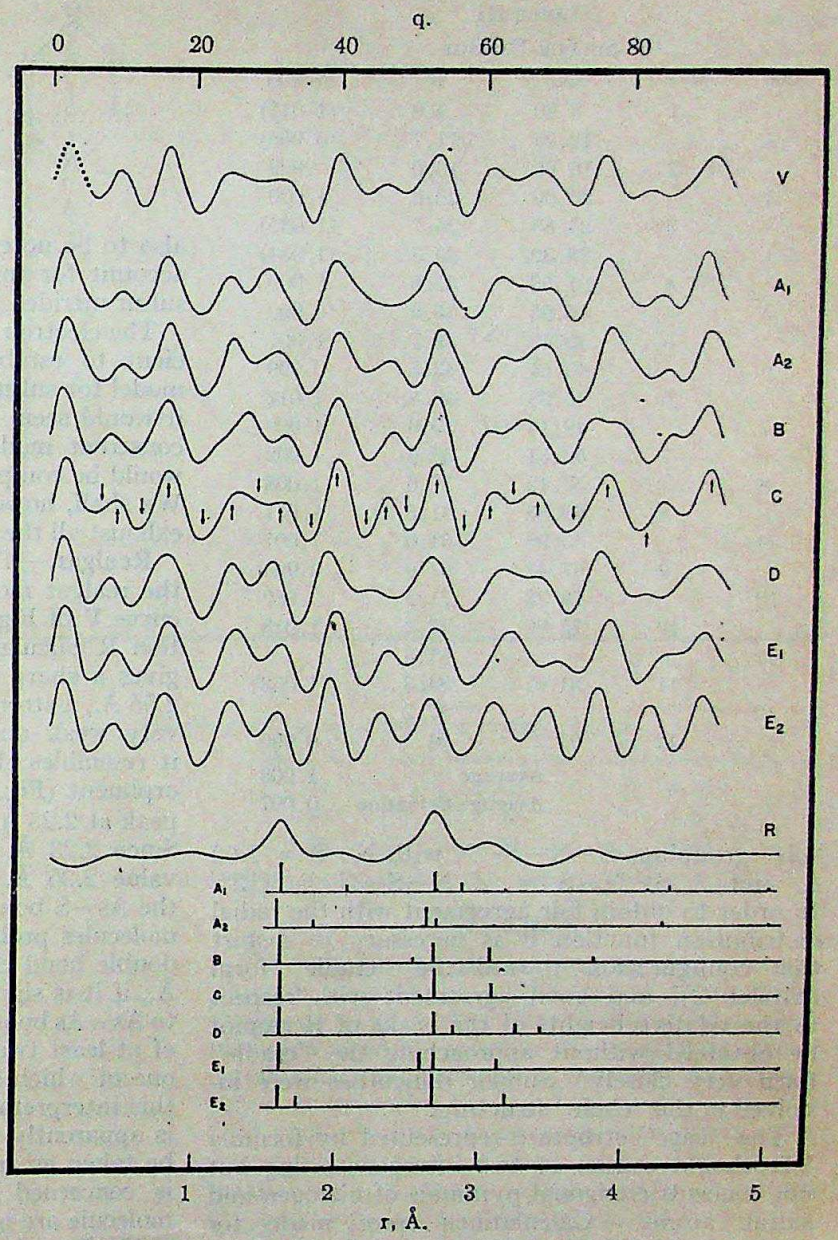

Fig. 5.—Electron diffraction curves for sulfur nitride, S_4N_4:

Configuration

- A_1 formula VI, planar, S–S = 2.08 Å.
- A_2 formula VI, planar, S–S = 1.88 Å.
- B "cradle," bisphenoid of nitrogen atoms, N–N = 2.55 Å.
- C Our proposed structure (*cf.* Fig. 7)
- D "tub" form
- E_1 "cage" form (formula VII), intervening N–S = 1.62 Å.
- E_2 "cage" form (formula VII), intervening N–S = 1.74 Å.

Models of the "chair" and of the "tub" forms derived from the puckered ring configuration were also considered but were found to be unsatisfactory. Curve D of Fig. 5 was calculated for a "tub" model involving four coplanar

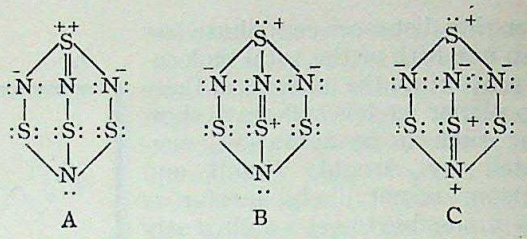
"*cis*" groupings S−N−S−N with N−S = 1.62 Å. and ∠ S−N−S = ∠ N−S−N = 112°. In order to obtain fair agreement with the radial distribution function it is necessary to distort this configuration toward the "cradle" form (Model C), and good agreement with respect to the relative heights of the peaks of R cannot be obtained without approaching the "cradle" form very closely. Similar difficulties were involved in the "chair" structure.

The "cage" structure represented by formula VII should consist of two interpenetrating but not concentric trigonal pyramids of nitrogen and sulfur atoms. Calculations were made for models with N−S = 1.62 Å., ∠ S−N−S = ∠ N−S−N = 112° for the two end groups NS_3 and SN_3 and the intervening N−S = 1.62 Å. and 1.74 Å., respectively. The theoretical intensity curves E_1 and E_2 are given in Fig. 5 together with the corresponding interatomic distance spectra. Since five parameters (namely, three distances for the S−N bonds and two pyramidal angles) are required to describe this structure if it has symmetry C_{3v}, it should be possible to construct models with this "cage" configuration in satisfactory agreement with the diffraction pattern. Nevertheless we believe that this configuration may be rejected by consideration of the following plausible bond structures which makes it difficult to understand how the N−S bonds could have such a considerable amount of double bond character as is indicated by the short average bond length 1.62 Å. It is also to be noted that this structure could hardly account for most of the chemical properties of sulfur nitride.



A B C

The electron diffraction data alone are not sufficient to establish with certainty the "cradle" model for sulfur nitride, and, as a matter of fact, it would seem to be not altogether impossible to construct models of other configurations which would be compatible with the diffraction pattern. We shall, however, make no further attempt to exhaust all the possibilities.

Realgar.—The electron diffraction pattern of the realgar molecule As_4S_4 is represented by the curve V of Fig. 6. The radial distribution function R calculated for this visual intensity curve gives a sharp peak at 2.23 Å., a small peak at 2.55 Å., a strong but broad peak at 3.50 Å., and a very weak and broad peak at about 4.75 Å.; it resembles the radial distribution function for orpiment (Fig. 4) to a certain extent. The first peak at 2.23 Å. must arise from the As−S bonds. Since 2.23 Å. is very close to the single bond value 2.25 Å. found in the orpiment molecule, the As−S bonds in the realgar and the orpiment molecules probably have comparable amounts of double bond character. The small peak at 2.55 Å., if it is significant, may be interpreted as due to As−As bonds. The next peak seems to consist of at least two unresolved interatomic distances, one of which is an As−As term. According to this interpretation the bond angle ∠ As−S−As is apparently not greater than 106°. This may be taken as an indication that as far as bonding is concerned the sulfur atoms in the realgar molecule are more like those in dimethyl disulfide (107°)[30] and in sulfur (105°) than like those in sulfur dioxide (120°).[31] It is interesting to note that there is no important long distance in the realgar molecule.

The formulas II–IV suggested for the sulfur nitride molecule could also be formulated for the realgar molecule. None of them, however, could be made to fit the radial distribution function. A regular puckered eight-ring of alternate arsenic and sulfur atoms is also not acceptable. Since the bond angle ∠ As−S−As is small relative to the tetrahedral angle we were unable to construct a satisfactory "cage" model.

On the other hand, a "cradle" configuration consisting of a bisphenoid of arsenic atoms and a

square of sulfur atoms (involving rearrangement of bonds in the formula proposed by Szarvasy and Messinger[11]) was found to be plausible. Theoretical intensity curves A–C were calculated for such "cradle" models with As–S = 2.23 Å., As–As = 2.44, 2.49, and 2.55 Å., respectively, and the weighted average value of the longer As–As and As–S terms at about 3.50 Å. These are shown in Fig. 6. Curve B reproduces the qualitative features rather satisfactorily. Quantitative comparison of the observed and the calculated features is given in Table IV. As in the case of sulfur nitride, no attempt is made to exhaust all the possible models of other configurations that are compatible with the diffraction pattern.

Incidentally it is to be noted that Medlin,[28] from the radial distribution treatment of x-ray powder photographs, obtained for realgar the following interatomic distance peaks: 2.16 (somewhat asymmetric), 3.54 and 4.52 Å. The agreement with our finding is not at all disappointing.

Discussion

The structure of the sulfur molecule is essentially the same as that in the crystal, as was to be expected. The large thermal libration of the puckered sulfur molecule is apparently associated with the flexibility of the eight-ring structure. In orpiment the bond angle ∠ As–S–As (100 ± 2°) is found to be much smaller than the corresponding angle ∠ As–O–As (128 ± 2°) in the As_4O_6 molecule. This effectively draws the neighbors to the arsenic atoms closer without perturbing the coördination of the sulfur atoms to an unnecessary extent. The double bond character of the As–S bonds is also diminished.

Our results on the sulfur nitride and realgar molecules are gratifying insofar as these help to make another step forward in the solution of these two unsolved problems in structural chemistry. These structures cannot yet be established with certainty, although several of the structures proposed by previous workers are definitely eliminated. We believe that a detailed analysis of the crystal structures of sulfur nitride and realgar, which should be simplified by our present results, will lead to the ultimate solution of these two problems. (The ease of sublimation of these substances and their solubility in several organic solvents indicate that the crystals are molecular. It seems likely that the structures in vapor and crystal are similar.) Wartime duties, however,

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

prevent us from undertaking an extensive x-ray investigation at this time.

We have shown from our electron diffraction data that "cradle" structures lead to satisfactory models (Fig. 7). For the sulfur nitride molecule this "cradle" model consists of a bisphenoid of sulfur atoms and a square of nitrogen atoms, with N−S = 1.62 Å., ∠ S−N−S = 112°, and ∠ N−S−N = 106°. For the realgar molecule the vertices of the bisphenoid are occupied by the arsenic atoms instead of the sulfur atoms, and these arsenic atoms are connected by single bonds. The dimensions are as follows: As−S = 2.23 Å. (±0.02 Å.), As−As = 2.49 (±0.04 Å.), ∠ As−S−As = 101°, ∠ S−As−S = 93°, and ∠ S−As−As = 100°.

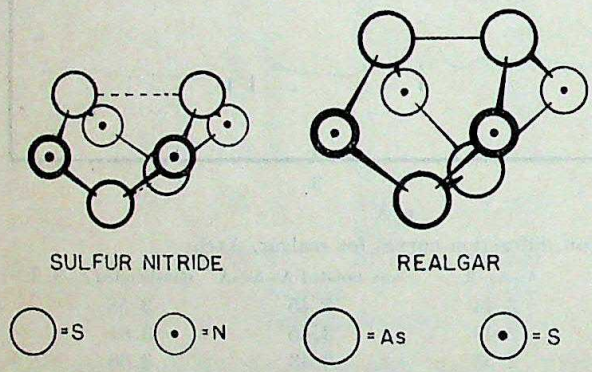

Fig. 7.—The molecular structures proposed for realgar and sulfur nitride.

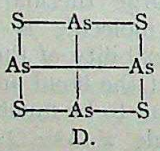
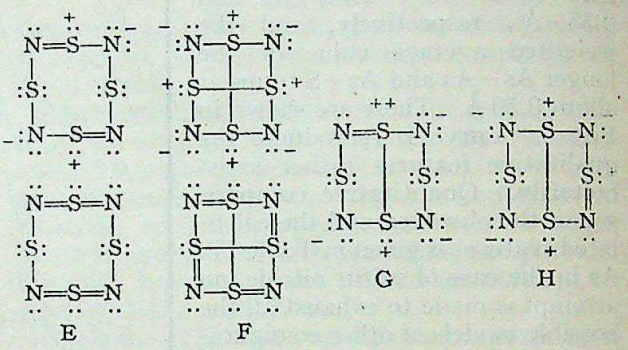
Our "cradle" structure for the realgar molecule is conventional as is indicated by the bond structure D and the observed bond lengths. Its



D.

simple relationship to the structure of the As_4S_6 molecule is borne out by the fact that orpiment and realgar can be easily converted into one another at high temperatures. The conversion of realgar to orpiment would involve simply inserting a sulfur atom between each As−As pair. Moreover, the chemical reactions of realgar are in general typical of sulfides and trivalent arsenic compounds.

If the arsenic atoms of this model for the realgar molecule were now replaced by nitrogen atoms and the N−N bonds across the "cradle" were made practically single bonds, then in order to make the side of the sulfur square *ca.* 2.7 Å. in length the non-bonded N−N distance and the sulfur bond angle would have to be too small to be reasonable; also, the stronger tendency of the sulfur atoms (compared with the nitrogen atoms) toward high coördination would never be realized. The "cradle" model for the sulfur nitride molecule, on the other hand, does not involve any such difficulty, although it should be noted that the S−S distances in this model are much shorter than the ordinary van der Waals separation (3.7 Å.[26]). Our structure probably involves resonance among the following bond structures, including some of those in which sulfur has a decet of electrons, and other less important ones.



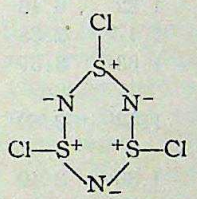
Of these structures E is probably the most important. Hence each N−S bond is expected to have about 25% double bond character, which is borne out by the short bond length of 1.62 Å. The bond angles, *ca.* 112° for ∠ S−N−S and 106° for ∠ N−S−N, are also reasonable for this type of bond structure. However, it must be pointed out that the deviation of the S−N−S−N groupings from the "*cis*" configuration is great (*ca.* 58°). Since a similar situation is found in the similar compact structures of As_4O_6, P_4O_6 and P_4O_{10} molecules, where it has been argued[26] that the bonds have considerable amounts of double bond character, it may well be true that the coplanarity condition for the configuration of such groupings is not stringent when other than first first-row atoms are involved because of the available *d* orbitals for bond formation. It should also be noted that the short S−S distances across the "cradle" (*ca.* 2.69 Å.) give an indication of the importance of the bond structures F, G and H. We believe that the stability of such structures as these and the choice between the two "cradle" structures for the sulfur nitride and realgar molecules depends to a large extent upon a delicate balance between the difference in sizes, coördination tendencies, and multiple-bond-forming powers of the two kinds of atoms on one hand and the difference in their electronegativities and the distribution of formal charges on the other. This helps us to understand why such molecules as N_4O_4 and P_4S_4 are unstable and are not known to exist.

It may be mentioned that our "cradle" structure for the sulfur nitride molecule is rather closely related to Arnold, Hugill and Hutson's model,[8] and also to the formula IV proposed by Ruff and Geisel[3] and supported by Meuwsen.[4] It is accordingly not surprising that our structure accounts satisfactorily for the chemical considerations Ruff and Geisel,[3] Meuwsen,[4] and Arnold, Hugill and Hutson[8] brought forward to support

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

their respective formulas. Thus when sulfur nitride is hydrogenated the resulting substance $H_4N_4S_4$,[4] presumably has a ring structure with alternate sulfur and (imino) nitrogen atoms. (The structure of $H_4N_4S_4$ reported by Jaeger and Zanstra[5] cannot be correct for the same reasons which we have discussed in regard to their structure of sulfur nitride.) In the formation of the thiotrithiazyl ion[9] $(N_3S_4)^+$ on boiling sulfur nitride with acetyl chloride, the "cradle" structure with its eight-ring is apparently torn open, giving rise to an ion having possibly the following chain structure: $S{=}N-{}^+S{=}N-S-N{=}S$, which derives its stability from resonance between two identical bond structures. The molecule is also degraded on chlorination with the formation of $(SNCl)_3$,[4] which possibly has the structure



The existence of $(SNCl)_4$ is probable, although it has not been definitely established. Regarding the formation of coördination compounds of sulfur nitride with metallic chlorides such as $SnCl_4$ and $MoCl_4$,[32] Arnold, Hugill and Hutson's explanation[8] in terms of a "unique" sulfur atom in the sulfur nitride molecule is by no means necessary.

We wish to thank Dr. V. Schomaker for helpful suggestions and illuminating discussions.

Summary

Sulfur (S_8), orpiment (As_4S_6), sulfur nitride (S_4N_4), and realgar (As_4S_4) were studied by the method of electron diffraction. The S_8 molecule is a regular puckered-ring with S—S = 2.07 ± 0.02 Å. and ∠ S—S—S = 105 ± 2°, and it exhibits a rather large amplitude of thermal vibration. Orpiment sublimes at high temperatures, presumably to give As_4S_6 molecules which have the As_4O_6 structure and the following dimensions: As—S = 2.25 ± 0.02 Å., ∠ As—S—As = 100 ± 2° (∠ S—As—S = 114 ± 2°). The molecular structures of sulfur nitride S_4N_4 and realgar As_4S_4 cannot be established with certainty from the electron diffraction data alone, although several structures proposed by previous workers are definitely eliminated. We have shown that cradle-shaped configurations of an alternating eight-ring lead to satisfactory models. For sulfur nitride this "cradle" model consists of a bisphenoid of sulfur atoms and a square of nitrogen atoms, with N—S = 1.62 ± 0.02 Å., S—S = 2.69 Å., ∠ S—N—S = 112° and ∠ N—S—N = 106°. For realgar the model consists of a bisphenoid of arsenic atoms and a square of sulfur atoms with As—S = 2.23 ± 0.02 Å., As—As = 2.49 ± 0.04 Å., and ∠ As—S—As = 101 ± 4° (∠ S—As—S = 93°; ∠ S—As—As = 100°). These results are discussed, special attention being given to the unconventional sulfur nitride structure and its relation to the realgar structure.

The Behavior of γ-Keto- and Aldehydo-Acid Derivatives at the Dropping Mercury Electrode. I. Esters and Anhydrides of 2-Benzoylbenzoic Acid

BY S. WAWZONEK,[1] H. A. LAITINEN AND S. J. KWIATKOWSKI

γ-Keto- and aldehydo-acids are of special interest since they and their derivatives can exist in two isomeric forms. Assignment of structure to these forms has been concerned mainly with the isomeric methyl and ethyl esters and has been accomplished both by chemical and physical means. Physical methods such as absorption spectra[2] and the use of refractive indices[3] have in general required both isomeric forms. Chemical methods used have been mainly generalizations. The most important of these is the rapid hydrolysis of the cyclic ester by means of concentrated sulfuric acid to give highly colored solutions in contrast to slow hydrolysis and a weaker color in the case of the normal esters.[4] Recent investigations have shown this test to be unsatisfactory in numerous cases.[5]

In this paper the use of the polarograph as a means of assigning structures to the esters of 2-benzoylbenzoic acid will be presented. The behavior of certain anhydrides at the dropping mercury electrode will likewise be mentioned. The study of certain amides of 2-benzoylbenzoic acid is described in the accompanying paper.[6] Work with other types of γ-keto- and aldehydo-acid derivatives is now in progress.

In general all of the compounds gave well-defined reduction waves. Maxima could be suppressed in most cases by means of gelatin. Addition of gelatin was noticed to cause a catalytic hydrogen discharge wave which decreased the voltage range of the buffers and prevented evaluation of waves at more negative potentials.

Absolute *p*H values for the buffers are not given because erratic behavior of hydrogen electrodes made accurate measurements impossible. Comparative values however were determined from the half-wave potentials obtained for anthraquinone. Buffer II was found to be 2.2 *p*H units more alkaline than buffer I.

Discussion of Results

An examination of the half-wave potentials obtained in 0.1 *M* tetrabutylammonium iodide–50% dioxane solution, in which a wide range of potential is possible, indicates that in general all the esters of 2-benzoylbenzoic acid are reduced to the same product, 3-phenylphthalide. A final wave of approximately 1.9 volts, which is characteristic of 3-phenylphthalide, is obtained in practically every case. The cyclic methyl and ethyl esters, apparent exceptions, are reduced at such negative potentials that their wave is combined with that of the resulting 3-phenylphthalide and only one wave with a much higher diffusion current constant than that observed for the other esters is obtained. The formation of such a product from the cyclic derivatives indicates that these compounds are reduced directly to 3-phenylphthalide and ROH (RSH). The normal derivatives on the other hand, must be first reduced to the benzhydrol and then lose ROH (RSH) spontaneously to form 3-phenylphthalide. Further reduction of 3-phenylphthalide probably involves the CO grouping and not the lactone linkage since ethyl benzilate, a vinylog of 3-phenylphthalide, showed no reduction whereas ethyl benzoate can be reduced at the dropping mercury electrode.

Data obtained from the half-wave potentials in buffers I and II indicate that the esters can be divided into two classes. One group which includes the cyclic methyl and ethyl esters is characterized by a stability toward hydrolysis in the more alkaline buffer II, and by half-wave potentials which are independent of *p*H. The stability of this class toward alkali is not surprising since they are ketal-like in structure. A comparison of the half-wave potentials of this group indicates that the ease of reduction increases with increasing ionization constant of the alcohol or phenol concerned. Thus the thiophenyl ester is the easiest to reduce while the reduction of the methyl and ethyl esters becomes more difficult in that order. This behavior is in agreement with the mode of reduction of these compounds to 3-phenylphthalide. This class contains without doubt all the cyclic esters and by coincidence contains the higher melting isomers.

The second class of compounds which contains the normal ethyl and methyl esters is rather irregular in its behavior. The variation of half-wave potentials for the aliphatic esters, ethyl and methyl, with *p*H is similar to that for benzophenone. The shift in value in buffer II, however, may be due to hydrolysis to the acid. The aromatic esters on the other hand are reduced at approximately the same potential of 1.28 volts in both buffers. In the more alkaline buffer II the phenyl ester is slightly hydrolyzed since it gives in addition to the wave at 1.28 volts, a wave with a half-wave potential of 1.53 volts which is characteristic of the acid. The thiophenyl ester gives waves at 1.22, 1.47 and 1.63 volts. The wave at 1.47 volts indicates the probable presence of some of the cyclic derivative. No explanation can be offered for the wave at 1.63 volts. The behavior of this class, provided no interaction has taken place with the buffers, is surprising since due to their structural similarity to benzophenone their half-wave potentials would be expected to vary with *p*H. The similarity in behavior of the isomeric β-naphthol esters as far as the half-wave potentials are concerned is anomalous and is being investigated further. This second class contains all the lower melting esters and must without doubt consist of the normal esters.

The behavior of 2-benzoylbenzoic acid in unbuffered medium, 0.1 *M* tetrabutylammonium iodide–50% dioxane is rather difficult to explain. Neither of the two waves obtained at 1.11 and 1.60 volts, respectively, represents a hydrogen wave since benzoic acid which has approximately the same acidity gives a curve with a half-wave potential of 1.87 volts. The first wave at 1.11 volts no doubt represents a reduction by a mechanism possible only in acid media, the acid being provided by the compound itself. This interpretation is confirmed by results obtained for 2-benzoylbenzoic acid in 0.1 *N* hydrochloric acid, 50% dioxane solution in which a wave with a half-wave potential of 0.95 volt was obtained. After 50% of the acid is reduced in the 0.1 *M* tetra-

Digitized by Arya Samaj Foundation Chennai and eGangotri

butylammonium iodide, 50% dioxane solution, the solution around the drop is no longer acid and a second type of reduction occurs.

The nature of this reduction is not clear but it may possibly be a reduction of the pseudo acid. This same type of reduction appears with some of the anhydrides. In buffered media where the acid is present as an anion, the ion must exist in the open form since the half-wave potential changes with *p*H. Such a behavior is in agreement with absorption spectra data obtained in dilute alkali.[2]

No definite structures can be assigned to the anhydrides due to the fact that they are hydrolyzed or interact with the more alkaline buffer II. The mixed acetic anhydride is largely hydrolyzed in both buffers, and gives a reduction wave characteristic of the 2-benzoylbenzoate ion. The anhydride and 3,3′-diphenyldiphthalyl sulfide are apparently stable in buffer I. The approximately equal reduction potentials observed for these two compounds in buffer I would suggest similar structures provided no interaction has occurred with the buffer.

Experimental

The current–voltage curves were determined with a Model XI, Heyrovsky Polarograph having a current scale calibrated in microamperes. Curves for anthraquinone in buffer I and II were obtained with a Fisher Elecdropode. No changes in anode potential with increasing potential was observed with either of these buffers.

The electrolysis cell had a simple cylindrical shape with a mercury pool anode and was provided with side arms for anode connections and for admission of nitrogen for the removal of dissolved oxygen. Anode potentials were measured against a saturated calomel electrode (S. C. E.) by using a sintered glass salt bridge of the type described by Laitinen.[7]

(7) H. A. Laitinen, *Ind. Eng. Chem., Anal. Ed.*, **13**, 393 (1941).

The dropping mercury electrode had the following characteristics. At a pressure of 46.5 cm. of mercury, the drop time in the solvent used was 3.34 seconds (open circuit). The value of m was 2.05 mg. sec.$^{-1}$ with a calculated value of $m^{2/3}t^{1/6}$ of 1.973 mg. $^{2/3}$ sec.$^{-1/2}$.

Materials.—The solutions used had the following compositions and anode potentials: 0.1 *M* tetrabutylammonium iodide,[8] 50% dioxane, anode potential, −0.400 volt; 0.1 *M* hydrochloric acid, 50% dioxane, anode potential, −0.249 volt.

Buffer I.—A mixture which was 0.172 *M* in tetramethylammonium hydroxide, 0.1 *M* in tetramethylammonium iodide, 0.102 *M* in phosphoric acid and 50% dioxane by volume, anode potential, −0.390 volt.

Buffer II.—A mixture which was 0.196 *M* in tetramethylammonium hydroxide, 0.10 *M* in tetramethylammonium iodide, 0.092 *M* in phosphoric acid and 50% dioxane by volume, anode potential, −0.382 volt.

2-Benzoylbenzoic acid, benzophenone, benzoic acid, ethyl benzoate and anthraquinone were obtained from stock. The aromatic esters,[5a,9] 3-phenylphthalide,[10] 4′-hydroxydiphenylphthalide,[11] anhydrides,[12] 3,3′-diphenyldiphthalyl sulfide,[13] methyl,[4] and ethyl esters[3] were prepared by appropriate methods given in the literature.

Summary

The polarographic method is a suitable means of distinguishing between the cyclic and normal esters of 2-benzoylbenzoic acid.

The anhydrides of 2-benzoylbenzoic acid cannot be assigned structures with certainty since they hydrolyze in more alkaline solutions.

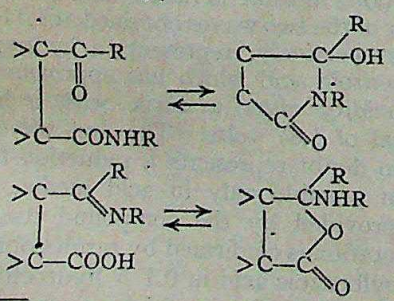
The Behavior of γ-Keto- and Aldehydo-Acid Derivatives at the Dropping Mercury Electrode. II. Amides of 2-Benzoylbenzoic Acid[1]

BY S. WAWZONEK,[2] H. A. LAITINEN AND S. J. KWIATKOWSKI

Amides of γ-keto- and aldehydo-acids can exist in two isomeric forms and can exhibit ring-chain tautomerism of the types



(1) Paper I, THIS JOURNAL, **66**, 827 (1944).

(2) Present address: Department of Chemistry, University of Tennessee, Knoxville, Tennessee.

Chemical evidence can indicate what type of ring-chain tautomerism exists or is possible but does not as a rule denote which form is the predominant one.

In this paper the use of the polarograph as a means of ascertaining the type and the approximate amount of ring-chain tautomerism present with amides of 2-benzoylbenzoic acid will be presented.

Results

The behavior of various amides of 2-benzoylbenzoic acid and their derivatives was studied in both unbuffered and buffered media. A summary of the observed half-wave potentials and individual diffusion current constants in the various solutions is given in Table I.

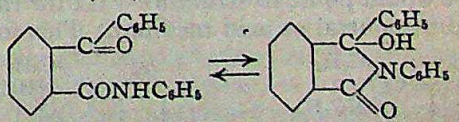
	1.48	3.61	1.12	3.22
	2.05	4.38		3.91

In general all of the compounds gave well-defined reduction waves. Maxima could be suppressed in most cases by means of gelatin. The buffers used are the same as those reported in the first paper.[1] No curves were obtained for the amide or anilide (195°) in buffer I.

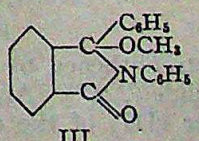
Discussion of Results

An examination of the half-wave potentials obtained in 0.1 *M* tetrabutylammonium iodide, 50% dioxane solution indicates that the amides and their derivatives are reduced in most cases to the corresponding 1-keto-3-phenylisoindole. In each case the final wave obtained corresponds to the values obtained for the related 1-keto-3-phenylisoindole. Both forms apparently yield the same reduction product through mechanisms similar in nature to those proposed for the production of 3-phenylphthalide from the normal and cyclic esters.[1] The normal N-methylanilide and anil-type compounds are reduced in a slightly different manner and will be discussed later.

The anilide (195°) assigned an open structure by Meyer[3] gave three waves. The first wave at 1.48 volts must be due to the reduction of the open form I since such a wave is not shown by the methyl ether (III). The second wave which could



I II



III

not be measured because of a maximum is due to the reduction of the cyclic form (II) and would without doubt be similar in value to the first wave obtained for the methyl ether (III). Disappearance of the wave at 1.48 volts in buffer I

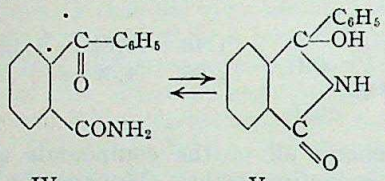
(3) Meyer, *Monatsh.*, **28**, 1211 (1907).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

indicates that alkali easily converts the open form (I) into the cyclic form (II). Comparison of the diffusion current constants of the first two waves would indicate that the anilide (195°) is almost completely present as the open form (I). The small amount of the cyclic form (II) present may be produced by the hydroxide ions formed at the mercury drop during the reduction.[4]

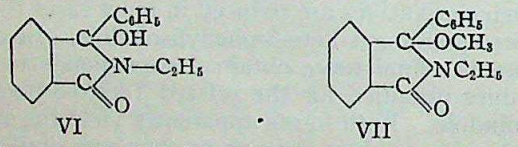
The amide is very similar to the *n*-anilide (195°) in its behavior giving three waves, the first at 1.52 volts disappearing in buffer I. Such a behavior together with a comparison of the diffusion current constants for the first two waves would



IV V

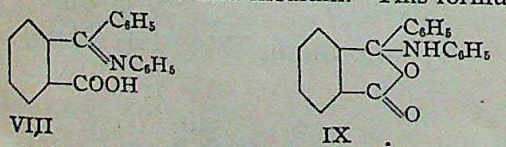
indicate an equilibrium structure for the amide in which approximately one-third is present as the open form (IV) and the remainder as the cyclic derivative (V).

The N-ethylamide (VI) gives only two waves which are very similar to those obtained for its methyl ether (VII). Such a behavior points to the existence of the N-ethylamide entirely in the cyclic form.



VI VII

The anilide (221°), which has been assigned the cyclic form (II) in neutral solution by Meyer,[3] exhibits a behavior at the dropping mercury electrode which is not in accordance with this structure. In unbuffered medium this compound's behavior resembles that of 2-benzoylbenzoic acid[1] in that an early reduction is obtained at 0.96 volt. This wave represents without doubt the reduction of the anil grouping in acid medium, the acid being provided by the compound itself. Such a behavior would point to structure VIII for the compound in neutral or acid medium. This formula-

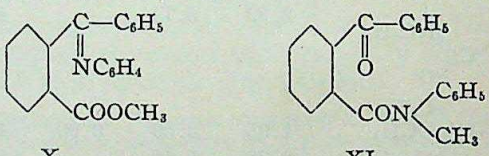


VIII IX

tion is further strengthened by the chemical behavior of the anilide (221°). Attempts to prepare the methyl ether (III) of the cyclic form using methanol and hydrochloric acid gave only the normal methyl ester of 2-benzoylbenzoic acid.

The behavior of the anilide (221°) in buffer I is somewhat irregular. The low diffusion current constant and positive half-wave potential (−1.15 volts) obtained are not in agreement with an anil structure for this compound in this buffer. The values would be expected to be similar to those obtained for the methyl ester (X). If the compound had a cyclic structure (IX), the value would likewise be expected to be more negative since cyclic forms are more difficult to reduce. In buffer II the value of −1.60 volts obtained is in agreement with the anil structure (VIII). The much more negative half-wave potential obtained for this compound than for the methyl ester (X) illustrates the effect of a carboxylate ion on the reduction of the anil group. A similar effect can be seen from a comparison of the half-wave potentials of 2-benzoylbenzoic acid and the normal methyl ester in buffer I.[1]

The methyl ester of the anil (X) and the N-methylanilide (XI) behaved rather similarly in buffered and unbuffered media. In buffered



X XI

media they resembled benzophenone[1] since their half-wave potentials varied with *p*H, and therefore they must have structures X and XI. In unbuffered media the final waves obtained would indicate the formation of an isoindole and 3-phenylphthalide, respectively. The high diffusion currents obtained however preclude the formation of such compounds, instead pointing to the reductions of the ester and anilide groupings respectively, since the values obtained are of approximately the same magnitude as has been observed for ethyl benzoate and benzamide.

Experimental[5]

The conditions and electrode used were exactly the same as described in the first paper of this series.[1]

Materials.—The amide,[6] anilides, anil, methyl ester of the anil, 1-keto-2,3-diphenylisoindole,[3] 1-keto-3-phenylisoindole[7] and N-ethylamide[8] were prepared by appropriate methods given in the literature.

1-Keto-2,3-diphenyl-3-methoxyisoindole (III).—A solution of the anilide (195°) (I) (1.0 g.) in thionyl chloride (10 ml.) was allowed to stand at room temperature for one hour. The excess thionyl chloride was removed under reduced pressure, the resulting solution treated with methanol (75 ml.) and allowed to stand for twelve hours. Addition of water followed by concentration in an air stream gave a white solid (1.0 g.) melting at 125–128°. After two recrystallizations from methanol the compound melted at 128–129°.

Anal. Calcd. for $C_{21}H_{17}O_2N$: C, 80.00; H, 5.40. Found: C, 79.97; H, 5.66.

(4) The estimation of the relative concentrations of the two tautomeric forms relative wave heights is based on the assumption that the rate of the tautomeric shift at the electrode surface is negligibly slow. Two opposing effects should be recognized. A shift to the more easily reduced open form because of its depletion would cause an abnormally high first wave to be obtained. However, the opposite shift is catalyzed by the hydroxyl ions produced at the electrode surface. The estimates of relative amounts of cyclic and open forms should be considered only semi-quantitative.

(5) Melting points are not corrected.

The compound could likewise be prepared in the following manner. A solution of the anilide (195°) (I) (1.0 g.) in methanol (100 ml.) treated with concentrated hydrochloric acid (2 ml.), was allowed to stand at room temperature for seven hours and then refluxed for eleven hours. The resulting solution was neutralized with a sodium carbonate solution, treated with water until precipitation occurred and then concentrated with an air stream. The white solid (1.0 g.) obtained melted at 128–129° and was identical with the compound from the thionyl chloride method.

The anil (221°) (VIII) when treated in a similar fashion to the above gave the normal methyl ester of 2-benzoylbenzoic acid.

Hydrolysis of 1-Keto-2,3-diphenyl-3-methoxyisoindole (III).—A solution of 1-keto-2,3-diphenyl-3-methoxyisoindole (III) (1.0 g.) in acetic acid (20 ml.) and concentrated hydrochloric acid (2 ml.) was allowed to stand for seventeen hours at room temperature. During this time white crystals (0.60 g.) melting at 195–197° separated. An additional amount (0.25 g.) was obtained by addition of water to the filtrate. A mixture with the anilide (195°) (I) gave no lowering when melted together.

1-Keto-2-ethyl-3-methoxy-3-phenylisoindole (VII).—A solution of the N-ethylamide (VI) (1.0 g.) in thionyl chloride (10 ml.) was allowed to stand at room temperature for twenty minutes. The excess thionyl chloride was removed under reduced pressure, methanol (50 ml.) added and the resulting solution allowed to stand at room temperature for eleven hours. Addition of water gave an oil which was taken up in ether and washed with a sodium carbonate solution. Removal of the ether gave an oil which gave white crystals (0.72 g.) upon the addition of 30–60° petroleum ether. After two crystallizations from the same solvent the compound melted at 73–75°.

Anal. Calcd. for $C_{17}H_{17}O_2N$: C, 76.40; H, 6.36. Found: C, 76.33; H, 6.68.

The compound (VII) could likewise be prepared in the following way. A solution of the N-ethylamide (VI) (1.0 g.) in methanol (40 ml.) and concentrated hydrochloric acid (1 ml.) was allowed to stand at room temperature for fourteen hours and then refluxed for ten hours. Neutralization with sodium carbonate followed by concentration in an air stream gave an oil which formed white crystals (0.45 g.) melting at 75–78° which were identical with the above (VII).

Hydrolysis of 1-Keto-2-ethyl-3-methoxy-3-phenylisoindole (VII).—A solution of 1-keto-2 ethyl-3-methoxy-3-phenylisoindole (VII) (0.5 g.) in a mixture of glacial acetic acid (10 ml.) and concentrated hydrochloric acid (1 ml.) was allowed to stand for twelve hours and poured into water. The N-ethyl amide (VI) (0.4 g.) thus obtained melted at 170–173° and gave no lowering when mixed with an authentic sample.

Normal N-Methyl Anilide (XI).—To a cold solution of the acid chloride of 2-benzoylbenzoic acid, prepared from the acid (7.5 g.) and thionyl chloride, in benzene (20 ml.), methylaniline (10 ml.) in dry benzene (10 ml.) was added and the resulting solution allowed to stand for twenty-four hours at room temperature and then poured into water. Extraction with ether followed by washing with dilute acid and sodium bicarbonate gave an oil upon removal of the solvent. The oil upon being taken up in a mixture of benzene and (80–90°) petroleum ether gave, after treatment with norite and aluminum oxide, upon cooling, white crystals (1.5 g.) (XI) which melted at 125–140°. Two crystallizations from the same mixture gave white crystals melting at 144–146°.

Anal. Calcd. for $C_{21}H_{17}O_2N$: C, 80.00; H, 5.39. Found: C, 80.23; H, 5.49.

Summary

The polarographic method offers a suitable means of ascertaining the type and the approximate amount of ring-chain tautomerism present with amides of 2-benzoylbenzoic acid.

Orientation in the Biphenyl System.[1] Derivatives of 2-Aminobiphenyl[2]

BY A. H. POPKIN, G. M. PERRETTA AND R. SELIG

As a continuation of the studies of orientation in the biphenyl system, it was decided to prepare 2-dimethylaminobiphenyl and to observe its behavior in various reactions. This compound should prove more versatile than the 4-isomer[3] because of the possible existence of an activated hydrogen in the 5 position in competition with the known activity of the 4′ hydroxygen.[1,4]

Evans and Williams[5] reported the preparation of 2-dimethylaminobiphenyl in 94% yield from the reaction of dimethyl sulfate on 2-aminobiphenyl. In duplicating this reaction, a 92% yield of methylated product was obtained. On treatment with acetic anhydride followed by distillation, 2-dimethylaminobiphenyl and 2-(N-methyl)-acetamidobiphenyl were obtained in 66:34 ratio. This indicates that the yield previously reported is for a mixture of dimethyl and monomethyl compounds rather than pure dimethyl compound.

The action of methyl alcohol and sulfuric acid on 2-aminobiphenyl at elevated temperature and pressure gave 82–85% yields of a methylated mixture. This when acetylated was found to consist of 2-dimethylaminobiphenyl and 2-(N-methyl)-acetamidobiphenyl in the ratio of 87:13. The identity of the latter was established by analysis and synthesis in 84% yield by the reaction of sodium and methyl iodide on a solution of 2-acetamidobiphenyl in dry xylene.

2-(N-Methyl)-acetamidobiphenyl showed a greater stability toward hydrolysis than 2-acetamidobiphenyl and its derivatives[6] which is in agreement with the observation of Schoorl[7] on the stability of N-methylacetanilide.

A preliminary study of the behavior of 2-dimethylaminobiphenyl indicated the existence of a para-bond activation similar to that in dimethylaniline. When dimethylaniline is oxidized with cupric chloride[8] Methyl Violet is formed. Oxidation of 2-dimethylaminobiphenyl under the same conditions resulted in a dyestuff having color and lake-forming properties characteristic of triphenylmethane dyes of the Methyl Violet type.

Experimental

Preparation of 2-Dimethylaminobiphenyl: Method 1.—Into a 2-liter beaker was placed 254 g. of 2-aminobiphenyl (Monsanto Chemical Company). To this was added slowly and with stirring 675 g. of dimethyl sulfate and 270 g. of 30% aqueous sodium hydroxide solution, the addition requiring four hours. The dimethyl sulfate was added in approximately 15-g. portions, each followed by a portion of sodium hydroxide solution until neutrality was obtained. The temperature was maintained below 30°. An additional 130 cc. of the sodium hydroxide solution then was required to bring about complete neutrality. The product was present as two layers. The upper layer, after separation and washing with two portions of 150 cc. of water, weighed 270 g., 92% yield. This was treated with 57 g. of acetic anhydride. A temperature rise of ten degrees was obtained indicating a substantial quantity of *n*-monomethylaminobiphenyl. The product was distilled at 30 mm. pressure through a Claisen flask to give: fractions 1 and 2, 26.5 g., 33–130°; 3–7, 161.8 g., 130–190°; 8 and 9, 84.0 g., 190–225°; 10, residue, 13.0 g.

Fractions 1 and 2 contained acetic acid and acetic anhydride. Fractions 3–7 are 2-dimethylaminobiphenyl, 0.82 mole, and 8–10 are 2-(N-methyl)-acetamidobiphenyl, m. p. 79–87°, 0.43 mole. This represents a ratio of 66% of dimethylaminobiphenyl to 34% of monomethyl compound.

Fractions 3–7 were redistilled through an efficient fractionating column of the total condensation, variable take-off type[9] having twelve theoretical plates. Acetic anhydride was not present in the first fractions and no appreciable residue was obtained. The purified 2-dimethylaminobiphenyl boiled at 115–116° (2–3 mm.); $n^{20}D$ 1.6052–1.6058.

Purification of a portion of fractions 8–10 by crystallization from a petroleum hydrocarbon (70–95°) gave 2-(N-methyl)-acetamidobiphenyl, m. p. 98–99°.

Anal. Calcd. for $C_{15}H_{15}NO$: C, 80.0; H, 6.71; N, 6.22. Found: C, 80.6; H, 6.77; N, 6.30.

Two similar reactions gave checking yields and comparable ratios of 2-dimethylaminobiphenyl and 2-(N-methyl)-acetamidobiphenyl.

Method 2.—A mixture was made of 67 g. of 2-aminobiphenyl, 74 g. of absolute methyl alcohol and 7 g. of concd. sulfuric acid. This was heated in an autoclave for five hours at 205–210° and 420–490 lb. pressure. The resulting mixture was brought to *p*H 11 with a 10% sodium hydroxide solution and the oil which formed was extracted with ether. The solvent was removed in a Claisen flask and the oil distilled at 143–147° (10 mm.); wt. 65.6 g., 85% yield. Several similar reactions gave 82–85% yield.

Treatment of this product with acetic anhydride and careful fractionation through an efficient column gave 2-dimethylaminobiphenyl, b. p. 118–120° (2.5 mm.), $n^{20}D$ 1.6046–1.6050, and a residue of 2-(N-methyl)-acetamidobiphenyl, m. p. 83–91°. Purification by crystallization from a low-boiling petroleum hydrocarbon resulted in crystals, m. p. 98–99°, which when mixed with the same material obtained above gave an identical melting point. The ratio of 2-dimethylaminobiphenyl to monomethyl compound was 87:13.

It was thought that the discrepancy in the boiling point and refractive index of 2-dimethylaminobiphenyl from the values obtained by Method 1 might be due to the presence of traces of 2-monomethylaminobiphenyl. A second treatment of the purified material with acetic anhydride followed by redistillation produced no change in the constants.

Preparation of 2-(N-Methyl)-acetamidobiphenyl.—A solution was made of 31.5 g. of 2-acetamidobiphenyl, m. p. 119–120°, in 200 cc. of dry xylene. To this was added 5 g. of metallic sodium and the mixture heated at 120–130° for three hours. A clear xylene solution was decanted from the excess of sodium and treated with 25 g. of methyl iodide. The mixture was refluxed and within fifteen minutes a white precipitate was formed. The xylene then was removed by heating and a thick white paste resulted. This was treated with 100 cc. of water and dilute acetic acid added to bring the *p*H to 6. The remaining xylene was removed by steam distillation until the density of the oil was greater than that of the water solution. The two phases were brought to room temperature, the upper aqueous portion decanted, and the oil washed with 300 cc. of water. This treatment converted the oil to a solid, m. p. 90–95°, wt. 28.2 g., 84% yield. One purification with Norite and two recrystallizations from a petroleum fraction (70–95°) gave crystals, m. p. 96–98°. A mixed m. p. with 2-(N-methyl)-acetamidobiphenyl (above) gave no depression in the melting point.

Stability of 2-(N-Methyl)-acetamidobiphenyl toward Hydrolysis.—Treatment of 2.5 g. of 2-(N-methyl)-acetamidobiphenyl in methyl alcohol solution with 5 cc. of concd. hydrochloric acid during fifteen minutes at reflux temperature[6] gave only unreacted 2-(N-methyl)-acetamidobiphenyl. Addition of 5 cc. of concd. hydrochloric acid to 1.5 g. of the same material resulted in a clear solution which when refluxed for fifteen minutes again gave the unhydrolyzed starting material. The reaction of 4 g. of the 2-(N-methyl)-acetamidobiphenyl, dissolved in 150 cc. of alcohol, with 3 cc. of a 30% sodium hydroxide solution at reflux temperature for ten hours,[7] produced only unreacted 2-(N-methyl)-acetamidobiphenyl.

Oxidation of 2-Dimethylaminobiphenyl.—A mixture of 2-dimethylaminobiphenyl, cupric sulfate, phenol, salt and water was treated in the usual manner.[8] A colored base thus was obtained corresponding to a Methyl Violet which has a phenyl group ortho to each of the three methylamino groups. It has the properties characteristic of Methyl Violet, resulting from oxidized dimethylaniline, *i. e.*, it forms a blue-violet solution with organic acids and alcohols, dissolves in concd. hydrochloric acid to give a reddish-brown solution which turns green and then blue on continued dilution with water, and forms insoluble tannic acid and phosphomolybdic acid salts.

Acknowledgment.—The authors are indebted to the General Printing Ink Corporation for permission to publish this work.

Summary

2-Dimethylaminobiphenyl was oxidized with cupric chloride to give a triphenylated Methyl Violet dyestuff indicating the existence of an active hydrogen in the 5 position.

The preparation of 2-dimethylaminobiphenyl by the reaction of 2-aminobiphenyl either with dimethyl sulfate or with methyl alcohol also gave the monomethyl compound, which was separated as 2-(N-methyl)-acetamidobiphenyl.

The stability of 2-(N-methyl)-acetamidobiphenyl toward hydrolysis is in agreement with the similar stability of N-methylacetanilide.

[COMMUNICATION NO. 965 FROM THE KODAK RESEARCH LABORATORIES]

Sulfonamides in the Benzimidazole, Benzothiazole and Benzotriazole Series

BY C. F. H. ALLEN, ALAN BELL AND C. V. WILSON

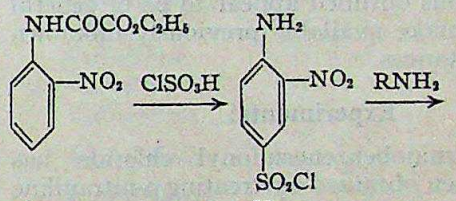
Conspicuously absent from the chemical literature are sulfonamides in the benzimidazole, benzothiazole and benzotriazole series. One reason for this may have been the lack of the corresponding sulfonic acids until the last decade.[1,2] Moreover, although the sulfonic acids are now available, they cannot be converted into the necessary sulfonyl chlorides by the usual methods, nor can the chlorides be prepared by the use of chlorosulfonic acid. A reaction appears to take place between this reagent and the heterocycle, but it is one of salt formation, for, on making the reaction product alkaline, the starting material is recovered unchanged. Benzimidazoles, however, after several hours of treatment with chlorosulfonic acid,[2] yield a sulfonic acid. Benzotriazole does not give a sulfonic acid under the same conditions; N-acetylbenzotriazole was unaffected by this reagent.

As a general reaction, the formation of sulfonic acids by ring closure of suitable *ortho* diamines is of doubtful utility, owing to the inaccessibility of the requisite starting materials, except 3,4-diaminobenzenesulfonic acid.[3,4,5,6] Even in this last instance we have failed to find references to the benzimidazole-5-sulfonic and benzotriazole-5-sulfonic acids, but we have found their preparations to be straightforward.

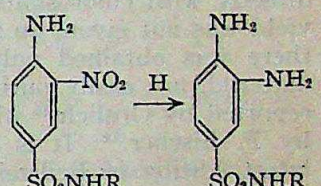
However, if there were other reactive groups in the molecule, the conversion of $-SO_3H$ to $-SO_2Cl$, without attacking the substituents, would be very difficult, even if it were possible. Since we had some interest in 2-mercapto derivatives, this method could not be used. A 2-mercaptobenzothiazole-5-sulfonic acid,[7] salts of 2-mercaptobenzimidazole-5-sulfonic acid,[8] and a benzotriazolesulfonic acid,[9] have been reported previously. 2-Aminobenzothiazole-6-sulfonamide appears in a table of compounds in a recent paper,[10] but its original source was not available nor was a method of preparation indicated.

Two procedures were therefore devised, whereby the sulfonamido group was introduced into the molecule prior to ring closure. The starting materials were relatively simple known substances.

In the first procedure, ethyl *o*-nitrophenyloxamate I,[11] was converted to 3-nitro-4-aminobenzenesulfonyl chloride in a single reaction by a treatment with chlorosulfonic acid—the protecting group was hydrolyzed off during the manipulation.

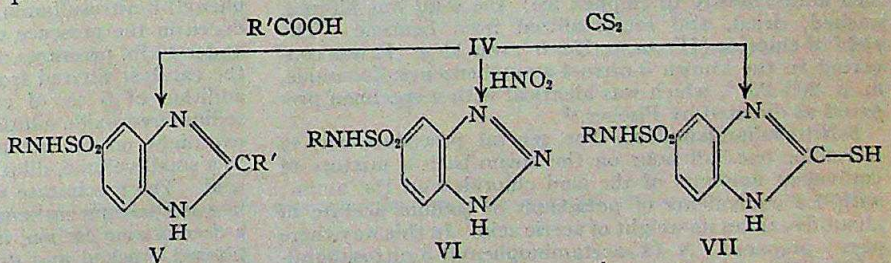


I II



III IV

The sulfonyl chloride II was then treated with an amine to form a sulfonamide III. Finally, the nitro group was reduced and the resulting diamine IV closed to whatever heterocyclic ring system was desired. By this procedure there were prepared 5-sulfonamidobenzimidazoles V, 5-sulfonamidobenzotriazole VI, (R = H), and 2-mercapto-5-sulfonamidobenzimidazoles, VII.



V VI VII

The second procedure started with the known[12] 3-nitro-4-chlorobenzenesulfonyl chloride, which was converted into a sulfonamide VIII. Upon treatment with hydrazine, this afforded 6-sulfonamidobenzazimidoles IX, whereas with carbon disulfide and sodium polysulfide, 2-mercapto-5-sulfonamidobenzothiazoles X resulted.

Von Auwers[13] described an indazolesulfonyl-chloride, prepared from a sodium indazolesulfon-

ate, but, when we employed sodium benzimidazolesulfonate under identical conditions, no sulfonyl chloride could be isolated.

The reactions outlined appear to be of general utility, and make available previously unknown types of substances.

Experimental

3-Nitro-4-aminobenzenesulfonyl chloride has previously been obtained by treating *o*-nitraniline directly with chlorosulfonic acid;[14] although the yield was not given, on repeating the procedure, there was obtained only 3–4% yield of crude material, not easily purified. It was incorrectly reported by Goslich,[15] whose error was corrected by P. Fischer.[12] It is still uncorrected in the latest edition of Beilstein's "Handbuch".[16] On treating the oxamic ethyl ester[11] with chlorosulfonic acid, an excellent yield of this chloride resulted; the oxalo group was hydrolyzed off during the manipulation.

To 187 g. of chlorosulfonic acid was added 45 g. of ethyl *o*-nitrophenyloxamate,[11] and the mixture was heated for three hours on the steam-bath. The cooled solution was then added slowly to chipped ice; the solid was filtered, washed, dried, and recrystallized from benzene. The yield of chloride (II), m. p. 152–3°, was 15 g. It was converted to the known 3-nitro-4-aminobenzenesulfonamide, m. p. 206–207°, which was identical with a specimen prepared as directed by Fischer.[12]

3-Nitrosulfanilamides.—The general procedure was to warm for one-half hour on the steam-bath a mixture of equivalent amounts of the acid chloride and the amine, with 1.5 equivalents of potassium or sodium acetate in about five times its weight of acetic acid. In this way there were prepared N′-(4′-acetaminophenyl)-3-nitrosulfanilamide (XI; III, R = 4-acetaminophenyl), and N′-(2′-hydroxyphenyl)-3-nitrosulfanilamide (XII; III, R = 2-hydroxyphenyl). Their properties are collected in Table I.

3-Nitro-4-chlorobenzenesulfonamides.—These were prepared by the same general procedure. In this way there were obtained N-(4′-chlorophenyl)-3-nitro-4-chlorobenzenesulfonamide (XIII; VIII, R = 4-chlorophenyl), N-(4′-acetaminophenyl)-3-nitro-4-chlorobenzenesulfonamide (XIV; VIII, R = 4-acetaminophenyl), N-(2′-hydroxyphenyl)-3-nitro-4-chlorobenzenesulfonamide (XV; VIII, R = 2-hydroxyphenyl), N-(2′-hydroxy-4′-methylphenyl)-3-nitro-4-chlorobenzenesulfonamide (XVI; VIII, R = 2-hydroxy-4-methylphenyl).

3,4-Diaminobenzenesulfonamide (XVII; IV, R = H) was secured by reducing the 3-nitro-4-aminobenzenesulfonamide preferably in the presence of a Raney nickel catalyst but also by the use of sodium hydrosulfite.

N-β-Hydroxyethyl Derivatives.—N-β-Hydroxyethyl-3-nitro-4-chlorobenzenesulfonamide, XVIII, was obtained as follows: to a boiling solution of 10 g. of 3-nitro-4-chlorobenzenesulfonyl chloride in 100 cc. of benzene was added 5 cc. of ethanolamine. The oil that separated was dissolved by the addition of a minimum of alcohol, the solution concentrated to a small volume, and diluted. After the last of the benzene had been removed, the solid that separated was crystallized from hot water.

N¹,N⁴-Di-β-hydroxyethyl-3-nitrosulfanilamide, XIX, was prepared in a similar manner, but using an excess of ethanolamine; the use of dioxane as a solvent was also satisfactory; there was no separation of an oil and the dioxane was evaporated on the steam-bath.

5-Sulfonamidobenzimidazole (XX; V; R,R′ = H), and 2-methyl-5-sulfonamidobenzimidazole (XXI; V, R = H, R′ = CH_3) were obtained by ring closure of 3,4-diaminobenzenesulfonamide, employing the desired acid and its sodium salt in the usual manner, and heating for at least three hours.

5-Sulfonamidobenzotriazole (XXII; VI, R = H) was prepared as follows: 2 g. of 3,4-diaminobenzenesulfonamide was dissolved in 20 cc. of water, 1.3 cc. of acetic acid, and 0.2 cc. of concentrated hydrochloric acid by warming. The solution was cooled to 10°, and 1 g. of sodium nitrite in 5 cc. of water was added all at once. After several color changes, the solid that separated was filtered, treated in hot aqueous solution with Norite, and allowed to crystallize.

Benzazimidoles were prepared by refluxing for two to three hours a mixture of the appropriate 3-nitro-4-chlorobenzenesulfonamide with twice its weight of 85% hydrazine hydrate in an equal volume of alcohol. They were not recrystallized; all melt with more or less violent decomposition. In this way there were secured 6-sulfonamidobenzazimidole (XXIII; IX, R = H), 6-sulfon-(2′-hydroxyanilido)-benzazimidole (XXIV; IX, R = 2-hydroxyphenyl), and 6-N-β-hydroxyethylsulfonamidobenzazimidole (XXV; IX, R = β-hydroxyethyl).

2-Mercaptobenzimidazoles; 2-mercapto-5-sulfon-(2′-hydroxyanilido)-benzimidazole (XXVI; VII, R = 2-hydroxyphenyl). A solution of 8.6 g. of N′-(2′-hydroxyphenyl)-3-nitrosulfanilamide in 25 cc. of alcohol was reduced in the presence of a Raney nickel catalyst at 90°, under 40 lb. pressure. The diamine was not isolated, but the catalyst filtered from the cooled solution. After the addition of 5 cc. of carbon disulfide and enough 40% sodium hydroxide solution to make it alkaline, it was heated overnight on the steam-bath, the solution concentrated to a small volume, diluted, and acidified with hydrochloric acid. The precipitate was filtered, washed, and dissolved in warm sodium carbonate solution. After treatment with a decolorizing carbon, it was acidified, and the precipitate filtered, washed and dried. The mercapto derivative so obtained melts, with decomposition, at 265°.

All these mercapto derivatives are slowly decomposed in solution, and are less pure after attempted recrystallizations. Sulfur analyses tend to give low results, but are useful in showing how many sulfur atoms have been introduced into the molecule.

Similarly, 2-mercapto-5-sulfon-(4′-acetaminoanilido)-benzimidazole (XXVII; VII, R = 4-acetaminophenyl) was obtained from the nitrosulfanilamide XI; upon hydrolysis for two hours on the steam-bath, using 12 g. of the acetyl derivative, 24 cc. of hydrochloric acid and 100 cc. of alcohol, the 2-mercapto-5-sulfon-(4′-anilidobenzimidazole) (XXVIII; VII, R = 4-aminophenyl) was formed.

2-Mercaptobenzothiazoles; 2-mercapto-5-sulfon-(4′-chloroanilido)-benzothiazole (XXIX; X, R = 4-chlorophenyl) was prepared by heating a mixture of 5.8 g. of sodium sulfide, 4.8 g. of sulfur, and 28 cc. of water until solution was complete, and then adding 8.5 parts of N-(4′-chlorophenyl)-3-nitro-4-chlorobenzenesulfonamide and 5 cc. of carbon disulfide, and warming on the steam-bath for

three hours. After filtering, the filtrate (at 20°) was acidified. The remainder of the treatment was similar to that in the previous example.

By a similar procedure there were prepared 2-mercapto-5-sulfon-(4′-acetaminoanilido)-benzothiazole (XXX; X, R = 4-acetaminophenyl), 2-mercapto-5-sulfon-(2′-hydroxyanilido)-benzothiazole (XXXI; X, R = 2-hydroxyphenyl), and 2-mercapto-5-sulfon-(2′-hydroxy-4′-methylanilido)-benzothiazole (XXXII; X, R = 2-hydroxy-4-methylphenyl).

Summary

A series of reactions is described, by which it is possible to obtain in considerable variety the hitherto unknown sulfonamides in the benzimidazole, benzotriazole, and benzothiazole series.

By these procedures there have been prepared 5-sulfonamidobenzimidazoles, 5-sulfonamidobenzotriazole, 6-sulfonamidobenzazimidoles, 2-mercapto-5-sulfonamidobenzimidazoles and 2-mercapto-5-sulfonamidobenzothiazoles.

ROCHESTER, N. Y. RECEIVED FEBRUARY 9, 1944

NOTES

1,3:2,4-Dibenzylidene-D-sorbitol

BY S. J. ANGYAL AND J. V. LAWLER

In their recent exhaustive paper, Wolfe, Hann and Hudson[1] proved that in dibenzylidine-D-sorbitol (m. p. 219–220°) the benzylidene groups are attached to carbon atoms 1,2,3,4 of D-sorbitol. They were unable, however, to assign a definite structure.

At the time their paper reached us, we were engaged in similar research. Our results agree with theirs, but in one respect we were able to go further. By careful hydrolysis of dibenzylidene-D-sorbitol with acetic acid in alcohol, we were able to isolate a monobenzylidene-D-sorbitol identical with Vargha's 2,4-monobenzylidene-D-sorbitol.[2] As under these mild conditions no migration is likely, we feel entitled to assign the 1,3:2,4 structure to dibenzylidene-D-sorbitol.

In a similar way we obtained 1,3:2,4-dibenzylidene-D-sorbitol from tribenzylidene-D-sorbitol,[3] which proves that the latter has the structure 1,3:2,4:5,6-tribenzylidene-D-sorbitol.

Neither during the synthesis from sorbitol and benzaldehyde, nor during hydrolysis experiments, did we encounter another isomer of dibenzylidene-D-sorbitol, such as the one described by Meunier,[4] m. p. 162°. This substance was probably a mixture of di- and tri-benzylidene-D-sorbitols.

In the experimental part we give improved physical constants of mono- and tri-benzylidene-D-sorbitol and of 5,6-diacetyl-1,3:2,4-dibenzylidene-D-sorbitol.

Experimental[5]

2,4-Monobenzylidene-D-sorbitol.—Vargha[2] gives m. p. 172–73°, $[\alpha]^{20}D$ 5.3°. His sample was obviously contaminated with dibenzylidene-D-sorbitol, because he recrystallized from alcohol, in which the latter substance is fairly soluble. We prepared the mono- compound according to his directions, but recrystallized it from 6 parts of water which left the diacetal undissolved. The substance so prepared had m. p. 176–77°, $[\alpha]^{17}D$ −1.1° (*c*, 1.0) in water.

Anal.[6] Calcd. for $C_{13}H_{18}O_6$: C_6H_5CH, 33.33. Found: C_6H_5CH, 33.1

2,4-Monobenzylidene-D-sorbitol from 1,3:2,4-dibenzylidene-D-sorbitol.—Three grams of the diacetal[1] was refluxed on the steam-bath with a mixture of 120 ml. 80% alcohol and 67 ml. glacial acetic acid for one hour. The solution was evaporated to dryness under reduced pressure. Thirteen ml. of water was added to the residue, the solution made carefully alkaline with sodium carbonate and boiled for a short time; 0.9 g. of unchanged dibenzylidene-D-sorbitol remained undissolved. The solution was filtered and on standing in the refrigerator deposited 0.27 g. of crystals (m. p. 173–74°, 17% yield on dibenzylidene-sorbitol not regained). After recrystallization from 1.5 ml. water the m. p. was 174–75°; mixed m. p. with the previous substance, 174–75°.

1,3:2,4:5,6-Tribenzylidene-D-sorbitol.—Prepared as directed by Karrer and Büchi.[3] Their method of purification is applicable to very small quantities only. We dissolved the crude triacetal (10 g.) in 100 ml. of chloroform, filtered from undissolved dibenzylidene-D-sorbitol and precipitated with 300 ml. alcohol (7–8 g.). The melting point of this substance shows a peculiar behavior. Pure samples recrystallized from chloroform–alcohol (1:3) or pyridine–water (3:1) have m. p.'s between 195 and 199°. Occasional pure samples had m. p.'s as low as 190°. When dissolved in pyridine and evaporated to dryness at 80° all these samples melted at 203°. Apparently the substance is dimorphous, one form melting at 203°, but we were unable to isolate the other in pure form. All pure samples have $[\alpha]^{16}D$ +26.9° (*c*, 2.0) in chloroform. Karrer and Büchi[3] give m. p. 191°, Simada and Matukawa[7] m. p. 201–204°, no rotation.

Anal. Calcd. for $C_{27}H_{26}O_6$: C_6H_5CH, 60.54. Found: C_6H_5CH, 60.4.

1,3:2,4-Dibenzylidene-D-sorbitol from Tribenzylidene-D-sorbitol.—Four grams of tribenzylidene-D-sorbitol (m. p. 203°) was dissolved in 40 ml. of hot chloroform, a mixture of 300 ml. 90% alcohol and 60 ml. of glacial acetic acid added, and refluxed on the steam-bath for two hours. The solution was evaporated to dryness under reduced pressure, the residue powdered and extracted, first with 50 ml. of chloroform, then with 30 ml. of boiling water. The residue weighs 2.1 g. (76% yield), and has m. p. 220–21°. On acetylation with pyridine (10 ml.) and acetic anhydride (6 ml.) it gives a substance similar in all properties to 5,6-diacetyl-1,3:2,4-dibenzylidene-D-sorbitol.

5,6-Diacetyl-1,3:2,4-dibenzylidene-D-sorbitol.—This substance shows the same peculiar behavior of its melting point as tribenzylidene-D-sorbitol. Samples from benzene or acetone have m. p.'s between 202 and 206°. On evaporation from pyridine at 80° it melts at 208–209°. Wolfe, Hann and Hudson[1] report 201–204°.

Anal. Calcd. for $C_{24}H_{26}O_8$: C_6H_5CH, 40.73. Found: C_6H_5CH, 40.8.

An Orange-colored Pigment of Cottonseed

BY CHARLOTTE H. BOATNER, MAIZIE CARAVELLA AND CAROLYN S. SAMUELS

We have isolated an orange-colored pigment from cottonseed by the following procedure. An ethereal extract of cottonseed was re-extracted with a dilute aqueous solution of sodium hydroxide containing sodium dithionite ($Na_2S_2O_4$). The yellow-colored ethereal layer which separated from the aqueous extract when it was exactly neutralized with concentrated hydrochloric acid was withdrawn. Addition of an equal volume of glacial acetic acid to the ethereal solution caused the precipitation of gossypol "acetate" within a few minutes. When the filtrate was allowed to stand for about a week, an orange-colored solid slowly precipitated. This solid was extracted with hot acetone from which orange-colored crystals precipitated on cooling. The product was recrystallized first from hot acetone and finally from a mixture of hot chloroform and ether.

The orange-colored pigment differs markedly from gossypol. It is less soluble than gossypol in most organic solvents. It melts at 212° (cor.) to form a more deeply colored solid, which melts with decomposition at 238–239° (cor.). It is insoluble in alkali. It does not form a precipitate with aniline, reduce Fehling solution, or give a positive fuchsin-aldehyde test. The orange-colored pigment reacts with hydroxylamine and with dinitrophenylhydrazine, but the products differ in melting point from the corresponding products obtained with gossypol.

The orange-colored pigment forms a brilliant yellow solution in concentrated sulfuric acid which slowly changes to the scarlet color characteristic of gossypol in sulfuric acid.

The absorption spectrum of a chloroform solution of the orange-colored pigment exhibits a well defined maximum at 435 mμ, whereas that of gossypol occurs at 365 mμ.[1] The unstable reaction product of the orange-colored pigment with antimony trichloride has an absorption maximum at 450–460 mμ; whereas that of gossypol exhibits two maxima, one at 380 mμ and the other at 510–

(1) Boatner, *Oil & Soap*, 21, 10–15 (1944).

Digitized by Arya Samaj Foundation Chennai and eGangotri

520 mμ.[1] When a chloroform solution of the orange-colored pigment is treated with concentrated hydrochloric acid and then with antimony trichloride, the solution exhibits the absorption spectrum characteristic of the gossypol–antimony trichloride reaction product. This observation indicates that the final reaction products of both pigments are the same and that concentrated hydrochloric acid converts the orange-colored pigment into gossypol.

The absorption spectra curves of chloroform extracts of some raw cottonseeds and cottonseed meals, as well as those of their reaction products with antimony trichloride, have maxima which indicate the presence of the orange-colored pigment.[2] The production of a characteristic gossypol reaction when such extracts are treated with concentrated hydrochloric acid prior to their reaction with antimony trichloride[2] confirms the presence of the orange-colored pigment in the seeds and meals. The occurrence of this pigment in high concentration in certain cottonseed meals may account, at least in part, for the frequently observed lack of correlation[3] of gossypol content with toxicity of these meals when the gossypol is determined as the dianilino compound.

The Preparation of Ethyl ϵ-Bromocaproate

BY GEORGE BOSWORTH BROWN AND C. W. H. PARTRIDGE

Ethyl ϵ-bromocaproate may be prepared conveniently and inexpensively from cyclohexanone. The crude mixed lactones of ϵ-hydroxycaproic acid, obtained by the procedure of Robinson and Smith,[1] may be treated directly with hydrobromic and sulfuric acids, thus obviating the losses involved in the use[2] of ethyl ϵ-hydroxycaproate as an intermediate.

The oxidation of 174 g. of cyclohexanone was carried out between 10 and 15° as described[1] in the preparation under the heading of ethyl 6-hydroxyhexoate using an oxidizing mixture prepared from 919 g. of potassium persulfate.

The 200 g. of crude lactones was then treated with a cooled mixture of 1 liter of 48% hydrobromic acid and 240 cc. of concentrated sulfuric acid. After standing for two hours at room temperature, this was heated for four hours on the steam cone, was cooled and poured into 2 liters of water. The organic layer was separated and the water solution was saturated with ammonium sulfate and was extracted four times with ether. The combined organic layer and extract were washed three times with saturated ammonium sulfate, and were dried and concentrated.

The 250 g. of crude bromo acid was esterified by refluxing for eight hours with 600 cc. of absolute alcohol and 15 cc. of sulfuric acid. After concentrating *in vacuo*, the residue was taken up in ether and was washed with water and with 5% sodium carbonate. The ether solution was dried over sodium sulfate and was distilled yielding 178 to 218 g. of the product distilling at 120–125° at 14 mm., $n^{21}D$ 1.4566, d^{23}_{23} 1.241, MR_D 48.92 (calcd. 48.57). This represents an over-all yield from cyclohexanone of 45–55%. No evidence of the inhomogeneity noted once by Barger, Robinson and Smith[2] has been observed. The product has been used satisfactorily in the preparation of η-ketopelargonic acid.[2]

Polymerization of Undecylenic Acid in the Presence of Boron Fluoride

BY JOHN R. CANN[1] AND E. D. AMSTUTZ

It has been found that when undecylenic acid is treated with gaseous boron fluoride at room temperature much heat is evolved and the acid polymerizes to a dark heavy oily material. This polymer, after having been freed of catalyst, exhibits the characteristic properties of an acid and also those of an ester. Thus it shows some tendency to dissolve in dilute aqueous caustic and regenerates carboxyl groups on refluxing in alkaline solutions.

The loss in carboxyl function has been found to be directly related to the fall in iodine value which indicates that one of the processes of polymerization is the esterification of the carboxyl group by means of the unsaturated linkage. (It had been previously demonstrated that the same treatment of stearic acid did not cause decarboxylation.) Since the fall in iodine value was stoichiometrically greater than the loss of carboxyl function it appeared that some double bond polymerization also took place. The analytical data show that this is a reaction of secondary importance with esterification assuming the major role.

The oil resulting from saponification of the polymer gave a positive iodoform test which indicates the hydroxy acid produced had the methylcarbinol structure. This proves the orientation of at least part of the polymerization process.

This type of polymerization[2] of undecylenic

(1) Raybestos-Manhattan Research Fellow in Chemistry 1942–1943. Present address, Frick Chemical Laboratory, Princeton, New Jersey.

(2) Unpublished results obtained in this Laboratory by Cann and by H. R. Nace indicate that this behavior is also shown by the fatty acids from drying oils and also by crotonic acid. The latter requires somewhat more strenuous conditions, however, due to its conjugated structure.

Digitized by Arya Samaj Foundation Chennai and eGangotri

acid in the presence of boron fluoride was to be expected from the work of Nieuwland and his collaborators[3] who found that simple olefins condensed with phenols and carboxylic acids to produce phenolic ethers and esters, respectively.

Experimental

The polymeric material was usually prepared by passage of gaseous boron fluoride[4] into the sample to the point of saturation. Heat was immediately evolved and the temperature was allowed to rise to 70–80°. The color darkened to a deep chocolate brown and the viscosity increased markedly. The material was then allowed to cool to room temperature overnight and was taken up in ether. The ethereal solution was washed exhaustively with water and dried over anhydrous magnesium sulfate. Removal of the ether was accomplished by heating on a hot-plate and finally in vacuum for several hours. The residual oil was clear brown in color, and possessed the odor of coconuts.

Saponification of the polymer was carried out in the usual manner with alcoholic potassium hydroxide. The alcohol was evaporated, the residue acidified and extracted with ether. The ether solution was then dried over magnesium sulfate, filtered and evaporated. The residual oil was finally warmed and placed in high vacuum.

The iodoform test on the saponified polymer was carried out in the usual manner using methanol (negative blank) as solvent. The unrecrystallized iodoform melted at 116–119.2°; authentic specimen, m. p. 116–118.5°; mixed m. p. 121°.

p-(2,5-Dimethylpyrryl-1)-phenyl-magnesium Bromide and -Lithium

BY HENRY GILMAN AND GORDON J. O'DONNELL

In connection with studies on nitrogen heterocycles, directions have been developed for the preparation of *p*-(2,5-dimethylpyrryl-1)-phenylmagnesium bromide and the corresponding organo-lithium compound. The yields of the RM compounds are quite satisfactory, and directions are also given for the preparation of the precursory *p*-(2,5-dimethylpyrryl-1)-phenyl bromide in 90% yield.

Experimental

***p*-(2,5-Dimethylpyrryl-1)-phenyl Bromide.**—This compound was prepared in accordance with the general procedure of Hazelwood, Hughes, and Lions.[1] To a warm solution of 172 g. (1 mole) of *p*-bromoaniline in 114 g. (1 mole) of acetonylacetone was added one or two drops of concd. hydrochloric acid. On the addition of the hydrochloric acid, the solution assumed a dark red color, and a vigorous reaction set in immediately with droplets of water forming on the surface of the solution. After the initial reaction subsided, the mixture was refluxed for three hours under an air condenser. The reaction mixture was poured upon crushed ice, and the precipitate was filtered. The yield of product melting at 72–74° was 240 g. (96%). Recrystallization from ethanol gave 225 g. (90%) of compound melting at 74°.

Reaction of *p*-(2,5-Dimethylpyrryl-1)-phenyl Bromide with Magnesium and with Lithium.—The Grignard reagent was prepared by conventional procedures, and the yield by acid titration[2] was 76%. From a second preparation, starting with 0.08 mole of the RBr compound, the yield of crude *p*-(2,5-dimethylpyrryl-1)-benzoic acid was 78%, and purification from ethanol gave a 72% yield of pure acid melting at 195–196°. The reaction with magnesium proceeds slowly, and ordinary catalysts like iodine or some activated magnesium, or some methylmagnesium iodide are helpful. There is no significant color change in the solution when reaction takes place, but color test I is of diagnostic value when methylmagnesium iodide is not used as a catalyst.

The organolithium compound was prepared by adding a solution of 12.5 g. (0.05 mole) of *p*-(2,5-dimethylpyrryl-1)-phenyl bromide in 60 cc. of ether to a stirred suspension of 1 g. (0.14 g. atom) of finely divided lithium in 30 cc. of ether. Twenty cc. of the solution was added at once, after which addition the mixture was warmed until the reaction started. The remaining solution was then added at a rate to maintain gentle refluxing. Carbonation by dry-ice gave 8.6 g. (80%) of *p*-(2,5-dimethylpyrryl-1)-benzoic acid which melted at 196–197° after crystallization from dilute ethanol. Identification was completed by a mixed m. p. determination with a sample prepared[1] by the condensation of *p*-aminobenzoic acid with acetonylacetone.

The observation that the bromide reacts more promptly with lithium than with magnesium finds a parallel in the preparation of RMgX and RLi compounds, in high yields, from *p*-dimethylarsinophenyl bromide and *p*-di-*n*-propylarsinophenyl bromide.[3]

Acknowledgments.—The authors are grateful to C. G. Stuckwisch and L. Fullhart, Jr., for assistance.

The System Sulfur Dioxide–Acetic Acid

BY W. H. SCHEUB AND C. R. MCCROSKY

To find out whether a definite compound of sulfur dioxide and acetic acid exists, the melting points of a series of mixtures of these two substances have been measured.

The acetic acid was dehydrated by successive treatments of glacial acetic acid with triacetyl borate and 20% oleum. In each treatment the mixture was first refluxed and then fractionally distilled. The mixtures were prepared by dissolving previously dried sulfur dioxide in the anhydrous acetic acid and were then frozen in a bath of solid carbon dioxide and acetone, or of liquid air. The melting points were determined by means of a chromel–alumel thermocouple and were accurate to well within ±0.1°. Melting points rather than freezing points were measured since the mixtures were found to supercool to a marked degree.

TABLE I

MELTING POINT DATA OF THE SYSTEM SULFUR DIOXIDE–ACETIC ACID

Mole % SO_2	M. p., °C.	Mole % SO_2	M. p., °C.
0.0	16.6	33.5	−40.4
7.7	11.5	46.4	−38.0
9.6	8.3	59.6	−38.7
13.1	−44.1	63.3	−39.2
18.0	−44.2	78.3	−75.6
24.7	−41.9	100.0	−72.7

The observations are collected in Table I and are represented graphically in Fig. 1.

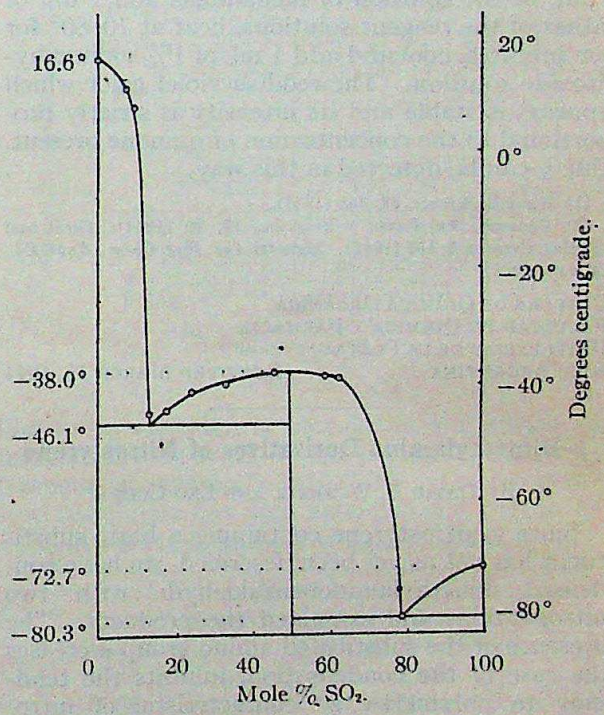

Fig. 1.

It can be seen that the melting point curve shows a maximum at 50 mole % sulfur dioxide and a temperature of −38°. The indicated compound, $HSO_2C_2H_3O_2$, solidifies in the form of thin, colorless flakes which show a tendency to sublime. The lower eutectic was established by a definite melting point at −80.3°; the upper eutectic at −46.1° was derived by extrapolation. These eutectic mixtures contained, respectively, 78.4 and 13.2 mole % of sulfur dioxide.

The Identification of 2-Methyl-1,4-naphthoquinone

BY ARMANDO NOVELLI AND JOSE S. CONTICELLO

2,4-Dinitrophenylhydrazine was proposed by Novelli[1] as a very sensitive reagent for 2-methyl-1,4-naphthoquinone (menadione), and it has been used for quantitative determinations.[2]

The reaction involves some inconvenience in that the colored substance formed is insoluble in water, and must be extracted with amyl alcohol; furthermore, when the amount of menadione is very small, the yellow color of 2,4-dinitrophenylhydrazine interferes with the green color of the reaction product. In order to avoid these disadvantages, we have tried other arylhydrazines of which the *p*-carboxy- and *p*-sulfonphenylhydrazine were the most convenient. The first is used in 1% alcoholic solution, and the latter in cold, saturated aqueous solution.

The reaction is carried out as follows: to 0.1–1 ml. of the solution of menadione, add 1 ml. of either of the reagent solutions, heat at 70–80° for ten minutes, cool and add 1 ml. of 1% sodium hydroxide solution. The reddish-violet color which appears is stable and its intensity is strictly proportional to the concentration of quinone present. One γ can be detected in this way.

p-Dimethylamino Derivatives of Nitrostyrene

BY DAVID E. WORRALL AND LEO COHEN

Since a nitrostyrene containing a basic substituent has not as yet been described, we have condensed dimethylaminobenzaldehyde with two nitroparaffins and examined the products. The presence of the substituted amino group increases the ease of the condensation, inhibits the tendency to polymerize so characteristic of nitrostyrene itself and to a marked extent deepens the color of the resulting unsaturated nitro compound. It also destroys the weak additive capacity of the conjugated unsaturated system for organic bases.

Experimental

1-Nitro-2-(*p*-dimethylaminophenyl)-ethene.—A mixture of 14.9 g. (0.1 mole) *p*-dimethylaminobenzaldehyde and 18.3 g. (0.03 mole) nitromethane was placed in a flask which was then heated on a water-bath until a dark green solution resulted. Then 0.43 g. of amylamine was added. On heating the mixture for one minute, the solution turned dark brown, solidifying within twenty minutes to a red crystalline mass. The mixture was filtered after standing overnight. The residue recrystallized from 2-nitropropane yielded 16 g. of sparkling, ruby red plates, m. p. 179–180.5°.

Anal. Calcd. for $C_{10}H_{12}N_2O_2$: C, 62.5; H, 6.3. Found: C, 62.2; H, 6.4.

It dissolved readily in hydrochloric acid, presumably through salt formation. The colorless solution became red on further dilution with water. Concentrating the acid solution produced colorless crystals which rapidly became discolored when attempts were made to isolate them. The original substance was only sparingly soluble in the common solvents but dissolved readily in the nitroparaffins on heating. Attempts to polymerize the substance by alkaline reagents or to add *p*-toluidine failed. A crystalline product was obtained by careful heating with an excess of phenylhydrazine. It was identified through analysis and a mixed melting point as the phenylhydrazone of dimethylaminobenzaldehyde.

1-Nitro-2-bromo-2-(*p*-dimethylaminophenyl)-ethene.—A mixture of 1.4 g. of the nitro compound and 1.2 g. of bromine in 10 cc. of chloroform was heated under a reflux condenser for thirty minutes followed by several hours exposure to sunlight. After concentration to a small volume at room temperature, the resulting light yellow needles were separated, washed with ether and immediately warmed on a water-bath for half an hour with alcoholic potassium acetate. The mixture was poured into a large volume of ice water. The product separated from alcohol as dark red platelets, m. p. 121°.

Anal. Calcd. for $C_{10}H_{11}BrN_2O_2$: Br, 29.5. Found: Br, 29.1.

2-Nitro-1-(*p*-dimethylaminophenyl)-1-propene.—A similar condensation of the aldehyde and nitroethane after several days produced a fair yield of red plate-like crystals, m. p. 118–120°.

Anal. Calcd. for $C_{11}H_{14}N_2O_2$: C, 64.1; H, 6.8. Found: C, 64.1; H, 6.8.

Attempts to condense nitropropane failed.

Trimethyl Silane and Trimethyl Silicon Chloride

BY A. G. TAYLOR AND B. V. DE G. WALDEN

Mono- and dimethyl silicon chlorides have been described by Gilliam, Liebhafsky and Winslow[1] who drew attention to their b. p.'s in relation to tetramethyl silane and silicon tetrachloride. Referring to work in the same laboratory the b. p.'s are given by Rochow[2] as 66.0–67.0° at 766 mm. for the monomethyl and 69.0–70.2° at 744.5 mm. for the dimethyl derivative.

These authors used the reaction between silicon tetrachloride and magnesium methyl chloride to prepare mixtures of monomethyl silicon trichloride, dimethyl silicon dichloride and trimethyl silicon chloride, together with ether, from which by fractionation they isolated specimens corresponding in composition and vapor density fairly closely with monomethyl silicon trichloride and dimethyl silicon dichloride.

We have prepared trimethyl silicon chloride by direct chlorination of trimethyl silane which was made from silicochloroform. This method previously has been used by Kraus and Nelson[3] for the preparation of triethyl silane and triethyl silicon bromide.

Experimental

Silicochloroform.—This was prepared by the action of hydrogen chloride gas on ferrosilicon containing 95–97% silicon.[4,5] The volatile products were condensed by alcohol and solid carbon dioxide and a fraction (75%) boiling between 28 and 36° was refractionated and a fraction boiling close to 31.8° collected (44.6% of original condensate).

Anal. Silicon and chlorine were determined after reaction with water as silica and hydrogen chloride. Calcd.: Si, 20.72; Cl, 78.53. Found: Si, 20.2, 20.6, 20.6; Cl, 79.6, 78.7, 78.7.

Trimethyl Silane.—To 500 cc. of an ether solution containing 175 g of methylmagnesium bromide was added slowly with strong cooling and stirring 60 g. of silicochloroform in 150 cc. of ether. The reflux condenser was cooled by circulating cold brine. After completion of the reaction, the reflux condenser was allowed to rise to room temperature and connection made to a cooled receiver through another condenser cooled by alcohol and solid carbon dioxide. Cooled dilute sulfuric acid was added slowly and trimethyl silane together with some ether distilled over. Concentrated sulfuric acid was added to the receiver and allowed to stand cold overnight. Trimethyl silane was then distilled off; b. p. uncor. 9 to 11°. A small amount of dissolved gas assumed to be methane was lost below 0°. The yield was poor. In each of several experiments 15 cc. of trimethyl silane was obtained from 40 cc. of silicochloroform.

Trimethyl Silicon Chloride.—Trimethyl silane was treated at −20° with chlorine and then allowed to stand at room temperature until most of the hydrogen chloride had escaped. A fraction boiling between 58 and 63° was collected and redistilled and collected between 57 and 59.4° at 747 mm. This represented 75% of the original total. There was a small residue, non-volatile at 100°, left from the first distillation.

Anal. Silicon content by adding concd. sulfuric acid, warming, then adding concd. nitric acid and finally weighing silica. Cl content by hydrolyzing and titration. Calcd.: Si, 25.85; Cl, 32.67. Found: Si, 25.4, 25.9, 25.8, 25.6; Cl, 32.1, 32.2, 33.0. Taking CH_3 by difference, the mean percentages correspond to $(CH_3)_{2.99}SiCl_{1.00}$.

Vapor Pressure of Trimethyl Silicon Chloride.—This was determined by the method of Smith and Menzies.[6] Temperatures were read on a thermometer corrected by reference to the b. p.'s of purified ether, carbon tetrachloride, and water. Interpolation by least squares gives

t, °C.	28.9	35.3	40.0	45.2	49.8	55.0	56.1
p, mm.	308	366	427	481	575	676	725

$\log_{10}p = 6.926 - 1344/T$. The b. p. at 760 mm. is calculated to be 59°; density, d^{25}_4, 0.846; freezing point, approx. −40°.

The Viscosity of the Methyl Ester of Dilinoleic Acid

BY DAVID W. YOUNG AND RUTH E. BIERTUEMPFEL

The purpose of this note is to present viscosity measurements on a pure sample of methyl dilinoleate over a range of temperature from −40 to 212°F. (−40–100°C.).

Experimental Procedure

The ester used for this work had been purified by double distillation in a molecular still by Dr. John C. Cowan in the Northern Regional Research Laboratory. The ester had an index of refraction of $n^{30}D$ 1.4766. Recently the method used to formulate and purify the methyl dilinoleate from soybean oil has been reported.[1]

The kinematic viscosity method used in the study is intended for determining the viscosity of any product which is a true viscous liquid at the temperature of the test. The viscometers available were the Ubbelohde type with one capillary tube. Care was taken to calibrate each viscometer against standard oils of known viscosity as determined in the National Bureau of Standards. The viscosity method is given under American Society for Testing Materials, Designation D 445-42 T.

For the viscosity determination at −40° the procedure given by Baldeschwieler and Wilcox[2] was used.

Results

Experimental results are listed in Table I and Fig. 1. A straight line relationship exists when

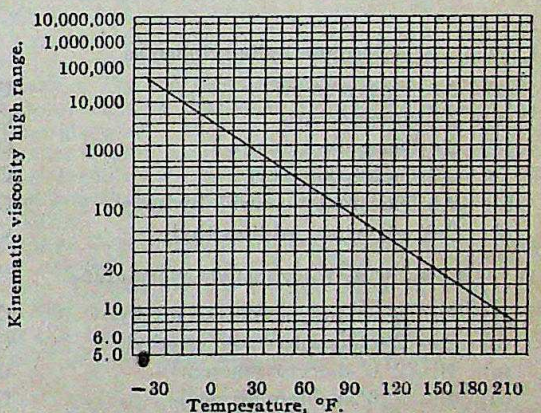

Fig. 1.

kinematic viscosity is plotted as a function of temperature on A. S. T. M. tentative viscosity–temperature chart (D 341–37 T). The temperature coördinate has been extended 10°, that is, to −40°, in order to present complete data.

TABLE I

KINEMATIC VISCOSITY OF METHYL DILINOLEATE

Temp., °F.	Viscosity in centistokes
−40	42,464
80	102.5
90	78.3
100	60.0
110	48.0
140	25.4
150	21.1
160	17.8
170	15.2
180	13.1
200	10.0
210	8.70

It was held that these results would be of interest as the pure material is rather difficult to

NEW COMPOUNDS

New Phenolic Mercurials[1]

In a study of the preparation of new phenols of possible pharmaceutical interest the following new derivatives, which include mercurials of *p-t*-octylmono-,[2a] cyclohexylidenedi-,[2b] and hexyl-tetraphenols,[2c] have been prepared and characterized.

Polyacetoxymercurials.—A molar equivalent of mercuric acetate was allowed for each free position ortho-to-the-hydroxyl group per mole of phenol. Knowing the ratio of the reactants to be used, the quantities of phenol and mercuric acetate could be calculated for any size batch desired or found to be convenient. A 2–6% solution of the phenol with the calculated amount of mercuric acetate was refluxed in 95% ethyl alcohol containing 5% glacial acetic acid in an appropriate flask, fitted with a reflux condenser, for one to two hours. The flask was then chilled in the refrigerator overnight, the polymercurial filtered off and recrystallized from ethanol or glacial acetic acid. The yields were in the neighborhood of 70–90%.

Monoacetoxymercurials.—For these one mole of phenol was allowed to react with only one-half the quantity of mercuric acetate as calculated above, in a 50% aqueous ethyl alcohol solution containing 5% glacial acetic acid, at room temperature, over a period of one to two weeks. When the solution no longer contained free mercuric ions, as shown by the absence of a positive reaction when tested for such ions with potassium iodide solution (red precipitate of mercuric iodide soluble in excess of reagent), the solution was then chilled in the refrigerator and the crude mono-mercurial filtered off and dried. The monomercurial was recrystallized from 50% aqueous alcohol containing 5% glacial acetic acid. The yield was about 80–85%.

Chloromercurials.—These were obtained by pouring an alcoholic or a glacial acetic acid solution of the acetoxymercuri derivative into an equal volume of a 20% aqueous solution of reagent grade sodium chloride. The chloromercurial was filtered off and recrystallized from ethanol or glacial acetic acid. The yields varied from 70–90%.

Double Invert Soaps: Symmetrical Di-piperidinium Salts[1]

Several long chain substituted dipiperidinium salts have been prepared in the course of investigation of various types of symmetrical double invert soaps. Methylene- and benzal-di-piperidine, prepared by condensing formaldehyde or benzaldehyde respectively with two moles of piperidine, were treated with double molar quantities of various *n*-alkyl bromides, such as *n*-heptyl, *n*-octyl, *n*-tetradecyl and *n*-hexadecyl bromides. Reaction took place rather readily in all cases and evidently proceeded as follows

$$(C_5H_{10}N)_2CH_2 + 2RBr \longrightarrow [(C_5H_{10}NR)_2CH_2]^{++}\ 2Br^{--}$$

$$(C_5H_{10}N)_2CHC_6H_5 + 2RBr \longrightarrow [(C_5H_{10}NR)_2CHC_6H_5]^{++}\ 2Br^{--}$$

$$R = -C_7H_{15-n},\ -C_8H_{17-n},\ -C_{14}H_{29-n},\ -C_{16}H_{33-n}$$

Procedure.—To 0.02 mole of methylene- or benzal-dipiperidine was added 0.04 mole of the respective alkyl bromide and 20 ml. of 95% ethyl alcohol. The mixture was then refluxed gently for four hours. The alcohol was then removed by evaporation under reduced pressure. The remaining residue was repeatedly crystallized from ethyl acetate; yields, 50–70%.

o-Biphenyl Isocyanate, *o*-Bicyclohexyl Isocyanate, N,N′-Di-*o*-biphenyl Urea, N,N′-Di-*o*-bicyclohexyl Urea

The isocyanates were prepared by the reaction of *o*-biphenylamine and *o*-bicyclohexylamine[1] with phosgene. Solutions of the amines in dry toluene were added gradually to a sixfold excess of phosgene, dissolved to 20 to 30% solution in toluene. The solutions were warmed during and after the addition of the base and finally refluxed for several hours. Most of the white crystals (hydrochloride) which formed with *o*-biphenylamine dissolved during heating. No precipitate appeared with *o*-bicyclohexylamine. Subsequently, the toluene and phosgene were distilled off; the residue was heated with carbon tetrachloride,[2] the solution was filtered if necessary, and the solvent was removed by distillation. From the residue the isocyanates were distilled as colorless oils, in yields of 60 to 70%. *o*-Biphenyl isocyanate distilled at 100° (0.5–1 mm.); *o*-bicyclohexyl isocyanate, at 89–90° (0.5–1 mm.).

o-Biphenyl isocyanate—calcd. for $C_{13}H_9NO$: N, 7.18. Found: N, 7.10.

o-Bicyclohexyl isocyanate—calcd. for $C_{13}H_{21}NO$: N, 6.75. Found: N, 6.63.

The corresponding symmetrical disubstituted ureas were prepared by treating the isocyanates with water containing 10% of pyridine as a catalyst. The biphenyl compound reacted in the cold but the bicyclohexyl isocyanate had to be heated on a steam-bath. The product obtained from the former showed a sharp and constant melting point of 182° (uncor.) after two recrystallizations from absolute alcohol. The crystals obtained from bicyclohexyl isocyanate showed a protracted melting point (218–228°) which did not become sharp after repeated recrystallizations (from methanol-water or, preferably, from dioxane). The final melting point was 225–228° (uncor.). Since several of the stereoisomeric ureas may be present, the lack of a sharp melting point is not surprising.

N,N′-Di-*o*-biphenyl urea—calcd. for $C_{25}H_{20}N_2O$: C, 82.5; H, 5.5; N, 7.7. Found: C, 82.2; H, 5.6; N, 7.2.

N,N′-Di-*o*-bicyclohexyl urea—calcd. for $C_{25}H_{44}N_2O$: C, 77.4; H, 11.4. Found: C, 77.2; H, 11.4.

Methyl 3-Methyl-4,6-ethylidene-α- and β-Glucosides

During the course of some work on the optical rotations of substituted glucose derivatives, preparations of the α- and β-methylglucosides of 3-methyl-4,6-ethylideneglucose were required. Catalytic deacetylation with sodium methylate of 16.5 g. of the non-crystalline triacetate, sp. rot. (D line, 25°) + 84° ($CHCl_3$, *C*, 7.8) gave 10.8 g. of a sirupy mixture of methyl 3-methyl-α- and β-glucosides. This was shaken with 45 ml. of freshly distilled paraldehyde and 0.2 ml. of concentrated sulfuric acid until solution was complete. The solution was allowed to stand at room temperature for fifteen minutes after which water and petroleum ether were added. The aqueous layer was separated, washed twice with petroleum ether, and extracted four times with chloroform. Evaporation of the chloroform solution left a crystalline mixture from which 0.6 g. of a substance of m. p. 106–107° and 0.022 g. of another of m. p. 133–134° were separated by fractional crystallization from ether–petroleum ether mixtures. An additional 0.215 g. of the high-melting substance (methyl 3-methyl-4,6-ethylidene-β-glucoside) was obtained in better yield from methyl 3-methyl-β-glucoside. Methylation of the high-melting compound with methyl iodide and silver oxide gave the known methyl 2,3-dimethyl-4,6-ethylidene-β-glucoside[1] melting at 103–105° alone or mixed with an authentic specimen, hence the high-melting compound is regarded as methyl 3-methyl-4,6-ethylidene-β-glucoside. The analyses and properties of the low-melting substance indicate that it is methyl 3-methyl-4,6-ethylidene-α-glucoside. It is noted that the difference in molecular rotation for the high and low-melting compounds is 42,120, while the corresponding value calculated for the α- and β-methylglucosides of 4,6-ethylidene glucose would be 40,920.[2]

Methyl 3-methyl-4,6-ethylidene-α-glucoside: melting point 106–107° (cor.); sp. rot. (D line, 25°) + 114° (H_2O, *C*, 0.6); (Hg blue line, 25°) + 246° (H_2O, *C*, 0.6).

Methyl 3-methyl-4,6-ethylidene-β-glucoside: melting point 133–134° (cor.); sp. rot. (D line, 25°) − 66° (H_2O, *C*, 0.7); (Hg blue line, 25°) − 126° (H_2O, *C*, 0.7).

n-Nonatriacontane

During some attempts to mono-alkylate acetone dicarboxylic ester (diethyl β-ketoglutarate) with octadecyl iodide, the dialkylated ester was also formed as a by-product, which after hydrolysis and decarboxylation yielded nonatriacontanone-20. Reduction of the latter by Clemmensen's method gave *n*-nonatriacontane. An alkyl halide having *n* carbon atoms thus yields a hydrocarbon with $2n + 3$ carbon atoms.

Nonatriacontanone-20.—To a solution of 1.15 g. of sodium in 30 cc. of dry *n*-butanol were added 10 g. of acetone-dicarboxylic ester and 19 g. of *n*-octadecyl iodide prepared from *n*-octadecanol-1 of f. p. 57.8° (thermometer in the liquid); the iodide was distilled *in vacuo* (b. p. 221–224°, 9 mm.) and crystallized twice from acetone and once from methanol–ether (2:1)) and the mixture refluxed until the reaction was neutral (ten hours). The solid which separated on cooling was collected and refluxed with 60 cc. of concentrated hydrochloric acid for 9.5 hours. The neutral material resulting from this treatment was separated and crystallized from hot ethanol; 4.5 g. of nonatria-

contanone-20 melting at 90–92.5° resulted. After treatment with charcoal to remove a yellow discoloration and two recrystallizations from light petroleum (b. p. 70–80°) the ketone melted at 91.2–91.4°.[1]

The long X-ray spacing (melted specimen) was 51.5 Å., indicating that this ketone, like the lower homologs, crystallizes with vertical molecules.

Anal.[2] Calcd. for $C_{39}H_{78}O$: C, 83.1; H, 13.9. Found: C, 83.1; H, 13.9.

n-Nonatriacontane.—1.9 grams of the ketone, 48 g. of amalgamated zinc, 48 cc. of concentrated hydrochloric acid and 10 cc. of glacial acetic acid were boiled under reflux. Every sixth hour the mixture was cooled, the liquid decanted and fresh hydrochloric acid, glacial acetic acid and zinc (10 g.) added. The reduction was followed by determination of the m. p. of the product. After eighty hours the m. p. became constant at 79.0–79.4°. The hydrocarbon was collected and purified by treatment with concentrated sulfuric acid at 130° for two hours.[3] Considerable darkening occurred and the process was repeated until on the fourth treatment darkening no longer took place. The hydrocarbon was carefully washed with hot water and treated with charcoal in benzene. It crystallized from benzene in small white lustrous plates and after three crystallizations from this solvent the m. p. was 80.0–80.2°. The phenomena observed on heating and cooling the hydrocarbon through the m. p. are similar to those observed for the lower homologs.[3] On heating the opaque crystalline material a transition is observed at approximately 75° (change into a transparent form with vertical rotating chains). The s. p. on cooling the melt lies at 79.8°. At this point transparent needles are formed in the melt. On further cooling to 75°, the transparent solid is changed to an opaque form stable at lower temperatures.

The X-ray investigation of the hydrocarbon, crystallized from benzene and pressed on to glass, gave a long spacing of 51.3 Å., corresponding to the normal (A) form with vertical molecules. A specimen melted on to glass by means of the hot-wire technique gave, however, a different diffraction pattern with a long spacing of 47.1 Å., indicating tilted molecules. Odd number hydrocarbons containing more than eleven carbon atoms have previously been found to crystallize only in the A form with vertical molecules.[3] The dimorphism of *n*-nonatriacontane was therefore unexpected, and the compound provides an exception to the rule[4] that a longer chain and an odd number of carbon atoms (and also a higher temperature and the presence of impurity) favors crystallization in vertical forms.

Anal.[2] Calcd. for $C_{39}H_{80}$: C, 85.4; H, 14.6. Found: C, 85.1; H, 14.6.

(1) The m. p.'s and s. p.'s were determined in capillary tubes using a glycerol bath and totally immersed calibrated Anschütz type thermometers. Heating and cooling were carried out very slowly.

COMMUNICATIONS TO THE EDITOR

STERIC STRAIN AND THE ANOMALOUS BASE STRENGTH OF THE NORMAL ALIPHATIC AMINES

Sir:

The strength of the normal aliphatic acids and amines changes with chain length in a peculiar manner. Thus K_a decreases for the first three members, but increases for the fourth (Table I). This curious behavior has been ascribed in the case of the carboxylic acids to hydrogen bond formation between the end methyl group of butyric acid (or of the γ-methylene group of the higher acids) with the carbonyl oxygen of the carboxyl group.[1] A similar explanation could be used for the amines.

As part of a study of generalized acids and bases in gaseous systems,[2] the measurement of the base strength of the normal aliphatic amines with trimethylboron as the reference acid was undertaken. The base strength thus measured (Table I) first increases markedly from ammonia to methylamine, then decreases with ethylamine, rises again with propylamine and then increases regularly. This behavior is so similar to that of the normal aliphatic acids and of the corresponding amides that it is not unreasonable to seek one fundamental explanation for the phenomena.

[a] From Dippy, ref. 1. [b] From Hall and Sprinkle, THIS JOURNAL, **54**, 3469 (1932), and from Hoerr, McCorkle and Ralston, *ibid.*, **65**, 328 (1943).

One important difference will be noted between the order obtained with trimethylboron and the orders obtained by classical methods. With trimethylboron the irregularity appears with the third member of the series, $C_2H_5NH_2$:BMe_3, rather than with the fourth. Since ethylamine cannot form a hydrogen bridge of the type postulated to account for the behavior of butyric acid and propylamine in aqueous solution, it is reasonable to seek some other explanation. (It might also be pointed out that according to the hydrogen bridge hypothesis the order should be independent

of the reference acid, a conclusion which is contrary to the observed facts.)

We suggest that the origin of this behavior is steric in nature—the observed weakening of the base occurring with the first member of the series in which the alkyl group of the base can interfere with the acid (H^+ or BMe_3). It is obvious that the point in the series at which the weakening is observed will depend upon the size of the reference acid. In the case of a large acid, such as trimethylboron, such interference occurs in a base having a shorter chain than in the case where the acid is the small proton. It would be expected that an even larger acid, *e. g.*, triethylboron or tri-*n*-propylboron, would lead to a shift of the irregularity to methylamine, or even to ammonia. This prediction is now being tested.

The assistance afforded by a grant from the Penrose Fund of the American Philosophical Society is gratefully acknowledged.

THE RELATIONSHIP OF STRUCTURE TO ACTIVITY OF SULFANILAMIDE TYPE COMPOUNDS

Sir:

Kumler and Daniels[1] have suggested that the resonating form of the *p*-amino group with a separation of charge is a fundamental factor for the bacteriostatic activity of sulfanilamide type compounds. The experimental evidence for this suggestion is "that sulfanilamide has a higher (ultraviolet) extinction coefficient in base than in water."[2]

Because of the theoretical importance placed on this single observation, and since previous studies in this Laboratory[3] were not in agreement with it, we have repeated the work using a more suitable instrument (Beckman Spectrophotometer Model DU).[4] The data obtained for sulfanilamide are recorded in Fig. 1 and Table I. The additive function $-\log_{10}T$ was used in Fig. 1 to demonstrate the reliability of the method of correcting for solvent absorption.

TABLE I

ULTRAVIOLET SPECTRAL DATA ON SULFANILAMIDE

Form	Wave length of peak absorption, Å.	Extinction coefficient
Molecular (1 *N* NaCl)	2585	16,380 ± 49[a]
Ionic (1 *N* NaOH)	2505	16,150 ± 48
Difference	80	230 ± 97
Per cent. difference		1.42 ± 0.6

[a] The limits of error are those encountered in quadruplicate determinations.

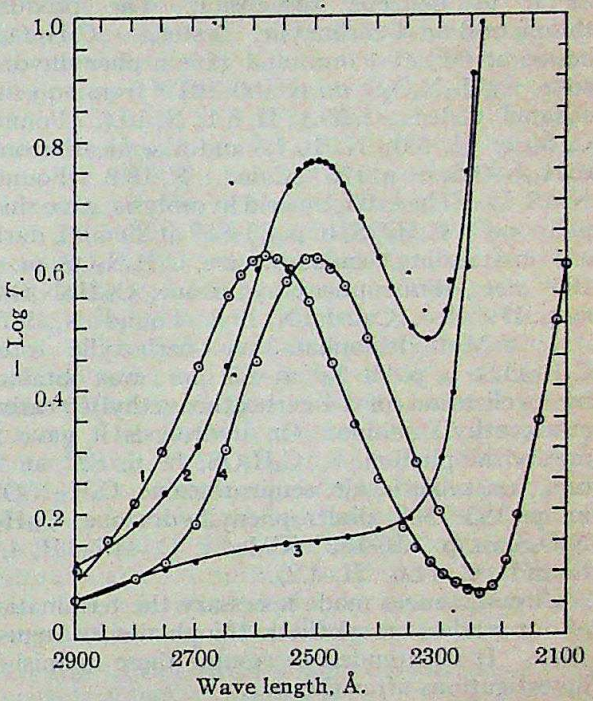

Fig. 1.—Log_{10} of per cent. light transmitted by a 1-cm. sample of: 1, 3.78×10^{-5} *M* sulfanilamide in 1 *N* NaCl, 1 *N* NaCl blank; 2, 3.78×10^{-5} *M* sulfanilamide in 1 *N* NaOH, water blank; 3, 1 *N* NaOH, water blank; 4, 3.78×10^{-5} *M* sulfanilamide in 1 *N* NaOH, solid line obtained by subtracting curve 3 from 2, and points -⊙- from measurements with 1 *N* NaOH blank.

These results do not confirm those of Kumler and Strait, and there appears to be no adequate experimental basis for the assumption that the resonating form with a separation of charge contributes more in a sulfonamide ion. Moreover, the lack of correlation between the base constants and bacteriostatic activity of sulfanilamide type compounds in general[5] does not support the hypothesis that the base weakening resonance form is a fundamental factor for activity.

(Carboethoxymethyl)-(β-carboethoxyethyl) sulfide, obtained by the reaction of thioglycolic ester with acrylic ester in the presence of a small amount of piperidine, was cyclized by means of sodium metal in benzene suspension. The product, thiophan-3-on-4-carboxylic ester,[2] $C_7H_{10}O_3S$, boiled at 96° at 4 mm. and gave a phenylhydrazone, $C_{13}H_{16}N_2O_2S$, m. p. 100–101°[3] from aqueous ethanol (Calcd.: C, 59.1; H, 6.1; N, 10.6. Found: C, 59.1; H, 6.0; N, 10.7), and a semicarbazone, $C_8H_{13}N_3O_3S$, m. p. 176° (Calcd.: N, 18.2. Found: N, 18.1). The ester, on acid hydrolysis, gave thiophanone-3, C_4H_6OS, b. p. 83–85° at 29 mm., darkens on standing, semicarbazone, $C_5H_9N_3OS$, m. p. 196° dec., dinitrophenylhydrazone, $C_{10}H_{10}N_4O_4S$, m. p. 179° dec. (Calcd.: N, 19.8. Found: N, 19.7).

2-Methylthiophan-3-on-4-carboxylic ester, $C_8H_{12}O_3S$, b. p. 93–95° at 4.5 mm., was obtained by cyclization of (α-carboethoxyethyl)(β-carboethoxyethyl) sulfide. On hydrolysis it gave 2-methylthiophanone-3, C_5H_8OS, b. p. 82° at 28 mm., unstable in air, semicarbazone, $C_6H_{11}N_3OS$, m. p. 185–186°, dinitrophenylhydrazone, $C_{11}H_{12}N_4O_4S$, m. p. 161–162° (Calcd.: C, 44.7; H, 4.1. Found: C, 44.6; H, 4.2).

Circumstances made necessary the termination of our studies on synthetic thiophanes in August, 1942. It is intended to resume these unfinished investigations after the war.

(2) The assigned formula is based on analogy; see Prill and McElvain, THIS JOURNAL, **55**, 1235 (1933).

(3) Karrer and Schmid (ref. 1, p. 127) obtained two phenylhydrazones, m. p. 141.5–142.5° and m. p. 167°; possible explanations to account for this discrepancy cannot be investigated at this time.

THE NATURE OF THE LUCIFERIN–LUCIFERASE SYSTEM

Sir:

In the luminescent system extracted from *Cypridina*, the substrate, luciferin, is dialyzable, while the enzyme, luciferase, is not.[1] Reduced luciferin undergoes reversible dark oxidation by oxygen or ferricyanide, and apparently irreversible luminescent oxidation by luciferase plus oxygen. Like dihydrocoenzyme, with an absorption maximum at 3400 Å., considerably purified, reduced luciferin solutions have an absorption peak near 3200 Å. On adding oxygen this absorption diminishes, while a new peak at 4300 Å. appears, shifting quickly to 4700 Å., then disappearing.[2] In presence of oxygen, aqueous luciferin is unstable. The absorption at 4700 Å. resembles that of certain flavoproteins, and practically coincides with the luminescence maximum at 4750 Å. The energy of this luminescent transition corresponds to 59,430 calories as compared to 57,340 calories available by direct oxidation of two hydrogen atoms on glucose, the substrate known to increase tremendously the luminescence of washed luminous bacteria.

We have now observed that a concentrated solution of luciferase, after prolonged dialysis with several hundred volumes of distilled water, and storage for some eighteen months in a refrigerator, will luminesce with oxygen, following reduction by (1) $Na_2S_2O_4$, (2) reduced Coenzyme I solution (partially reduced by pure hydrogen and platinized platinum, then added anaerobically to luciferase), (3) reduced riboflavin (similarly treated), (4) washed cells of *E. coli* plus glucose, and (5) growing culture of *E. coli*.[3] A portion of the luciferase solution gave luminescence repeatedly on successive additions of an excess of hydrosulfite then oxygen, but finally ceased. Luminescence continuous for some hours resulted when hydrogen, plus slight oxygen impurity, was passed through some luciferase solution containing platinized asbestos. Oxidized coenzyme, oxidized riboflavin, ferrocyanide, or glucose without bacteria, as expected, did not reduce the luciferase.

A consideration of the above facts indicates that the luminescent system consists of a pyridine nucleotide plus flavoprotein. According to the absorption spectrum, "luciferin" apparently contains both Coenzyme (I or II) and a flavine prosthetic group, the former component providing a reductant, and the latter, after loose combination with its specific protein, comprising molecules excitable by oxidation. Some of the excited molecules radiate and are not destroyed, but others, failing to radiate are destroyed by their absorbed energy. This phenomenon causes the "irreversible reaction" of luminescence. Such destruction of non-radiating excited molecules is responsible for the familiar degradation of riboflavin in solution in the light, and also phthalhydrazides during luminescent oxidation.

Thus, in luminous bacteria, light emission presumably occurs when flavoprotein, reduced by hydrogen from suitable substrates (*e. g.*, glucose) via the dehydrogenase–coenzyme system, is oxidized directly by oxygen. The effects of cyanide on oxygen consumption and luminescence, respectively, indicate that most of the hydrogen proceeds step-wise, by electron transfer, through the cytochrome–heme system to oxygen. With chlorophyll substituted for the related heme molecule, the same system of catalysts operating in the reverse direction would lead to photosynthesis. In luminescence two hydrogens are oxidized for the quantum emitted, while in photosynthesis single hydrogens are made available.

THE TOTAL SYNTHESIS OF QUININE[1]

Sir:

Quinine preparations have been known and used for centuries in the treatment of malaria. The pure crystalline alkaloid was isolated in 1820, and the extensive degradative researches of the last century culminated in the proposal of the correct structure in 1908, but the complexity of the molecule has placed hitherto insurmountable difficulties in the way of the total synthesis of the drug. We wish to record the first total synthesis of quinine.

7-Hydroxyisoquinoline was converted through its 8-piperidinomethyl derivative (m. p. 81.5–82.5°; *Anal.* Calcd. for $C_{15}H_{18}ON_2$: C, 74.36; H, 7.49; N, 11.57. Found: C, 73.79; H, 7.65; N, 11.86) into 7-hydroxy-8-methylisoquinoline (m. p. 232.0–233.5°; *Anal.* Calcd. for $C_{10}H_9ON$: C, 75.44; H, 5.70; N, 8.80. Found: C, 74.96; H, 5.51; N, 8.94). Hydrogenation over platinum oxide to 7-hydroxy-8-methyl-1,2,3,4-tetrahydroisoquinoline (m. p. 246–250°; *Anal.* Calcd. for $C_{10}H_{13}ON$: C, 73.59; H, 8.03; N, 8.58. Found: C, 73.41; H, 8.26; N, 8.63), and acetylation gave N-acetyl-2,7-hydroxy-8-methyl-1,2,3,4-tetrahydroisoquinoline (m. p. 191–198°; *Anal.* Calcd. for $C_{12}H_{15}O_2N$: C, 70.22; H, 7.35. Found: C, 70.54; H, 7.20). Further hydrogenation over Raney nickel led to a mixture of stereoisomeric N-acetyl-7-hydroxy-8-methyldecahydroisoquinolines (*Anal.* Calcd. for $C_{12}H_{21}O_2N$: C, 68.20; H, 10.02; N, 6.63. Found: C, 68.06; H, 9.75. Pure *cis*-isomer, m. p. 126.0–128.0°. *Anal.* Found: C, 68.34; H, 9.58; N, 6.59) which was oxidized directly to the corresponding N-acetyl-7-keto-8-methyldecahydroisoquinolines. From the latter, the pure *cis*-N-acetyl-7-keto-8-methyldecahydroisoquinoline (*cis* refers to the mode of locking of the rings) was isolated as the crystalline monohydrate (m. p. 80.5–82.5°; *Anal.* Calcd. for $C_{12}H_{19}O_2N \cdot H_2O$: C, 63.40; H, 9.32; N, 6.16. Found: C, 63.34; H, 8.85; N, 6.40) and converted by ethyl nitrite and sodium ethoxide to N-acetyl-10-oximinodihydrohomomeroquinene ethyl ester (two polymorphic forms—*labile*, m. p. 96–98°; *stable*, m. p. 108.5–109.0°; *Anal.* Calcd. for $C_{14}H_{24}O_4N_2$: C, 59.14; H, 8.51; N, 9.85. Found: C, 59.39; H, 8.24; N, 10.02). Reduction of the oximino-ester to the corresponding amine (characterized as the free 10-aminodihydrohomomeroquinene dihydrate, m. p. 186.5–188°; *Anal.* Calcd. for $C_{10}H_{20}O_2N_2 \cdot 2H_2O$: C, 51.20; H, 10.24; N, 11.86. Found: C, 50.83; H, 9.90; N, 12.04), complete methylation by methyl iodide and potassium carbonate, followed by alkali treatment of the resulting quaternary salt (*Anal.* Calcd. for $C_{17}H_{33}O_3N_2I$: C, 46.45; H, 7.55; N, 6.35. Found: C, 46.67; H, 7.14; N, 6.18) gave *dl*-homomeroquinene, isolated as the N-uramido derivative (m. p. 165.2–165.8° [dec.]; *Anal.* Calcd. for $C_{11}H_{18}O_3N_2$: C, 58.40; H, 8.02; N, 12.39; CH_3-C, nil. Found: C, 58.13; H, 7.45; N, 12.39; CH_3-C, nil). The free *dl*-homomeroquinene (m. p. 219–220° [dec.]) obtained on cleavage of the uramido group was converted by esterification and benzoylation to N-benzoylhomomeroquinene ethyl ester. Condensation of the latter with ethyl quininate, following the general methods elaborated by Rabe [*Ber.*, **51**, 1360 (1918); *ibid.*, **52**, 1842 (1919)], working with related natural materials [*cf.* Prožtenik and Prelog, *Helv. Chim. Acta*, **26**, 1965 (1943)], gave *dl*-quinotoxine. The racemic alkaloid was resolved through its salts with dibenzoyl-*d*-tartaric acid. The pure synthetic *d*-quinotoxine dibenzoyl-*d*-tartrate had m. p. 185.5–186°, and showed no depression in melting point on admixture with a sample of authentic material prepared from natural quinotoxine. The synthetic *d*-quinotoxine regenerated from the salt was a very pale yellow viscous oil, $[\alpha]_D$ +43°. Conversion of *d*-quinotoxine to quinine was first effected over twenty-five years ago by Rabe [*Ber.*, **51**, 466 (1918)], working with natural materials, during the course of his elegant work which resulted in the determination of the correct structures of the cinchona alkaloids.

THIOPHANE DERIVATIVES

Sir:

The appearance of reports by Karrer, Schmid and Kehrer [*Helv. Chim. Acta*, **27**, 116, 124, 127, 142 (1944), Received April 3, 1944] on thiophane derivatives prompts us to record our experiments in that field.

The dimethyl ester of β-mercaptopropionic acid S-acetic acid, obtained by addition of methyl thioglycolate to methyl acrylate in the presence of piperidine, was cyclized in two ways. With sodium methoxide in toluene at 110°, the main product was 4-carbomethoxy-3-ketothiophane (m. p. 37–38°, b. p. 128.5–129.5° [20 mm.]. *Anal.* Calcd. for $C_6H_8O_3S$: C, 45.1; H, 5.0; S, 20.0. Found: C, 44.3; H, 5.2; S, 19.8). This substance gave a permanent red-violet coloration with ferric chloride, and from it a *semicarbazone* (m. p. 189.5–190.0°. *Anal.* Calcd. for $C_7H_{11}O_3N_3S$: C, 38.7; H, 5.1; N, 19.3. Found: C, 39.2; H, 4.7; N, 19.1), a *monobenzylidene derivative* (m. p. 158–159°. *Anal.* Calcd. for $C_{13}H_{12}O_3S$: C, 62.9; H, 4.8. Found: C, 62.7; H, 5.2) and a *monofurfurylidene derivative* (m. p. 157–158°. *Anal.* Calcd. for $C_{11}H_{10}O_4S$: C, 55.5; H, 4.2. Found: C, 55.6; H, 4.6) were obtained. When the initial condensation was carried out at room temperature in ether with sodium

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

methoxide, the major product was 2-carbomethoxy-3-ketothiophane (oil, b. p. 116–116.5° [9 mm.]). From this keto-ester, a *semicarbazone* (m. p. 187–187.5° [mixed with the semicarbazone of the other isomer, m. p. 170–176°]. *Anal.* Calcd. for $C_7H_{11}O_3N_3S$: C, 38.7; H, 5.1. Found: C, 38.8; H, 4.7), a *monobenzylidene derivative* (m. p. 129–130°. *Anal.* Calcd. for $C_{13}H_{12}O_3S$: C, 62.9; H, 4.8. Found: C, 62.7; H, 4.9) and a *monofurfurylidene derivative* (m. p. 139.5–140.0°. *Anal.* Calcd. for $C_{11}H_{10}O_4S$: C, 55.5; H, 4.2. Found: C, 55.7; H, 4.3) were prepared.

Either of the isomeric β-keto-esters gave on hydrolysis 3-ketothiophane (oil, b. p. 58.2–58.4° [7 mm.]. *Anal.* Calcd. for C_4H_6OS: S, 31.4. Found: S, 30.3). A *dibenzylidene derivative* (m. p. 187.5°. *Anal.* Calcd. for $C_{18}H_{14}OS$: C, 77.8; H, 5.1; S, 11.5. Found: C, 77.9; H, 5.3; S, 11.7) and a *difurfurylidene derivative* (m. p. 191–192°. *Anal.* Calcd. for $C_{14}H_{10}O_3S$: C, 65.1; H, 4.2. Found: C, 65.1; H, 3.9) were prepared.

The 2-carbomethoxy-3-ketothiophane is remarkable in that on treatment with weak oxidizing agents (iodine, ferric chloride) it is rapidly and quantitatively converted to a double compound, $C_{12}H_{14}O_6S_2$ (m. p. 188.5–189.5°. *Anal.* Calcd. for C, 45.3; H, 4.4; S, 20.1. Found: C, 45.3; H, 4.6; S, 20.3), *dibenzylidene derivative* (m. p. 236°. *Anal.* Calcd. for $C_{26}H_{22}O_6S_2$: C, 63.0; H, 4.5. Found: C, 63.0; H, 4.6). From the double compound, by desulfurization, a *substance*, $C_{12}H_{18}O_6$ (m. p. 125–126°. *Anal.* Calcd. for C, 55.8; H, 7.0. Found: C, 56.7; H, 7.3), and from the latter by treatment with dilute mineral acids, an *acid*, $C_{10}H_{12}O_5$ (m. p. 152–153°. *Anal.* Calcd. for C, 56.7; H, 5.7. Found: C, 56.8; H, 6.0) were obtained, which we believe to be, respectively, dimethyl α,α'-dipropionyl succinate, and 2,5-diethylfuran-3,4-dicarboxylic acid.

We should like to take this opportunity to point out that the 2-furfurylidene-3-ketothiophane-4-carboxylic acid methyl ester described above possesses the complete continuous carbon–sulfur skeleton of biotin.

NEW BOOKS

The Chemistry of Organic Medicinal Products. By GLEN L. JENKINS, Dean and Professor of Pharmaceutical Chemistry, School of Pharmacy, Purdue University, and WALTER G. HARTUNG, Professor of Pharmaceutical Chemistry, School of Pharmacy, The University of Maryland. Second Edition. John Wiley & Sons, Inc., New York, N. Y.; Chapman and Hall, Ltd., London. iv + 675 pp. 14.5 × 12 cm. $6.50.

The second edition of this excellent compilation of organic medicinal compounds according to the accepted scheme of chemical classification is, in many respects, a much improved revision of the first planographed edition of 1941. Care has been taken to eliminate the trivial typographical errors, misspellings, misuse of words and phrases, and careless punctuation which marred the initial text. Rearrangement of the material into more compact paragraphs and better classified sections, and the gathering of the literature references into terminal chapter bibliographies have made the matter more easily and pleasantly readable. New material has been introduced and in many sections the explanatory text has been expanded, particularly in the chapter on Stereoisomerism where an excellent discussion of *cis–trans* isomerism about the ethylene bond is presented; a matter of some present importance in view of the recent revival of interest in the vitamin properties of the unsaturated fatty acids. A novel and interesting chapter entitled "Some Physical Chemical Properties of Medicinal Products" has been added. It is realized that a critical review and discussion of all theories and hypotheses is beyond the scope of this book but one would have liked to have seen some mention of the importance of physical chemical factors in the evaluation of the sulfonamides. This present text is intended for students in the more advanced courses in pharmaceutical, chemical, biological and medical science but will undoubtedly prove of great value and interest, not only to practitioners in these fields, but to the growing army of workers in the medicinal chemical industry.

C. R. ADDINALL

The Extra Pharmacopoeia. By MARTINDALE. 22nd Edition in Two Volumes. Published by Direction of the Council of the Pharmaceutical Society of Great Britain. The Pharmaceutical Press, 17 Bloomsbury Square, W.C. 1, London, England, 1943. xxxiii + 1217 pp. 11.5 × 18 cm. Price, 27/6; postage 6d. extra.

The first edition of "The Extra Pharmacopoeia" appeared in 1883 as a manual of 313 pages. The latest edition, the 22nd, published by direction of the Council of the Pharmaceutical Society of Great Britain, consists of two volumes: volume I, published in 1941, contains 1289 pages; volume II, the subject of this review, is a book of 1217 pages. It hardly seems possible to account for the 60-year existence and the continual growth in size of this particular "pharmacopoeia" except by the explanation that there has been a steady demand for a work of this nature, and that these volumes have satisfied the demand.

"The Extra Pharmacopoeia" is a repository of a vast amount of important, interesting and up-to-date information, and has been written particularly for the pharmacist, the physician, and the chemist who deals with foods and medicinal products. A rough estimate of the number of very diverse subjects, listed in the common index for the two volumes, is 13,000. Although too much space would be required to mention all of the chapter headings for volume II, 42 in number, the following examples will convey some idea of the nature of the topics which are discussed: Proprietary Medicines, Nomenclature of Organic Compounds, Chemotherapy, Polarographic Analysis, Nutrition and Food Values, Notes on Water Analysis, X-Ray Diagnosis and Actinotherapy.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Naturally, due to its brevity, the chapter which deals with some particular subject is hardly apt to contain information which will be new to the specialist in that field. However, this very brevity will be appreciated by the specialist who may wish to review very rapidly the developments and most outstanding facts in some cognate field with which he is only partially acquainted.

It is to be regretted that so much of the text appears in very fine print; probably any improvement in this respect is not feasible because of economic factors.

F. F. BLICKE

Supplement to The Extra Pharmacopoeia, Vol. I, 22nd Edition, 1941. By MARTINDALE. The Pharmaceutical Press, 17 Bloomsbury Square, London, W.C. 1, England, 1943. 48 pp. 11 × 17.5 cm. Price 2s., postage 2d.

The best manner in which to describe this Supplement is to mention a few of the fifteen subject headings listed in the table of contents: Summary of the Principal Changes made by the 4th, 5th and 6th Addenda to the British Pharmacopoeia, 1932, Additions in the 2nd, 3rd, 4th and 5th Supplements to the British Pharmaceutical Codex, 1934, Deletions from the British Pharmaceutical Codex, 1934, Amendments in the 2nd, 3rd, 4th and 5th Supplements to monographs of the British Pharmaceutical Codex, 1934, Preparations of the National War Formulary, 1943, Articles added to the United States Pharmacopoeia (U. S. P. XII) and Volume I Corrigenda.

It seems evident that the information in this booklet will be of especial importance to those who manufacture and dispense pharmaceutical products.

F. F. BLICKE

Semimicro Qualitative Analysis. A Course in Applied Chemical Equilibrium. By JOHN F. FLAGG, Ph.D., Assistant Professor of Chemistry, and WILLARD R. LINE, Ph.D., Professor of Chemistry, The University of Rochester. D. Van Nostrand Company, Inc., 250 Fourth Avenue, New York, N. Y., 1943. viii + 140 pp. 2 figs. 14.5 × 22.5 cm. Price, $1.50.

This book is another addition to the already large list of semi-micro texts with chapters on related theoretical and factual matter. Its six preliminary chapters deal with the definition and field of qualitative analysis, chemical equilibrium, homogeneous equilibria, heterogeneous equilibria, oxidation–reduction reactions and technique of semimicro qualitative analysis, all in 56 pages. The treatment of the topics is clear and readable, but necessarily brief.

The analytical part takes up cation, anion and alloy analysis. The cations are separated and identified in much the usual way, some interesting points being: separation of the acid sulfide group with sodium sulfide reagent; separation of lead and bismuth with ammonia from copper and cadmium; use of salicylaldoxime to divide copper and cadmium; the precipitation of zinc as sulfide in a formate buffer prior to the rest of the alkaline sulfide family; and the separation of calcium and magnesium nitrates with methyl alcohol from barium and strontium. The anion analysis is not treated very systematically. The alloy section deals very briefly with certain alloys, giving the appropriate methods, including additional ones needed for silicon, tungsten, molybdenum, vanadium and titanium.

Although it should prove to be a good average text for the student, the book suffers from bad planning and poor style editing. The trimmed head margin is $^3/_8$", the side margin $^7/_8$", while the bottom is $1^3/_8$", giving a distinctly "short-skirted" appearance which belies the prominent statement that production was carried out in line with war economy. There are several places where additional section heads might well have been used, especially on pp. 95 and 99. A good and consistent editorial style seems almost absent, resulting in numerous irregular and unsightly details, such as: bold, roman and italics for mathematical symbols, formulas instead of names, the use of P for procedure, and the space-wasting use of bulky text type for illustrative chemical and mathematical formulas.

ALLEN D. BLISS

Pyrotechnics, Civil and Military. By G. W. WEINGART. Chemical Publishing Co., Inc., Brooklyn, New York, 1943. xii + 220 pp. 96 figs. 14.5 × 22 cm. Price, $5.00.

Books on fireworks are rare. Weingart's book, so far as the reviewer knows, is the only book devoted entirely to this subject which has been published in the United States since the three volumes of Faber's "Military Pyrotechnics" were issued by the Government Printing Office in 1919. The present revision is really a third edition, or, more exactly, a fourth if the early mimeographed edition is counted. It contains more and better pictures than its predecessors, and new formulas which the author has tried for himself. Its price seems rather high. It lacks a much needed index. The glossary is important and useful. The List of Pyrotechnical Books which terminates the volume gives titles which are too much abbreviated, does not indicate which books are translations, and fails to show the places of publication. It does not by any means furnish "a complete record of the development of the art of pyrotechny up to the present time." Except for a few passing references to military uses, the book deals entirely with recreational fireworks and contains nothing which justifies the assertion on the title-page that it deals with military pyrotechnics as well.

Weingart's book is a practical book by a practical man. Recognized as such, it is extremely valuable. It summarizes an experience of about fifty years. Its principal parts deal, respectively, with I. Ingredients, with II. Manipulation, Tools and Appliances Used, with III. Articles of Manufacture and Formulas, and with IV. Exhibition Fireworks. It contains many observations, sometimes homely but always useful, on safety, on procedure, on the properties of substances. It tells the amateur how to construct fireworks pieces, and it shows the chemist what the tricks and contrivances are by which a few rather ordinary chemical substances are made to produce some extraordinary audible and visible effects. The same devices are applied in military as in civil pyrotechnics—and Weingart's book will supply a needed acquaintance with them to anyone who may have to work with explosive and pyrotechnic instruments of war.

TENNEY L. DAVIS

The Optical Properties of Organic Compounds. By ALEXANDER WINCHELL, University of Wisconsin. University of Wisconsin Press, Madison, Wisconsin. 1943. xiii + 342 pp. 157 figs., 1 chart. 17.8 × 26.2 cm. (Photo offset.) Price, $5.00.

While optical methods have been widely used in identifications of natural and synthetic inorganic compounds they have seldom been applied to organic compounds. This limitation has several causes, among which are: faults of an educational scheme, some difficulties in application, and absence of a summary of previous observations. Professor Winchell has successfully answered the last need.

Optical data for about 1700 compounds are tabulated, in a determinative scheme, according to their mean refractive indices and 910 are plotted on a chart, according to their birefringences and mean refractive indices. The limited numbers and types of compounds are disappointing from the point of view of usefulness in determinative organic chemistry, but the lists are quite complete as far as published data are concerned and previously unpublished values are included. Alkaloids are the most numerous class treated, being represented by 280 compounds. Optical properties are listed for approximately 250 salts.

The designation of refractive indices is confusing and does not follow the widely accepted usage of α, β and γ.

Since the book is strictly a tabulation of constants the untrained worker must look elsewhere for methods of measurement.

S. B. HENDRICKS

Synthetic Resins and Rubbers. By PAUL O. POWERS, Chief, Organic Research, Armstrong Cork Company. John Wiley & Sons, Inc., 440 Fourth Avenue, New York, N. Y., 1943. v + 296 pp. 49 figs. 13.5 × 21.5 cm. Price, $3.00.

This little book gives a clear and interesting account of the chemistry of more important synthetic resins and rubbers. It opens with a general historical and statistical introduction, including a table listing the name, structural formula, physical properties and source of the raw materials from which the industrially important resins are derived. The next chapter discusses the mechanism and kinetics of polymerization and the distinction between linear and cross linked polymers and the behavior of catalysts and inhibitors of polymerization. This is followed by separate chapters describing the more important classes of resins now in use industrially. Trade names are avoided throughout. Finally there is a very brief summary of solvents and plasticizers and of the technique of molding and the use of resins in formulating protective coatings. Each chapter is followed by review questions and a few additional references, but there is no attempt to cite a literature reference in support of every statement in the text.

This book does not compete with the larger books available in completeness, in detail and in giving numerous references. It does not give enough numerical data as to properties of the commercially available resins to be of much help to anyone trying to choose the best resin for a particular application. However, this book can be recommended to a chemist who has not specialized in the field but wishes a readable and reliable general introduction to synthetic resins and synthetic rubbers.

GRINNELL JONES

Principles and Applications of Electrochemistry. Volume II. Applications. By W. A. KOEHLER, Professor of Chemical and Ceramic Engineering, West Virginia University. Second Edition. John Wiley and Sons, Inc., New York, N. Y., 1944. v + 573 pp. 260 figs. 14.5 × 21.5 cm. Price, $5.00.

This volume on applications of electrochemistry is intended for use in conjunction with Prof. H. J. Creighton's volume dealing with the principles of electrochemistry. The author has included the following new topics in the second edition: continuous tin strip plating, magnesium from sea water, hydrogen peroxide manufacture, fluorescent lamps, induction heating of non-conducting materials, new carbon bisulfide furnace, new phosphorus furnace, and nickel–cadmium alkaline storage battery.

The second chapter, "Review of Theoretical Electrochemistry," leaves some confusion in the reader's mind regarding the relative merits of the Arrhenius theory and the complete dissociation theory. The author presents both theories and then arbitrarily chooses the Arrhenius theory for the balance of his discussion.

The descriptions of the various applications are as complete as is practical in one volume. The descriptions are, for the most part, accurate; there are numerous errors that will no doubt be corrected in the subsequent printings. One of the more notable errors is the statement on page 175: "the platinum metals go into solution in the electrolytic parting." They remain in the slimes along with gold, but go into solution in the gold refining cell.

The book is well illustrated with photographs and line drawings of the various types of equipment used and operating data given for all of the important applications. This is supplemented with numerous references to the literature for the use of the reader interested in any one particular application.

The following classes of applications are discussed: primary and secondary cells, electroplating, refining and electrometallurgy of metals, electrolysis of halides, electrolytic oxidation and reduction, hydrogen and oxygen, corrosion, electroanalysis, electric furnaces, electronics, ozone, nitrogen fixation, separation by electrical means, and miscellaneous electrochemical processes (such as anodizing, electrolytic polishing, etc.).

The revised edition is now up to date and will no doubt continue to serve the same purposes as the first edition, that is, as a text for college students and a reference for those in the industry.

HENRY B. LINFORD

A Short Course in Quantitative Analysis. By HOBART H. WILLARD, Ph.D., Professor of Analytical Chemistry, University of Michigan, N. HOWELL FURMAN, Ph.D., Professor of Chemistry in Princeton University, and JOHN F. FLAGG, Ph.D., Assistant Professor of Chemistry, University of Rochester. D. Van Nostrand Company, Inc., 250 Fourth Ave., New York, N. Y., 1943. ix + 253 pp. 15 × 22 cm. Price, $2.50.

This book is intended as a text for brief, one-semester courses in elementary quantitative analysis for premedical, agricultural, and certain classes of engineering students, and not for students concentrating in chemistry. As the authors state in the Preface the book is more or less an abbreviated version of the two senior authors' well-known "Elementary Quantitative Analysis," and a number of the good features of the latter text have been retained.

The first three chapters, I, Introduction; Fundamental Theory, II, Introduction to Laboratory Work, and III, The Measurements of Quantitative Analysis, furnish a concise introduction to techniques that are common to both gravimetric and volumetric analysis. As an example of one way in which brevity has been attained it may be noted that in Chapter III in connection with the discussion of the analytical balance and weighing no mention is made of the use of calibrated weights, nor of correction for air buoyancy. Such omissions are probably necessary in short courses for which the book is intended.

The following eight chapters are devoted to the theory and practice of volumetric analysis. Procedures are given for the following volumetric determinations: Sodium Oxide in Soda Ash; Replaceable Hydrogen in an Acid; Nitrogen in Organic Compounds by the Kjeldahl method; Chloride by the Mohr, Fajans (adsorption indicator), and Volhard methods; Iron in ores by the permanganate, dichromate, and ceric sulfate methods; Calcium Oxide in "calcium carbonate"; Available Oxygen in Pyrolusite (oxalic acid–permanganate method); Available Chlorine in Bleaching Powder (iodometrically); Copper in ores; and Arsenic in "arsenious oxide" (iodometrically). These determinations illustrate most of the important types of volumetric methods. Considerable emphasis has been placed on the theory of protolytic titrations (the illustrative titration curves on pages 58 and 59 are excellent), on the interpretation of oxidation–reduction titrations in terms of the oxidation potential, and on the use of modern oxidation–reduction indicators.

Most of the procedural details appear to be quite satisfactory. As one of the few exceptions may be noted the recommendation on p. 155 that *ammonium* thiocyanate be used to metathesize cuprous iodide in the iodometric copper determination; ammonium thiocyanate may not be used because it usually contains impurities which consume iodine, and the potassium salt should be employed.

Gravimetric analysis is discussed in the last three chapters, and procedures are provided for the following determinations: Chloride; Sulfate in a soluble sulfate; Magnesium Oxide; Phosphoric Anhydride in a soluble phosphate; and an abbreviated analysis of limestone for loss on ignition, siliceous matter, "R_2O_3," calcium oxide, and magnesium oxide. Among the few novelties noted in the gravimetric procedures is the employment of calcium carbonate as the final weighing form for calcium, which avoids

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the difficulty of weighing ignited calcium oxide, but which usually is not attempted in elementary courses because it requires rather careful control of temperature (electric furnace) during the ignition of the calcium oxalate.

In keeping with its intended use in abbreviated courses the text contains no mention of electrolytic, colorimetric, or other special analytical methods.

Most of the chapters conclude with sets of problems which, in the words of the authors, "have been roughly arranged in order of increasing difficulty, with answers to about one-third included."

In the reviewer's opinion one undesirable feature of the text is the consistent disregard of the actual molecular and ionic states of the substances involved in the reaction equations which are given. For example the equation "$Fe^{+++} + 6KCNS = Fe(CNS)_6^{=} + 6K^{+}$" given on p. 96 leads to some rather weird conclusions when interpreted literally. The same is true of numerous other equations throughout the text, of which the following on p. 115 is typical: "$5Na_2C_2O_4 + 2KMnO_4 + 8H_2SO_4 = 10CO_2 + 5Na_2SO_4 + K_2SO_4 + 2MnSO_4 + 8H_2O$." Since equations of this sort are misleading, and serve only to obscure the real reactions that take place as well as the essential equilibria involved, the reviewer cannot agree with the statement on p. 104 that they "are very useful in understanding the fundamental stoichiometry of a process."

The Appendix contains an outline of the general literature of analytical chemistry, a section on Mathematical Operations, a list of stock solutions of protolytic indicators, a table of dissociation constants of the commoner acids and bases, a table of solubility products, and a five-place logarithm table.

Since the reviewer has the highest regard for Willard and Furman's "Elementary Quantitative Analysis," which has contributed so much to the maintenance of high standards in the teaching of quantitative analysis, he cannot become very enthusiastic over this emasculated version.

JAMES J. LINGANE

Industrial Chemistry of Colloidal and Amorphous Materials. By WARREN K. LEWIS, Ph.D., Professor in the Department of Chemical Engineering, Massachusetts Institute of Technology, LOMBARD SQUIRES, S.M., Chemical Engineer with E. I. du Pont de Nemours Company, Wilmington, Delaware, and GEOFFREY BROUGHTON, Sc.D., A.I.C., Chemical Engineer with the Eastman Kodak Company, Rochester, N. Y. The Macmillan Company, 60 Fifth Avenue, New York, N. Y., 1942. xi + 540 pp. Illustrated. 16 × 24 cm. Price, $5.50.

The authors of this very interesting and well-written manual set out to write a text on the industrial chemistry of colloidal and amorphous materials. These they list as emulsions and foams, thermoplastics, glass, paper, plastic fibers, leather, rubber, clays, synthetic resins and plastics, and textile fibers.

The technology of each of these materials is clearly and briefly discussed, together with the scientific interpretation of each process and product. For example, the X-ray diagrams and other physical chemical data are correlated with the industrial procedures. This provides a very interesting and clarified conspectus such as is hardly to be found elsewhere.

In order to lay a foundation for this treatment, the authors devote the first half of the book to a review of physics and of colloid science, beginning with structure of liquids and proceeding through viscosity, surface tension, orientation, adsorption, suspensoids, amorphous solids, emulsoids, electrochemical behavior of colloids, gelation, to plastic distortion and flow.

The treatment as well as the choice of the data is orthodox, and in accordance with the earlier development of the subject. For example, there is no mention of the essential stabilizing agent in the whole chapter on suspensoids, whereas a stabilizing agent is as necessary here as it is in the formation of emulsions or foams. On the other hand, the authors have rationalized for themselves the subject matter that they discuss, and this is done so clearly that the reader is shown the facts as well as the way in which the authors interpret them. The explanations are reasonable and appeal to the engineering mind. The reader is invited by the authors to formulate his own opinions.

The authors state—"In a specific problem knowledge of the facts is often inadequate and occasionally in dispute, while understanding of underlying causes is limited and uncertain. Experts disagree on the explanations of phenomena of fundamental importance. In such a situation the scientist tends to withhold judgment but the technologist is faced with the necessity of making decisions and taking action. Many individuals prefer a purely empirical approach, but it is the conviction of the writers that it is best to submit each problem to a careful, theoretical analysis, even though in the nature of the specific case this may be known to be inadequate. A major purpose, therefore, is the introduction of the student to such a method of attack." To assist in this purpose they supply numerous cross references and append a bibliography to each chapter.

The book has stood the test of time, embodying the results of twenty-five years teaching of the subject at the Massachusetts Institute of Technology. The preparation of the manuscript was begun over a dozen years ago by Dr. P. K. Frolich and it has been constantly revised because of the very rapid developments in most of the fields discussed.

This admirable book is not only an excellent text but is a unique contribution to the advancement of science and industry.

JAMES W. MCBAIN

Laboratory Manual of Spot Tests. By Dr. FRITZ FEIGL. Translated from the German manuscript by Ralph E. Oesper, Ph.D., Professor of Chemistry, University of Cincinnati. Academic Press, Inc., 125 E. 23d Street, New York, N. Y., 1943. xii + 276 pp. 46 figs. 15.5 × 23.5 cm. Price, $3.90.

To one familiar with Dr. Feigl's previous books on spot reactions the first question prompted by this book is its relation to the earlier works. The other two translations—that by Matthews in 1937 and that by Oesper in 1940—covered, respectively, the practical and the theoretical parts of the German edition, "Qualitative Analyse mit Hilfe von Tüpfelreaktionen." Whereas they are primarily reference monographs, this book, containing both old and new material, is a laboratory manual based upon them, designed for teaching the analytical applications of the principle of accomplishing a chemical reaction within the volume of one drop of solution.

To achieve best pedagogic results with it, Dr. Feigl recommends a special course following elementary training in inorganic, organic, and physical chemistry. The possibility of adding much of this undoubtedly meritorious technic to our present curricula seems to the reviewer unpromising. Educational institutions in the United States are moving in the opposite direction. In the course of buying, making, using, and selling commodities and products, chemical industry and research are applying more and more analytical methods and apparatus, of greater and greater complexity. But perhaps even more rapidly analytical chemistry is being accorded less and less academic importance. If we are to reverse the process and incorporate new technics into our courses, analytical teachers having breadth of training and interest in the subject must be selected, and they must have better support of administrators.

The opening summary of the theoretical foundations of spot test analysis (22 p.) is followed by an adequately illustrated section on technic (40 p.). The appendix lists the reagents and includes a floor plan of a spot test laboratory.

There follows a section on surface and capillary effects (38 p.), especially interesting in connection with the use of filter paper as a medium for observing the reactions. Some

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

thirty experiments are described which, quite apart from spot tests, should prove suggestive to demonstratively inclined instructors.

The portion devoted to actual analytical applications covers the following divisions: (a) inorganic analysis (69 p.), including inorganic and organic reagents, masking and catalytic reactions, and induced precipitations; (b) organic analysis (29 p.), including selected elements, groups and compounds; (c) rocks and minerals (16 p.); (d) technical products (17 p.); (e) biological material (12 p.); and (f) spot colorimetry by means of a standard series technic (16 p.). In the first two of these divisions the material is arranged systematically under the headings chemical basis, procedure, identification and concentration limits, and application in the presence of other materials.

Although mistakes noted are rare, a few items of usage seem to the reviewer to be questionable. Illustrative of his preference to that of the author are the following examples: (a) the spellings buret, pipet, and dichromate; (b) the I. U. C. names biacetyl, 2,2′-bipyridyl, and 1,10-phenanthroline; (c) the names recently recommended by an international committee for various inorganic complex ions; and (d) consistency in the formulation of heteropoly compounds, preferably in accordance with Keggin's work (including naming in terms of the central atom).

As a whole, the selection, arrangement, and treatment of material seems well done for teaching purposes. The smoothly reading translation renders American chemists indebted to Professor Oesper for making the information readily available. The book should prove valuable, not only for teaching but also as a source of ideas for practical analysts and research workers.

M. G. MELLON

The Organic Chemistry of Sulfur. Tetracovalent Sulfur Compounds. By CHESTER MERLE SUTER, Director of Chemical Research, Winthrop Chemical Company, Formerly Professor of Chemistry, Northwestern University. John Wiley and Sons, Inc., 440 Fourth Avenue, New York, N. Y., 1944. v + 858 pp. 14.5 × 21.5 cm. Price, $10.00.

Chemists, academic as well as industrial, are indebted to Dr. Suter, who has been prominent as a university professor and as a director of industrial research, for a comprehensive review of this important field.

This book covers organic compounds of the types: $RO{\cdot}SO_2{\cdot}OR$, $R{\cdot}SO_2{\cdot}OR$, $R{\cdot}SO_2{\cdot}R$ and $R{\cdot}SO_2{\cdot}X$ in which R is either aliphatic or aromatic and X is —OH, —Cl, $—NH_2$, —NHR, etc. Sixty per cent. of the space is devoted to aromatic sulfonic acids and their derivatives, 93 pages to esters of sulfuric acid, 101 pages to aliphatic sulfonic acids and 117 pages to sulfones which include aliphatic, aromatic and mixed. There are about 4700 numbered references, but as there are frequently five, ten or twenty references under one number the total may pass ten thousand. *Chemical Abstracts* references are given for patents. This vast amount of material is arranged in an orderly way and presented clearly.

Aromatic sulfonic acids and their derivatives have been an important part of the old organic chemistry and aliphatic sulfates and sulfonates are of intense present interest as wetting agents and detergents; the old and the new are here brought together. This book is an important addition to chemical literature; no chemical library can be complete without it.

JOURNAL OF THE AMERICAN CHEMICAL SOCIETY

Published monthly by the American Chemical Society at Easton, Penna.

Editorial Office: Chemical Laboratory of Harvard University, 12 Oxford St., Cambridge 38, Mass.

Assistant to the Editor (Proof and Make-up): Allen D. Bliss, Department of Chemistry, Simmons College, 300 The Fenway, Boston 15, Mass.

Business Office: American Chemical Society, 1155 16th St., N.W., Washington 6, D. C.

Advertising Office: American Chemical Society, 332 West 42nd St., New York 18, N. Y.

The American Chemical Society and the Editors of the *Journal of the American Chemical Society* assume no responsibility for the statements and opinions advanced by contributors to THIS JOURNAL.

Remittances and orders for subscriptions and for single copies, notices of changes of address and new professional connections, and claims for missing numbers should be sent to the American Chemical Society, 1155 16th Street, N.W., Washington 6, D. C. Changes of address for the *Journal of the American Chemical Society* must be received on or before the 18th of the preceding month.

Claims for missing numbers will not be allowed (1) if received more than sixty days from date of issue (owing to the hazards of war-time delivery, no claims can be honored from subscribers outside of North America), (2) if loss was due to failure of notice of change of address to be received before the date specified in the preceding paragraph, or (3) if the reason for the claim is "missing from files."

Annual subscription—$8.50 to non-members, $3.00 to members. Postage to countries not in the Pan American Union, $1.50; Canadian postage, $0.50. Single copies—current issues $0.75, back numbers $0.80; special rates to members.

The American Chemical Society also publishes *Chemical Abstracts*, *Industrial and Engineering Chemistry* (Industrial and Analytical Editions), and *Chemical and Engineering News*. Rates on request.

NOTICE TO AUTHORS OF PAPERS

Manuscripts for THIS JOURNAL should be submitted to the Editor ready for publication, typewritten (double space), with 2–3 cm. margins, on a good quality, durable paper, preferably of 8.5″ × 11″ size. In addition to the original typewritten copy, one or more carbon copies should be submitted so that the time required for examination by the Editorial Board may thus be considerably shortened. Care should be taken that all pages in a manuscript, including tables (but not the diagrams) be numbered consecutively. In preparing manuscripts authors are requested to observe, for reasons of economy, the utmost conciseness consistent with clarity of presentation. The manuscripts should be addressed to specialists in their particular field rather than to the general reader. Extensive reviews of the literature cannot be accepted. When well-known or previously published procedures have been followed in the experimental work they should only be designated or referred to.

Form of Presentation.—There should be one or more introductory paragraphs setting forth the occasion, significance and main objectives of the investigation and the method of attack. This should be followed by the experimental results and a discussion of them, either *seriatim* or at their conclusion. Finally, there should be a brief summary of the main achievements of the investigation. Sometimes, particularly when the subject matter is involved and there are many details which, though essential for a successful repetition of the experiments, are unnecessary for the main account of the investigation, these details can with advantage be relegated to an appendix or supplement, just preceding the Summary. In intermediate cases it is often advisable to retain a single, straightforward presentation but to intercalate sections in fine print giving the experimental details of procedure. This has the great advantage of keeping the experimental details close to the more general statements based upon them and yet at the same time permitting the reader if he wishes to pass over this section without inconvenience.

It will be of great assistance to the Editor's Office if the style, arrangement and orthography of the manuscripts are made to conform to the usages of the JOURNAL as exemplified in its recent issues and as set forth in the following paragraphs.

Center headings should be employed sparingly; side headings should be indented and run into the text to which they apply, using period and dash. References to the literature and all footnotes regardless of their nature (except those in tables) should be numbered in one consecutive series, repetition of notes being avoided by using simply the superscript number corresponding to the original reference. They should follow immediately in separate lines the line of text containing the text words to which they refer, and may be set off by short rules above and below. The items in the references to the literature should conform to the uniform usages of the Journal as regards order and punctuation, and to the abbreviations as given by *Chemical Abstracts* in its "List of Periodicals Abstracted." The names of all simple compounds rather than their formulas should be used whenever they occur in the text. Periods of time (unless fractional) should be written in words and quantities of material in Arabic numerals, unless occurring at the beginning of a sentence. Letters used to represent quantities in mathematical expressions should be underscored to indicate that they are to be printed in italics, and Greek or other unusual characters should be written plainly or should be explained by annotations. Simple fractional expressions should be written with a slant line rather than in the conventional manner, so that only a single line of type is required. All subscripts and superscripts should be carefully made and placed (the degree sign ° or a small o should not be used to represent zero). For economy, except in unusual circumstances the abbreviations %, °A., cm., cc., ml., g., Å., m. p., f. p., b. p., cal., kcal., expt. and Fig., should be used rather than the words.

Figures and graphs should be carefully prepared line drawings on plain white drawing paper, blue drawing cloth or coördinate paper printed in blue only. The

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

originals are preferable, but clear, well-prepared photographic prints or photostats are acceptable. Illustrations are most conveniently handled when made in the conventional 8.5″ × 11″ manuscript size; if they are of necessity larger, and therefore liable to damage in mailing, duplicate rough sketches or photographic prints of smaller size should be furnished for dispatch to the Referees. Diagrams should be designed to occupy a single column width and should therefore be tall rather than wide. Particular attention should be given to the correct proportions of the various parts of the figure, especially the experimental points, and if any letters, numbers, or legends must be placed on the diagram to their proportions also. In graphs the frame and actual curves should be ruled and inked more heavily than the coördinate lines, and these latter should not be too close together. Experimental points should always be given and should be indicated not by crosses but by circles or other symbols carefully drawn with drafting instruments. Where feasible it is often helpful to have the diameter of the circles indicate the precision of the measurements. The numbers and legends on coördinate axes are set up in type by the printer; the author, therefore, should place them in pencil outside the axes. The numbers and titles of figures should be placed below the diagrams, or on the back, or collected on a separate sheet. Small photographic prints should be mounted on cardboard and any composite series of photographic prints should be mounted in the order and arrangement desired. Each piece of illustration copy should be marked on the margin or back with the name of the author and brief title of the article (for identification purposes).

Tables.—Tables should not be used indiscriminately as they are much more expensive, line for line, than running text. If reasonably possible, they should be designed to occupy fully a single column (3 inches), which will take 50–75 characters and spaces. Tables occupying the full width can be used, but they are undesirable for the same reasons advanced with regard to page wide figures; their preparation should follow the same principles as for those of single width. Care should be taken to avoid any arrangement which unduly increases the depth of a table, and column heads should be made as small as possible, using abbreviations liberally. Lines of data should not be numbered nor run numbers given unless these numbers are needed for reference in the text. Columns should not be used to contain only one or two entries, nor should the same entry be repeated numerous times consecutively, since these cases may be taken care of more economically in footnotes, or by entries following the title of the table. Data should not be included in one column which are deducible easily by simple arithmetic from data in another column. Tables should be interspersed in the manuscript as near as possible to the places where they are referred to in the text, and need not be placed alone on separate sheets.

Formulas and Equations.—Empirical and structural formulas and mathematical and chemical equations should be arranged to fill adequately the width of a single column. This will often require a continuation of the equation in additional lines, and although this is a disadvantage it is in general preferable to intrusion into the adjoining column. Subscripts and superscripts, especially the latter, should be written with care and the conventional fractional arrangements should not be used in exponents. Organic structural formulas should be arranged to fill the space economically, and arrows should be used horizontally or vertically, not diagonally, wherever possible.

Notes do not differ fundamentally from Articles. They describe fragmentary or less complete studies and hence particular attention must be given to brevity and conciseness of presentation. Summaries are not included. They are collected in a special section near the end of each number of the Journal.

New Compounds.—This department is for brief accounts of new substances which do not appear of sufficient importance to justify separate publication and cannot be described appropriately as part of any other Article or Note. These accounts should report the preparation of the new compound succinctly, yet fully enough so that the operations can be duplicated. Significant properties, formulas and analytical data to establish the identity and purity of the substance should be given. Material appearing in this classification will not be accepted for subsequent publication.

Communications to the Editor are designed to afford prompt, brief, preliminary publication in our Journal of new and significant observations or discoveries. Their total length may in no case exceed 500 words or the equivalent. They will be given as rapid editorial consideration as possible, but at best it will usually be out of the question to include them in a given issue of the Journal if they arrive at the Editor's office later than the 20th of the preceding month. Communications like other contributions should be self-sustaining; that is, they should present experimental or other evidence adequate to establish the *prima facie* credibility of the results or conclusions stated or to permit their appraisal by an expert in the field although because of the 500-word limit a complete presentation cannot usually be expected. These requirements make Communications on many subjects impracticable, particularly those of an involved or theoretical nature.

Communications differ from ordinary Articles or Notes in that their publication does not prevent the re-publication of their subject matter in a later, more complete article in the Journal. In view of this special provision and their expedited publication, it is clear that the contribution made by the Communication should be of special interest or timeliness; mere abstracts of forthcoming articles cannot be accepted. Proof and reprint order will be sent to authors whenever possible, but as this cannot always be done, a memorandum as to the reprints desired should accompany the manuscript.

Microfilm Supplements.—By arrangement with Science Service material supplementary to articles in THIS JOURNAL, such for instance as extensive tables, graphs or calculations, can be distributed at small cost as American Documentation Institute Documents in the form of microfilms with images 25 mm. high on standard 35-mm. film or photoprints 6 × 8 inches legible to the unaided eye. Such material must, however, have been submitted to the Editor of the Journal and must have been approved by him for publication. Attention will then be called to these documents by means of footnotes at appropriate points in the text of the article concerned.

Polyenes. II. The Purification of β-Ionone[1,2]

BY WILLIAM G. YOUNG, STANLEY J. CRISTOL, LAWRENCE J. ANDREWS AND SEYMOUR L. LINDENBAUM

The purification of commercial β-ionone by decomposition of its highly purified semicarbazone[3] according to the frequently reported method of steam distilling the semicarbazone in the presence of phthalic anhydride was carried out in the usual manner.[4] A spectrophotometric comparison of the β-ionone prepared by this procedure with the original starting material indicated that both products had identical maximum extinction coefficients. The failure of this well-known method of purification led to an investigation of the effects of various acidic media on the decomposition of β-ionone semicarbazone. The results of this study are presented in this paper along with a brief report of an attempted purification of β-ionone based on an expected difference in reaction rates of α- and β-ionone with perbenzoic acid.

The Purity of β-Ionone Prepared from its Semicarbazone.—Commercial β-ionone having absorption maxima at 296 mμ (ε 8600) and 222 mμ (ε 7350) was converted to the semicarbazone. This derivative was recrystallized repeatedly to constant melting point (148–149°) and extinction coefficient.[5] The purified semicarbazone was decomposed in various acidic media, and the extinction coefficients (296 mμ) of the product were measured in 95% ethanol to determine the degree to which isomerization into α-ionone occurred (see Table I).

TABLE I

THE PURITY OF β-IONONE

Method of semicarbazone decomposition	Semicarbazone, g.	Amount of acid	$n^{20}D$	ϵ_{max} (296 mμ)[a]	% Purity
Phthalic anhydride[b]	72	72 g.	1.5175	8600[c]	80
Phthalic anhydride[b]	5	5 g.	1.5157	9600	90
Succinic acid[b]	5	0.17 eq.	1.5198	10100	95
Phosphoric acid[b]	5	0.12 eq.	1.5200	10100	95
Sulfuric acid[c]	68	1.0 eq.	1.5205	10100	95
Sulfuric acid[b]	5	0.12 eq.	1.5211	10500	98
Cold sulfuric acid[d]	5	0.10 eq.	1.5211	10700	100

[a] The solvent was 95% ethanol. [b] The liberated β-ionone was steam distilled from the acid mixture. [c] Refluxed three hours with 300 ml. of 3 *N* sulfuric acid. [d] Method of Heilbron and co-workers[6]; it should be noted that the properties of purified β-ionone obtained by Heilbron (ε 12900, $n^{19}D$ 1.5178) are considerably different from those reported here. [e] Burawoy[4b] reports ε max 8700 (abs. ethanol) and Ruzicka[4c] reports ε max 8900 in absolute ethanol using the phthalic anhydride method.

Of the several methods tried for decomposing the semicarbazone, the one using sulfuric acid was the most reliable. In fact the modification of this procedure reported by Heilbron and co-workers[6] while these studies were in progress has been tried and found to give β-ionone of the highest maximum extinction coefficient (λ_{max} 296 mμ, ϵ_{max} 10700). This is considerably higher than that of the product obtained by the usual method with phthalic anhydride. In view of the fact that neither β-ionone nor its semicarbazone are isomerized by the conditions used in the hydrolysis it is likely that this method of Heilbron gives pure β-ionone. The extinction coefficients of β-ionone samples were not altered by exposing the samples to cold or hot dilute sulfuric acid.

(1) This paper was presented before the Organic Division of the American Chemical Society, Pittsburgh, Pa., September, 1943.

Neither did exposing a sample of β-ionone semicarbazone to cold dilute sulfuric acid until about one-third of it had been hydrolyzed change the spectrum of the unhydrolyzed semicarbazone.

It does not seem likely that the presence of α-ionone in the product from the hydrolysis of β-ionone semicarbazone with phthalic anhydride should be attributed to the effect of the acidic medium on the liberated β-ionone since the ionone was steam distilled from the mixture as soon as it was formed. Attempts to study the effects of the phthalic anhydride medium on the semicarbazone itself have so far failed owing to difficulties involved in purifying the partially decomposed semicarbazone recovered from the medium.

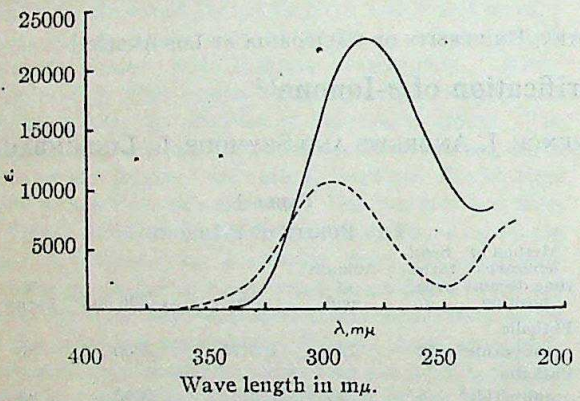

Fig. 1.—Spectra of pure β-ionone and β-ionone semicarbazone: β-ionone, – – –; β-ionone, —— semicarbazone.

In Fig. 1 are presented the absorption spectra of pure β-ionone semicarbazone and of β-ionone liberated from the semicarbazone by the use of sulfuric acid at room temperature measured in a solution of 95% ethanol. In Fig. 2 are given the spectra of commercial α- and β-ionone. The commercial α-ionone has absorption maxima at 227 mμ, ε 12850 and 296 mμ, ε 1950. Assuming that β-ionone obtained from its semicarbazone by decomposition with sulfuric acid at room temperature is 100% pure and that pure α-ionone

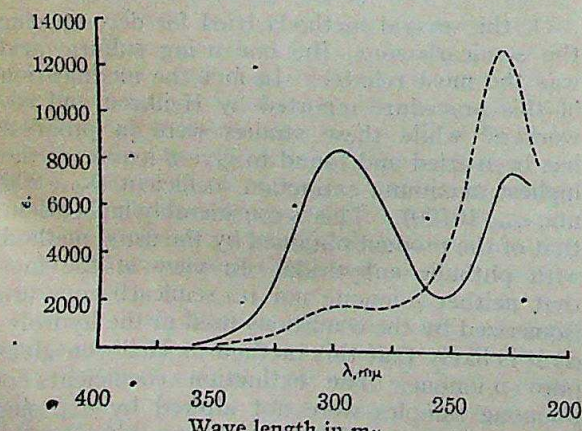

Fig. 2.—Spectra of commercial α- and β-ionone: α, – – –; β, —·—.

displays no light absorption at 296 mμ it was calculated by use of the extinction coefficients at 296 mμ that the commercial α-ionone sample was 82% pure and that the commercial β-ionone (λ_{max} 296 mμ, ε 8600) was 80% pure.[7]

The Rates of Reaction of Some Unsaturated Carbonyl Compounds with Perbenzoic Acid.—It has been reported that α,β-unsaturated carbonyl compounds react only very slowly with perbenzoic acid.[8] It was hoped that this hindered reactivity toward perbenzoic acid would be transmitted through two double bonds conjugated with a carbonyl group and that the isolated double bond in the α-ionone ring would react with perbenzoic acid much faster than would the double bond in the β-ionone ring, affording a means of purifying β-ionone. A comparative study of the rates of reaction of perbenzoic acid with commerical β-ionone (ϵ_{max} 8600) and with relatively pure β-ionone (ϵ_{max} 10100) showed that the samples consumed perbenzoic acid at an equal rate which was much faster than the rate for ordinary α,β-unsaturated carbonyl compounds (ethylideneacetone, crotonaldehyde, and benzalacetone).

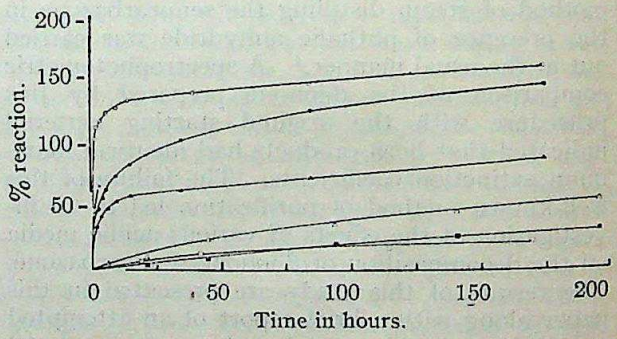

Fig. 3.—Reaction rates of unsaturated carbonyl compounds with perbenzoic acid at 8°.

Compound	Init. concn.	Init. concn. $C_6H_5CO_3H$
○, β-ionone (ϵ_{max} 10100)	0.0297*M*	0.0605*M*
×, β-ionone (ϵ_{max} 8600)	.0309	.0313
×, β-ionone (ϵ_{max} 10100)	.0332	.0313
●, cinnamalacetone	.0275	.0605
▲, dibenzalacetone	.0309	.0605
△, ethylideneacetone	.0288	.0299
■, crotonaldehyde	.0333	.0299
□, benzalacetophenone	.0394	.0312

In Fig. 3 are plotted the rates of reaction of several unsaturated carbonyl compounds with perbenzoic acid at 8° in toluene or benzene solution. Values of the per cent. reaction vary from 0 to 200, since in some of the rate studies on dienes sufficient perbenzoic acid was used to react with two moles of carbon–carbon double bond.

In order to determine whether or not the rapid reaction of β-ionone with perbenzoic acid was

(7) These are the commercial ionones used in synthetic work reported by Young, Andrews and Cristol, THIS JOURNAL, 66, 520 (1944).

(8) Böeseken, *Rec. trav. chim.*, 45, 838 (1926).

characteristic of α,β-, γ,δ-unsaturated carbonyl compounds the rates of reaction of β-ionone and cinnamalacetone with two moles of perbenzoic acid were measured and compared. In both cases when one mole of perbenzoic acid was consumed, the reaction rate dropped off rapidly and became comparable to that of an α,β-unsaturated carbonyl compound. Presumably, then, the double bond in the β-ionone ring is the one which consumes the first mole of perbenzoic acid. Dibenzalacetone in the presence of two moles of perbenzoic acid reacted very rapidly until about half a mole of perbenzoic acid had been consumed. Then the rate of reaction decreased to that of a compound having one ethylenic linkage to a carbonyl group.

Experimental Part

β-Ionone Semicarbazone.—To a solution of 50 g. of semicarbazide hydrochloride and 44 g. of potassium acetate in 150 ml. of water was added a solution of 85 g. of commercial β-ionone in 150 ml. of ethanol. Sufficient ethanol to dissolve the β-ionone was added. The solution was cooled in an ice-bath to induce crystal formation. The crude product was purified by four to six recrystallizations from absolute ethanol or 75% methanol to constant melting point (148–149°) and extinction coefficient in 95% ethanol (λ_{max} 282 mμ, ϵ_{max} 22300). Fifty grams of purified product was obtained (45%).

Acid Decomposition of β-Ionone Semicarbazone.—β-Ionone semicarbazone (68 g.) was refluxed with 300 ml. of 3 *N* sulfuric acid for three hours. The liberated oil was extracted with 100 ml. of ether, and the ether solution was dried over sodium sulfate. After removal of the ether, the β-ionone was distilled, b. p. 142–144° (18 mm.) (wt. 35 g., 76%).

In one experiment carried out according to the directions of Kuhn and Morris[4a] a mixture of 58.6 g. of β-ionone semicarbazone and an equal weight of phthalic anhydride was steam distilled and the β-ionone in the distillate extracted with ether. The distilled product, b. p. 143–146° (18–20 mm.), weighed 35.7 g. (75%).

In separate experiments 5.0 g. of β-ionone semicarbazone was steam distilled from a constant volume of 40 ml. of water containing 5 g. of phthalic anhydride, 0.17 equiv. of succinic acid, 0.12 equiv. of phosphoric acid, or 0.12 equiv. of sulfuric acid. The recovered β-ionone weighed 3.0 g. (78%) in each case (properties in Table I).

Five grams of the semicarbazone was shaken at room temperature for three and one-half days with a mixture of 20 ml. of petroleum ether and 48 ml. of 2 *N* sulfuric acid.[6] The organic layer was washed with water and dilute sodium bicarbonate solution and dried. The distilled β-ionone weighed 2.7 g. (70%).

The Stability of β-Ionone and its Semicarbazone toward Dilute Sulfuric Acid.—Five grams of β-ionone semicarbazone (m. p. 148–9°, ϵ_{max} 21400), 20 ml. of petroleum ether, and 48 ml. of 2 *N* sulfuric acid were shaken at room temperature for twenty-four hours. The remaining white solid was filtered, washed with petroleum ether and water and dried. The 3.1 g. of recovered semicarbazone melted 148–149.5° and had ϵ_{max} 21300 in 95% ethanol.

Five grams of β-ionone (ϵ_{max} 8600) was shaken for two days with petroleum ether and 2 *N* sulfuric acid as described for the decomposition of β-ionone semicarbazone. The β-ionone recovered (3.3 g.) as previously described had ϵ_{max} 8900 in 95% ethanol.

Ten-gram samples of β-ionone were refluxed for four hours with 100 ml. of 3 *N* sulfuric acid. The ionone was extracted with ether and the solution washed with water and dilute sodium bicarbonate solution and dried. The distilled product weighed 8 g. A sample of β-ionone, ϵ_{max} 8600, gave a product, ϵ_{max} 8400, and a sample having ϵ_{max} 5560 gave a product of ϵ_{max} 5200 in 95% ethanol.

Absorption Spectrum Measurements.—The ultraviolet absorption spectra in 95% ethanol solution of the several ionone samples were measured on a Beckman spectrophotometer.

Reaction Rates of Unsaturated Carbonyl Compounds with Perbenzoic Acid.—A chloroform solution of 0.343 *M* perbenzoic acid was prepared according to the method of Braun.[9] A sample (about 0.003 mole) of the unsaturated compound was weighed into a 100-ml. volumetric flask which was then partially filled with solvent (dry benzene or toluene), and a 10 or 20 ml. pipet sample of the perbenzoic acid solution was added. The flask was filled to the mark with solvent and placed in the refrigerator (8°). Ten-ml. pipet samples were removed from time to time and analyzed according to the method of Braun.[9] A blank run was made to follow the rate of perbenzoic acid decomposition. These determinations were not strictly quantitative owing to the somewhat inaccurate temperature control and timing used. The percentage of the unsaturated compound which had reacted over any given length of time *t* was calculated from the amount of perbenzoic acid consumed in this length of time by the use of the equation

$$\%\ \text{unsaturated compound reacted at time } t = \frac{\text{moles of perbenzoic acid consumed at time } t}{\text{moles of unsaturated compound at } t = 0} \times 100$$

Summary

The method of purification of β-ionone by decomposition of its semicarbazone in acid media has been studied. Decomposition with sulfuric acid gives β-ionone of greater purity than decomposition with weaker acids.

A study of the reaction rates of perbenzoic acid with α,β-, γ,δ-unsaturated carbonyl compounds including β-ionone, indicates that the hindrance to reactivity furnished to one double bond by a carbonyl group is not transmitted through two conjugated double bonds.

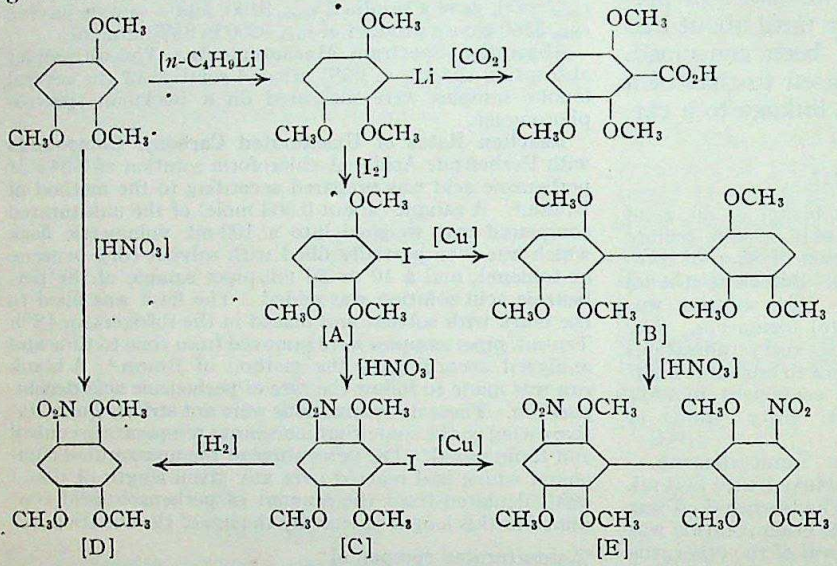
Dibenzofuran. XXI. Benzene and Biphenyl Intermediates for 1,9-Derivatives[1]

BY HENRY GILMAN AND JOHN R. THIRTLE

In the preparation of intermediates which, by ring-closure reactions, might give some reference 1,9-dibenzofuran derivatives, several benzene and biphenyl derivatives have been prepared. The general transformations are as follows:



Metalation of 1,2,4-trimethoxybenzene by *n*-butyllithium was shown to take place almost entirely in the 3-position. This was particularly interesting because of the possibilities of three isomeric monolithium derivatives due to the ortho-directing effect of methoxy groups in metalation. A parallel illustration is the metalation of resorcinol dimethyl ether to give, subsequent to carbonation and hydrolysis, practically exclusively 2,6-dimethoxybenzoic acid.[2]

The structure of the metalation product was established by carbonation to 2,3,6-trimethoxybenzoic acid and comparison with a sample prepared earlier by Smith and LaForge[3] by another procedure. Treatment of the lithium compound with iodine gave 2,3,6-trimethoxyiodobenzene [A] from which was obtained, by an Ullmann coupling, the 2,2′,3,3′,6,6′-hexamethoxybiphenyl [B]. Attempted ring closure of [B], by heating with an acetic acid solution of hydrobromic acid, gave a colored unstable polyphenolic type. Under corresponding conditions using hydrochloric acid there was recovered 85% of [B]; and with constant boiling hydriodic acid much as yet unresolved tarry material resulted.

Nitration of [A] gave 2,3,6-trimethoxy-5-nitroiodobenzene [C] the structure of which was established by hydrogenolysis to 1,2,4-trimethoxy-5-nitrobenzene [D]. The authentic specimen used to identify [D] was prepared, in accordance with the directions of Schüler,[4] by the nitration of 1,2,4-trimethoxybenzene. 2,2′,3,3′,6,6′-Hexamethoxy-5,5′-dinitrobiphenyl [E] was prepared by the coupling of [C] and also, in excellent yield, by the direct nitration of [B]. Inasmuch as [B] was essentially unaffected by hydrochloric acid, it was hoped that the nitro groups in [E] might preferentially labilize the ortho-methoxy groups in a cleavage reaction. However, no dibenzofuran derivative has been isolated.

Experimental

Quinone was converted to 1,2,4-triacetoxybenzene in 80% yield by the method of Thiele.[5] 1,2,4-Trimethoxybenzene was prepared in one step in 90% yield from 1,2,4-triacetoxybenzene by the procedure of Bargellini and Martegiani.[6]

2,3,6-Trimethoxyiodobenzene.—To a stirring and refluxing solution of 9.8 g. (0.0583 mole) of 1,2,4-trimethoxybenzene in 100 cc. of dry ether was added 0.0655 mole of *n*-butyllithium dissolved in 100 cc. of ether. The reaction mixture was refluxed with stirring for two hours. The system was allowed to cool under nitrogen, and a Gooch adapter was placed between the reaction flask and the reflux condenser. A Soxhlet thimble was charged with 17.8 g. (0.14 g. atom) of iodine and was supported in the adapter by means of a piece of clay plate. Stirring was continued and heating was regulated in such a manner that the iodine was dissolved slowly. The reaction of the iodine with the organolithium compound was very vigorous at the start. As the reaction heat diminished, heating was regulated to extract the iodine more rapidly. The entire extraction required forty-five minutes. Toward the end a distinct yellow to orange color due to excess iodine was noted and the white, insoluble, organolithium compound had disappeared, a clear solution resulting.

The ether solution was extracted with dil. sodium bisulfite to remove iodine and lithium iodide. After drying over calcium chloride, the ether was evaporated, leaving 10.6 g. (61.5% crude yield) of somewhat oily crystals. Recrystallization from 40 cc. of ethanol gave 8.7 g. (51%) melting at 107–108°. A second recrystallization raised the melting point to 108–108.5°.

Anal. Calcd. for $C_9H_{11}O_3I$: OCH_3, 31.63. Found: OCH_3, 31.61, 31.61.

2,3,6-Trimethoxybenzoic Acid.—Carbonation of the *n*-butyl-lithium-metalation product of 6.72 g. (0.04 mole) of 1,2,4-trimethoxybenzene by dry-ice gave, subsequent to hydrolysis, 4 g. (47%) of crystals melting at 148–149°.

Recrystallization from water raised the melting point to 149–150°. Smith and LaForge[3] reported a melting point of 145–146°, and a mixed m. p. with the sample kindly provided by them and our acid was 146–149°.

Anal. Calcd. for $C_{10}H_{12}O_5$: neut. equiv., 212. Found: neut. equiv., 219.

Methyl 2,3,6-Trimethoxybenzoate.—2,3,6-Trimethoxybenzoic acid was esterified with great difficulty. One gram was dissolved in 10 cc. of methanol and saturated with dry hydrogen chloride. After refluxing for one hour and cooling no crystals formed, but evaporation left an oil. The oil was dissolved in ether and washed twice with 10% sodium carbonate solution. From the dried ethereal solution there was obtained 0.3 g. (28%) of white crystals melting at 54–56°. Recrystallization from petroleum ether (b. p. 60–68°) raised the melting point to 57–57.5°.

Anal. Calcd. for $C_{11}H_{14}O_5$: OCH_3, 54.87. Found: OCH_3, 54.88.

Ethyl 2,3,6-Trimethoxybenzoate.—One gram of 2,3,6-trimethoxybenzoic acid was dissolved in 6 cc. of ethanol and 1 cc. of concd. sulfuric acid. After refluxing for one-half hour the reaction mixture was poured into 20 cc. of water. The solid was dissolved in ether and shaken with dilute sodium carbonate solution. After drying the ether layer over anhydrous potassium carbonate, the ether was evaporated, leaving an oil which crystallized on agitation. The crude product melted at 38–41°. Recrystallization from petroleum ether (b. p. 60–68°) raised the melting point to 42.5–43°.

Anal. Calcd. for $C_{12}H_{16}O_5$: alkoxyl, 57.50. Found: alkoxyl, 57.41.

2,2′,3,3′,6,6′-Hexamethoxybiphenyl.—Copper powder (50 g.) was purified by the method of Kleiderer and Adams.[7] After drying, an intimate mixture was made with 17.3 g. (0.0588 mole) of 2,3,6-trimethoxyiodobenzene. The mixture was heated by an oil-bath at 185–190° for three hours, in a nitrogen atmosphere. The temperature was finally raised to 210–215° for fifteen minutes.

Extraction in a Soxhlet apparatus was effected by 250 cc. of acetone. Concentration of the extract to a small volume and dilution with water gave 9.5 g. (97%) of crystals melting at 122–124°. Recrystallization from 30 cc. of hot acetone, diluted with water until crystals began to form, gave 7.5 g. (76.4%) of product melting at 125.0–125.5°.

Anal. Calcd. for $C_{18}H_{22}O_6$: OCH_3, 55.69. Found: OCH_3, 55.50, 55.68.

2,2′,3,3′,6,6′-Hexamethoxy-5,5′-dinitrobiphenyl.—This preparation is similar to the procedure used for 2,2′,6,6′-tetramethoxy-3,3′-dinitrobiphenyl.[8]

One gram (0.003 mole) of 2,2′,3,3′,6,6′-hexamethoxybiphenyl in a shell vial was dissolved in 10 cc. of acetic anhydride and 0.5 cc. of concd. nitric acid, which was prepared by warming fuming nitric acid until colorless. The mixture was heated gently on a hot-plate to start the reaction and then removed from the heat. After boiling had ceased, heating was continued at incipient boiling for five minutes. When cool, the product was isolated as follows. Six reaction mixtures were combined in an Erlenmeyer flask. Ten cubic centimeters of boiling acetic acid was used to rinse all of the shell vials. The crystals which formed were redissolved by slight warming, and 10 cc. of water was added dropwise to hydrolyze the excess acetic anhydride. The solution was kept at 0° overnight giving 6.9 g. (90.5%) of yellow crystals melting at 149–150°. Recrystallization from ethanol raised the melting point to 151–151.5°.

Anal. Calcd. for $C_{18}H_{20}O_{10}N_2$: OCH_3, 43.87. Found: OCH_3, 43.91, 43.77.

2,3,6-Trimethoxy-5-nitroiodobenzene.—A solution of 3.34 g. (0.0114 mole) of 2,3,6-trimethoxyiodobenzene in 12 cc. of glacial acetic acid at 60° was stirred while 6 cc. of concd. nitric acid in 20 cc. of acetic acid was added over a period of five minutes. Stirring was continued at 60° for fifteen minutes longer. After cooling, the crystals were filtered and washed with acetic acid and with water. Two and nine-tenths grams (75.3%) of pale yellow needles melting at 119.5–120° was obtained. Dilution of the filtrate gave 0.8 g. melting at 115–118°. Crystallization of the latter from acetic acid gave 0.45 g. more pure product. Dilution of the filtrate again and crystallization from dilute acetic acid gave an additional 0.27 g. The total yield of pure product was 3.62 g. (94.1%).

Anal. Calcd. for $C_9H_{10}O_5NI$: OCH_3, 27.43. Found: OCH_3, 27.25.

The position of the nitro group was proved by removal of the iodine atom by hydrogen and palladium–calcium carbonate catalyst. Two-tenths g. of the compound was shaken with 1 g. of the catalyst in 20 cc. of absolute ethanol at 30 pounds pressure of hydrogen for two hours. After filtering, concentrating to small volume, and cooling, crystals formed which melted at 125–127°. Recrystallization from ethanol raised the melting point to 128–129° and a mixed melting point with an authentic sample of 2,4,5-trimethoxynitrobenzene[4] was not depressed.

Coupling of 2,3,6-Trimethoxy-5-nitroiodobenzene.—An intimate mixture of 2.0 g. (0.0059 mole) of 2,3,6-trimethoxy-5-nitroiodobenzene and 6.0 g. of the specially prepared copper powder[7] was placed in a Pyrex test-tube, covered with a thin layer of copper powder, and protected from air by a closely-fitting cork stopper placed just above the reaction mixture. The tube was placed in a heating bath at 210°. Heating was continued at 210° for one hour and ten minutes. The temperature was raised to 230° and held there for thirty minutes.

The reaction mixture was extracted in a Soxhlet apparatus with acetone. Evaporation of the acetone gave 0.9 g. of a tarry material. Extraction of this product with boiling petroleum ether (b. p. 60–68°) gave 0.2 g. of yellow crystals melting at 142–149°. Recrystallization from dilute acetic acid raised the melting point to 147–149°. A recrystallization from ethanol gave pale yellow crystals melting at 149.5–151°, and a mixed melting point with the 2,2′,3,3′,6,6′-hexamethoxydinitrobiphenyl prepared by direct nitration, was not depressed. This establishes the nitro groups in the 5,5′-positions.

Summary

It has been shown that the metalation of 1,2,4-trimethoxybenzene by *n*-butyllithium gives almost exclusively 2,3,6-trimethoxyphenyllithium. This RLi compound with iodine gives the corresponding iodo compound which, when coupled by copper, yields 2,2′,3,3′,6,6′-hexamethoxybiphenyl. Nitration of the iodo compound gives 2,3,6-trimethoxy-5-nitroiodobenzene which was coupled to 2,2′,3,3′,6,6′-hexamethoxy-5,5′-dinitrobiphenyl. Neither of the polymethoxybiphenyls has yielded any 1,9-dibenzofurans.

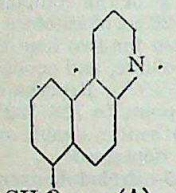
Some Derivatives of 7-Methoxy- and 10-Methoxybenzo(f)quinoline

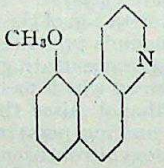
BY ALBERT C. MUELLER[1] AND CLIFF S. HAMILTON

In an earlier paper[2] the preparation of a number of 1-substituted aminobenzo(f)quinolines was described. As a continuation of this work the synthesis of two series of methoxybenzo(f)quinolines with a basic substituent in the 1-position has been undertaken. It was hoped that the presence of the methoxyl would enhance the antimalarial activity of this type of compound. Pharmacological testing of a number of these derivatives is in progress.

The particular isomers chosen for study were 7-methoxybenzo(f)quinoline (A) and 10-methoxybenzo(f)quinoline (B).



(A)



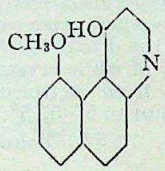
(B)

The starting materials required were 5-methoxy-2-naphthylamine and 8-methoxy-2-naphthylamine. Synthesis of neither of these compounds has been reported in the literature. The aminonaphthols, from which the methyl ethers were prepared, were obtained by the alkali fusion of the appropriate naphthylaminesulfonic acid. To insure efficient conversion of the naphthols to their methyl ethers with dimethyl sulfate, it was necessary to protect the amino groups by acetylation, the acetyl groups being removed by subsequent hydrolysis.

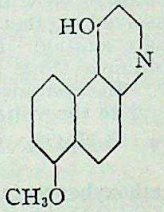
In this investigation the intermediate, 2-acetamido-5-naphthol, was isolated as a stable crystalline hydrate with a melting point higher than that reported by earlier workers.[3,4] Since 8-methoxy-2-naphthylamine was an unstable oil, it was isolated as the hydrochloride.

The conversion of the methoxyamines into the desired methoxybenzo(f)quinolines was accomplished by previously described methods.[2]

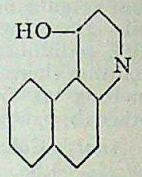
In order to introduce a basic substituent into the 1-position it was necessary to replace the hydroxyl with the more reactive chloro group which, normally, is easily displaced by an amino group. The 7-methoxy isomer reacted smoothly with phosphorus oxychloride to give the desired chloro compound, but all of our attempts to replace the hydroxyl in the 10-methoxy isomer were unsuccessful. It is believed that the group in the 10- or *peri*-position exerts a blocking effect upon the 1-position of the nucleus. Furthermore, IX differed noticeably from XVII and XXI,[2] in other properties, namely, melting point, color and solubility in alkali.



(IX)
m. p. 183°, yellow, insol. in OH^-



(XVII)
m. p. 309°, white, sol. in OH^-



(XXI)
m. p. 288°, white, sol. in OH^-

Two amines, morpholine and piperidine, were condensed with 1-chloro-7-methoxybenzo(f)quinoline yielding the corresponding 1-substituted aminobenzo(f)quinolines.

Experimental

2-Naphthylamine-5-sulfonic acid (I) and 2-naphthylamine-8-sulfonic acid (II) were prepared by the sulfonation of 2-naphthylamine according to the procedure of Green and Vakil.[5]

2-Amino-8-naphthol (III).—A mixture of 83 g. of II and 250 g. of potassium hydroxide was heated in an iron autoclave, equipped with a stirrer, for two and one-half hours at 260°. The fusion melt was cooled and treated with two liters of water. Some insoluble tarry material was removed by filtration and the solution was acidified with concentrated hydrochloric acid. The mixture was filtered again to remove the acid-insoluble portion and the filtrate was neutralized with sodium bicarbonate. The crude product which precipitated was collected on a filter, washed and dried; yield, 44 g. (74%). This was used to prepare the acetyl derivative without further purification. A portion was crystallized from water, then ethanol, yielding pale pink crystals melting at 156–158°; lit.[6] gives 158°.

2-Acetamido-8-naphthol (IV).—Twenty-five grams of III was refluxed briefly in 70 ml. of glacial acetic acid and 30 ml. of acetic anhydride. The mixture was poured into 500 ml. of water and the resulting oil solidified slowly. The crude product was taken up in dilute alkali, filtered and reprecipitated with hydrochloric acid. It was collected by filtration, washed with water and dried; yield, 29 g. (90%). After recrystallization from ethanol it melted at 215–216°. Friedländer and Zinberg reported 210–211°.[7]

2-Acetamido-8-methoxynaphthalene (V).—A solution of 24 g. of IV in 200 ml. of 2 *N* sodium hydroxide was placed in a 500-ml. three-necked flask fitted with a stirrer. Thirty milliliters of dimethyl sulfate was added slowly from a dropping funnel during a period of six hours, the temperature being held at 30°. The product, which precipitated as the reaction proceeded, was collected by filtration, washed with 0.5 *N* alkali and then with water. It was decolorized by charcoal treatment in ethanol and crystallized from ethanol–water solution; yield, 18 g. (70%).

This compound is a white crystalline solid melting at 163–164°. It is soluble in the common organic solvents and sparingly soluble in hot water.

Anal. Calcd. for $C_{13}H_{13}O_2N$: C, 72.54; H, 6.09. Found: C, 72.27, 72.40; H, 6.02, 6.15.

8-Methoxy-2-naphthylamine Hydrochloride (VI).—Twenty-three grams of V was refluxed in 200 ml. of ethanol containing 30 ml. of concentrated hydrochloric acid. After three hours the alcohol was removed by distillation and 200 ml. of water was introduced. The resulting solution was treated with charcoal until it was nearly colorless, then concentrated to 100 ml. and cooled slowly. The amine hydrochloride precipitated in long light-pink needles which were collected on a filter. Further concentration of the filtrate yielded additional product; combined yield, 18 g. (81%).

Anal. Calcd. for $C_{11}H_{12}ONCl$: Cl, 16.91. Found: Cl, 16.89, 16.98.

1-Hydroxy-3-carbethoxy-10-methoxybenzo(f)quinoline (VII).—Diethyl sodio-oxalacetate (2 g.) was added to 2 g. of VI in 25 ml. of absolute ethanol. A drop of concentrated hydrochloric acid was introduced and the mixture was shaken intermittently for sixty hours. It was then poured into 70 ml. of water and the alcohol was evaporated. The viscous yellow-brown oil which separated was extracted with ether. The ether was removed *in vacuo*, and the methoxynaphthyliminosuccinate was added slowly to 50 ml. of mineral oil which had been preheated to 260°. After five minutes the mixture was cooled and the crude product separated upon the addition of ether. It was washed with small portions of benzene, decolorized with charcoal and crystallized from ethanol–water mixture yielding 1.7 g. (61%) of pale white crystals; m. p. 181–183°.

Anal. Calcd. for $C_{17}H_{15}O_4N$: C, 68.67; H, 5.09; N, 4.71. Found: C, 68.59; H, 5.15; N, 4.70.

1-Hydroxy-3-carboxy-10-methoxybenzo(f)quinoline (VIII) resulted in quantitative yield when VII was refluxed briefly in 2 *N* alkali and the resulting solution was acidified with dilute hydrochloric acid. The bright-yellow gelatinous product was digested for two hours before it was collected on a filter, washed and dried.

It is a slightly hygroscopic amorphous powder which decomposes at 250–253° with loss of carbon dioxide. It is soluble in basic solutions, but very insoluble in the usual organic solvents.

Anal. Calcd. for $C_{15}H_{11}O_4N$: C, 66.91; H, 4.12. Found: C, 66.79; H, 3.99.

This acid forms a deep-yellow crystalline hydrochloride from 6 *N* hydrochloric acid solution. The salt hydrolyzes readily in water.

Anal. Calcd. for $C_{15}H_{12}O_4NCl$: C, 59.12; H, 3.97. Found: C, 58.77; H, 3.99.

1-Hydroxy-10-methoxybenzo(f)quinoline (IX).—When 2.5 g. of VIII was heated at its decomposition point (250°) until no more gas was evolved, IX was formed in poor yield. The black residue was pulverized, extracted with 100 ml. of boiling ethanol and filtered free of insoluble material. The extract was clarified with charcoal and concentrated to yield 0.6 g. (28%) of bright yellow crystals which were recrystallized from ethanol–water mixture; m. p. 180–182°.

Anal. Calcd. for $C_{14}H_{11}O_2N$: C, 74.65; H, 4.92. Found: C, 74.62, 74.81; H, 4.92, 5.01.

2-Amino-5-naphthol (X) was prepared from I by the same procedure used for making the 2,8 isomer. The product was obtained in yields of 70%; m. p. 198–200°; lit.[4] gives 199.5°.

2-Acetamido-5-naphthol Monohydrate (XI).—Fifty grams of X was treated with 50 ml. of glacial acetic acid and 18 ml. of acetic anhydride. The mixture was refluxed for ten minutes before being poured into 300 ml. of water. The crude product crystallized slowly to yield a gray solid which was reprecipitated from 2 *N* alkali solution with dilute acid. It was decolorized with charcoal and crystallized from ethanol–water solution as nearly white needles; yield (63%); m. p. 117–121°. Sander[3] and Bucherer and Wahl[4] reported 100° and 98–99°, respectively.

This compound contains water of crystallization. Its anhydrous form appeared as an oil and was not obtained in the solid state. It is soluble in alkaline solutions and in the usual organic solvents.

Anal. Calcd. for $C_{12}H_{13}O_3N$: C, 65.74; H, 5.98; H_2O, 8.21. Found: C, 65.63, 65.80; H, 5.83, 6.05; H_2O, 8.17.

2-Acetamido-5-methoxynaphthalene (XII) resulted upon treatment of XI with dimethyl sulfate according to the procedure for making the 8-methoxy isomer. Yields up to 61% were obtained. The product crystallized from methanol–water solution as white platelets, m. p. 151–152°.

Anal. Calcd. for $C_{13}H_{13}O_2N$: C, 72.54; H, 6.09. Found: C, 72.30, 72.39; H, 6.07, 6.08.

5-Methoxy-2-naphthylamine Hydrochloride (XIII).—A suspension of 8 g. of XII in 250 ml. of 5 *N* hydrochloric acid was refluxed for three hours, during which time the solid dissolved. The hot solution was treated with decolorizing charcoal, filtered and slowly cooled. The sparingly soluble hydrochloride precipitated as tiny gray crystals and was collected by filtration. The filtrate was concentrated to yield more product. When recrystallized from hot water the hydrochloride appeared as long white needles; yield 7 g. (95%).

Anal. Calcd. for $C_{11}H_{12}ONCl$: Cl, 16.91. Found: Cl, 16.99, 16.88.

5-Methoxy-2-naphthylamine (XIV).—When XIII was neutralized with cold alcoholic alkali solution, and the alcohol evaporated, the free amine was liberated quantitatively. It crystallized from ethanol–water solution in pink platelets, m. p. 71–72°. Solutions of this compound darken on standing.

Anal. Calcd. for $C_{11}H_{11}ON$: C, 76.27; H, 6.40. Found: C, 75.98, 76.04; H, 6.43, 6.35.

1-Hydroxy-3-carbethoxy-7-methoxybenzo(f)quinoline (XV).—An intimate mixture of XIV (3.5 g.) and diethyl oxalacetate (4 g.) was desiccated over concentrated sulfuric acid for three days with occasional stirring. The viscous brown anil which formed was added with stirring to 100 ml. of preheated (250°) mineral oil. After ten minutes the mixture was cooled, and a light-yellow solid separated. It was removed and washed with benzene, yielding 4 g. (66%) of a light-brown crystalline powder. Repeated crystallizations from ethanol gave nearly white needles, m. p. 256–258°.

Anal. Calcd. for $C_{17}H_{15}O_4N$: C, 68.67; H, 5.09. Found: C, 68.57, 68.75; H, 5.02, 5.07.

1-Hydroxy-3-carboxy-7-methoyxbenzo(f)quinoline (XVI) was formed when XV was heated briefly in 2 *N* alkali and the resulting solution was acidified with dilute hydrochloric acid. The bright-yellow amorphous product was digested on the steam-bath for one hour, collected on a filter, washed and dried. Purification was effected by regenerating the acid from its sodium salt solution after charcoal treatment, m. p. 292–295°, (dec.).

Anal. Calcd. for $C_{15}H_{11}O_4N$: C, 66.91; H, 4.12 Found: C, 66.84, 66.69; H, 4.29. 4.17.

1-Hydroxy-7-methoxybenzo(f)quinoline (XVII).—By means of a molten potassium–sodium nitrate bath, 0.35 g. of XVI was heated carefully to 295°. When the first sign of decomposition was noticed the temperature was lowered and maintained at 280° until the evolution of carbon dioxide had ceased. The brittle residue was extracted with 200 ml. of ethanol and the extract was decolorized with charcoal. The product precipitated when water was added and the mixture was concentrated. It was taken up in 40 ml. of 2 *N* hydrochloric acid and treated again with charcoal, yielding a bright-yellow solution. When made basic with ammonium hydroxide, a white finely-divided crystalline solid precipitated. This was digested on the steam-bath before being collected, dried and weighed, m. p. 308–311°. The yield was 0.14 g. (55%).

Anal. Calcd. for $C_{14}H_{11}O_2N$: C, 74.65; H, 4.92. Found: C, 74.31, 74.44; H, 5.08, 5.09.

1-Chloro-7-methoxybenzo(f)quinoline (XVIII).—A mixture of 10 ml. of phosphorus oxychloride and 0.5 g. of

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

XVII was refluxed for four hours. Most of the excess phosphorus oxychloride was removed by distillation and the residue was poured onto 30 g. of ice. The resulting mixture was heated to boiling, treated with charcoal, filtered and cooled. It was made basic with aqueous sodium hydroxide (10%) yielding a white curdy precipitate. The product was crystallized from ethanol–water mixture from which it formed long silky needles, m. p. 118–119°; lit.[8] gives 119°; yield, 0.4 g. (74%).

Anal. Calcd. for $C_{14}H_{10}ONCl$: C, 69.00; H, 4.30. Found: C, 69.08, 69.23; H, 4.28, 4.41.

1-Morpholino-7-methoxybenzo(f)quinoline (XIX) was formed when 0.3 g. of XVIII and 2 ml. of morpholine was refluxed for eight hours. The mixture was poured into 25 ml. of water and a white precipitate formed. The product was treated with charcoal in dilute hydrochloric acid and regenerated by the addition of alkali. A small amount of gummy impurity was removed at *p*H of 6–7. Two crystallizations from ethanol–water, gave tiny white crystals, m. p. 136–137°.

This compound forms a water soluble yellow hydrochloride and is also soluble in the common organic solvents.

Anal. Calcd. for $C_{16}H_{16}O_2N_2$: C, 73.45; H, 6.16. Found: C, 73.54, 73.23; H, 6.16, 6.23.

1-Piperidino-7-methoxybenzo(f)quinoline (XX) was prepared from XVIII and piperidine, similar to the morpholine analog. The product crystallized from acetone–water mixture as white needles, m. p. 116–117°.

Anal. Calcd. for $C_{19}H_{20}ON_2$: C, 78.06; H, 6.90. Found: C, 78.24; H, 7.13.

(8) Carpmael, English Patent 481,874, *Chem. Zentr.*, **109**, II, 117 (1938).

Summary

1. The preparation of the hydrochlorides of 5-methoxy- and 8-methoxy-2-naphthylamine, respectively, from the corresponding aminonaphthols, has been described.

2. These methoxyamines have been converted to benzo(f)quinoline derivatives by condensation with oxalacetic ester and cyclization of the resulting products.

3. 1-Hydroxy-7-methoxybenzo(f)quinoline yielded 1-chloro-7-methoxybenzo(f)quinoline which gave the 1-substituted amino derivatives with morpholine and piperidine.

4. Apparently steric hindrance by the 10-methoxyl in 1-hydroxy-10-methoxybenzo(f)-quinoline prevented replacement of the hydroxyl group by halogen.

LINCOLN, NEBRASKA RECEIVED JANUARY 31, 1944

The Carbonation and Carbethoxylation of Certain Ketones Using Sodium Triphenylmethide Reagent: β-Keto Ester Synthesis[1,2,3]

BY ERWIN BAUMGARTEN, ROBERT LEVINE AND CHARLES R. HAUSER

Ketones may be converted to β-keto esters by carbethoxylation by means of an alkyl carbonate or by carbonation followed by esterification of the resulting β-keto-acid. Both reactions are brought about by bases. In the present paper, certain examples of these reactions brought about by sodium triphenylmethide are discussed.

Carbethoxylations.—The carbethoxylation of a number of ketones with diethyl carbonate has been effected by means of sodium ethoxide.[4] The reaction has failed, however, with certain ketones in the presence of this base.[4] One of these ketones, di-isobutyl ketone, has now been carbethoxylated with diethyl carbonate by means of the stronger base, sodium triphenylmethide, to form ethyl α-isovalerylisovalerate. Since certain ketones react

$$[(CH_3)_2CHCH_2]_2CO \xrightarrow[\text{by } CO(OC_2H_5)_2]{(C_6H_5)_3CNa \text{ followed}} (CH_3)_2CHCH_2COCH(COOC_2H_5)CH(CH_3)_2$$

with diethyl carbonate in the presence of sodium ethoxide to give an ethyl vinyl carbonate (the "oxygen derivative" of the ketone),[4] instead of the β-keto ester (the "carbon derivative" of the ketone), the β-keto ester obtained in the present case has been characterized not only by the usual ketonic cleavage but also by acidic cleavage. While the regeneration of the original ketone on ketonic cleavage might result from either the β-keto ester or the "oxygen derivative," the formation of isovaleric acid on acidic cleavage could result only from the β-keto ester.

Previous attempts to carbethoxylate methyl ethyl ketone with diethyl carbonate by means of sodium ethoxide[4] or sodium triphenylmethide[5] have failed, presumably because of the ease with which this ketone self-condenses. We have found that the carbethoxylation fails even in the presence of the more reactive carbethoxylating reagent, ethyl 4-phenyl phenyl carbonate, and sodium triphenylmethide.

Carbonations Followed by Esterification.—The carbonation of ketones to form β-keto acids has been carried out previously apparently only with camphor and a few cyclic ketones,[6] sodium amide being used to effect the reaction.

In the present investigation methyl ethyl, methyl *t*-butyl, di-isopropyl and di-isobutyl ketones have been carbonated using sodim triphenylmethide and the resulting β-keto acids esterified with diazomethane to give, respectively, methyl propionylacetate (37%), methyl γ,γ,γ-trimethylacetylacetate (58%), methyl α-iso-butyrylisobutyrate (56%) and methyl α-isovalerylisovalerate (42%). None of these β-keto esters, or the corresponding ethyl esters, can be prepared satisfactorily by means of sodium alkoxides. The formation of methyl propionylacetate from methyl ethyl ketone, for example, may be represented as follows.

$$C_2H_5COCH_3 \xrightarrow[\text{by } CO_2 \text{ and acid}]{(C_6H_5)_3CNa \text{ followed}} C_2H_5COCH_2COOH \xrightarrow{CH_2N_2} C_2H_5COCH_2COOCH_3$$

Desoxybenzoin appeared to form the corresponding β-keto acid in good yield but it decomposed before it could be esterified. The pronounced instability of this acid has been observed previously.[7]

Methyl propionylacetate has been characterized by several reactive hydrogen and carbonyl group reactions. With phenylhydrazine, methyl propionylacetate gave a pyrazolone, identical with that obtained from authentic ethyl propionylacetate, although the yield of the derivative from the methyl β-keto ester was low. That carbonation occurred at the methyl group of methyl ethyl ketone, rather than at the methylene group, was confirmed by the alkylation of the propionylacetate with *n*-butyl bromide and subsequent ketonic cleavage of the alkylated product to give ethyl *n*-amyl ketone in good yield.

$$C_2H_5COCH_2COOCH_3 \xrightarrow{n\text{-}C_4H_9Br} C_2H_5COCH(C_4H_9)COOCH_3 \longrightarrow C_2H_5COC_5H_{11}$$

Methyl γ,γ,γ-trimethylacetylacetate has been characterized by the formation of a phenylpyrazolone and by ketonic cleavage. Methyl α-isobutylisobutyrate and methyl α-isovalerylisovalerate, which do not exhibit satisfactory reactive hydrogen and carbonyl group reactions, have been characterized by both acidic and ketonic cleavage.

Carbonations *versus* Carbethoxylations Using Sodium Triphenylmethide.—The mechanism of the carbonation of ketones is represented by the ionic[8] equations (1) and (2), while that for the carbethoxylation of ketones (which is similar to that for the acetoacetic ester reaction[9]) is represented in somewhat simplified form by the equations (1), (3) and (4).

(1) $RCOCH_2R' + (C_6H_5)_3C^- \longrightarrow [RCOCHR']^- + (C_6H_5)_3CH$

(2) $[RCOCHR']^- + CO_2 \longrightarrow RCOCHR'COO^-$

(3) $[RCOCHR']^- + CO(OC_2H_5)_2 \longrightarrow RCOCHR'COOC_2H_5 + C_2H_5O^-$

(4) $RCOCHR'COOC_2H_5 + [RCOCHR']^- \longrightarrow [RCOCR'COOC_2H_5]^- + RCOCH_2R'$

One mole of sodium triphenylmethide ion converts one mole of the ketone essentially completely into its anion (1). In the carbonation, the ketone anion condenses with carbon dioxide to form the carboxylate anion (2) which does not appear to react further[10] under the conditions employed; in the carbethoxylation, however, the ketone anion condenses with diethyl carbonate to form a β-keto ester (3) which generally undergoes a rapid proton exchange with unchanged ketone anion regenerating one-half of the original ketone (4). Thus, on the basis of these mechanisms, one mole of sodium triphenylmethide reagent may effect the carbonation of one mole of the ketone, but the carbethoxylation of only one-half mole of ketone.

Actually, per mole of sodium triphenylmethide the yield of α-isovalerylisovaleric ester obtained by the carbonation of di-isobutyl ketone followed by esterification has been much better than that obtained by the carbethoxylation of the same ketone. Similarly, the carbonation of methyl ethyl ketone followed by esterification gave a higher yield of propionylacetic ester per mole of sodium triphenylmethide used than the acylation of ethyl acetate with 4-phenylphenyl propionate,[5] the mechanism of which is similar to a carbethoxylation.

In general, for the synthesis of β-keto esters using sodium triphenylmethide, the method of carbonation of ketones followed by esterification is probably to be preferred to that of the carbethoxylation of ketones or that of the acylation of esters with esters.

Experimental[11]

Preparation of Ketone Anions (Sodium Derivatives).—Sodium triphenylmethide reagent was prepared from one mole of triphenylchloromethane and analyzed.[12,13] By means of the apparatus described elsewhere,[14] approximately two-tenths mole aliquots of the reagent were transferred to one-liter Pyrex bottles. In most cases, the reagent was chilled, air being excluded by an atmosphere of nitrogen. A molecular equivalent of the ketone was added to the reagent with shaking; the ketone anion was formed instantaneously as shown by the discharge of the characteristic color of the reagent. The solution of the ketone anion thus formed was used immediately for the carbonation and carbethoxylation reactions described below.

Ethyl α-Isovalerylisovalerate.—Di-isobutyl ketone (28.4 g., 0.2 mole) was converted to its anion at 0° and the

(7) Beckmann and Paul, *Ann.*, **266**, 1 (1891).

(8) The representation of the reactions of only the anions is simpler and, we believe, adequate for the present purpose, although the positive sodium ion also might play an important role in the detailed mechanism in the ether medium. In this connection, see Morton, Little and Strong, THIS JOURNAL, **65**, 1339 (1943).

resulting solution was carbethoxylated with 23.7 g. (0.2 mole) of diethyl carbonate. After seven days at room temperature glacial acetic acid and water were added to the reaction mixture. The ether phase (after extraction with saturated bicarbonate solution) was dried (sodium sulfate followed by "Drierite") and the solvent removed at atmospheric pressure. The residue was distilled *in vacuo* (up to 170° 15 mm.); the distillate gave on redistillation 11 g. (50%) of ethyl α-isovalerylisovalerate, b. p. 118–119.5° (15 mm.).[12]

Ethyl α-isovalerylisovalerate was characterized by ketonic cleavage[15] to di-isobutyl ketone, identified by its semicarbazone, m. p. 121–122°.[16] Acidic cleavage was carried out by refluxing for two hours a solution of 2 g. of ethyl α-isovalerylisovalerate and 0.03 mole of sodium ethoxide in 25 ml. of absolute ethanol, diluting with 5 ml. of water and refluxing for two hours longer. The solvent was evaporated and the solid residue was heated with an excess of thionyl chloride for thirty minutes. The crude acid chloride was converted[17] to isovaleryl anilide, m. p. 109–111°.[18]

Methyl Ethyl Ketone with Ethyl 4-Phenylphenylcarbonate.—The carbethoxylation of the anion of methyl ethyl ketone (0.2 mole, prepared at 0°) with 48.4 g. (0.2 mole) of ethyl 4-phenylphenyl carbonate[19] gave after four and one-half hours at room temperature 9.2 g. of material, b. p. 60–80° (20 mm.) (mainly at 64–69° 20 mm.), consisting presumably of 3-methylheptene-3-one-5 (reported, 66–68°).[5]

Carbonation Followed by Esterification: General Procedure.—The ether solution of the ketone anion, prepared as described above, was transferred onto an approximately ten-fold excess of Dry-Ice by means of a siphon under nitrogen pressure. After the excess of Dry-Ice had evaporated, water and ether were added to the mixture with shaking. The aqueous phase was combined with an ice-cold alkaline extract of the ether phase and acidified with iced mineral acid. The liberated β-keto acid was taken up in ether and the ether solution was dried with sodium sulfate at 0°. Esterification of the β-keto acid was effected with a 10–20% excess of diazomethane[20] (prepared from nitrosomethyl urea), and the excess diazomethane destroyed with glacial acetic acid, which in turn was removed by saturated sodium bicarbonate solution. The ether solution of the β-keto ester was dried over sodium sulfate followed by "Drierite" and the product was isolated by distillation.

Methyl Propionylacetate.—Methyl ethyl ketone (22.4 g., 0.312 mole) was converted at −15° to its anion which was carbonated immediately. Ether and the minimum of water (200 ml.) were added and the ether solution was extracted with 100 ml. of 5% sodium hydroxide solution. The combined aqueous solutions (washed with ether) were acidified with 75 ml. of 12 *N* hydrochloric acid in 100 g. of crushed ice, saturated with sodium chloride and extracted with successive 200-ml. portions of ether until the extract was substantially free from titratable acidity. The combined ether extracts, containing 0.22 equivalent of acid, were dried and esterified as indicated above. Material boiling up to 77° (15 mm.) was redistilled, giving 4.2 g. of a combined fore-run, b. p. 71–73° (16 mm.), and after-run, b. p. 76–78° (16 mm.), and 15.1 g. (37%) of methyl propionylacetate, b. p. 73–76° (16 mm.). A mid-fraction was analyzed:

Anal. Calcd. for $C_6H_{10}O_3$: C, 55.37; H, 7.74. Found: C, 55.04; H, 7.57.

With ammoniacal copper acetate solution, methyl propionylacetate formed a copper salt, m. p. 154–156°, and m. p. 160.3–160.9° after recrystallization from benzene–petroleum ether. With phenylhydrazine in glacial acetic acid solution, the β-keto ester gave, after recrystallization from very dilute ethanol, a low yield of 3-ethyl-1-phenylpyrazolone-5, m. p. and mixed m. p. 97–98° (reported,[21] 100°).

Methyl propionylacetate (26 g., 0.2 mole) was alkylated with an equivalent of sodium methoxide and an excess of *n*-butyl bromide in methanolic solution at 60° for seventy-two hours. Sodium bromide was removed by filtration and the solution concentrated. The reaction mixture was diluted with iced dilute hydrochloric acid and extracted with ether. The ether solution (neutralized with sodium bicarbonate and dried) was distilled, yielding 17.5 g. (47%) of methyl α-butylpropionylacetate, b. p. 108–120° (16 mm.). Redistillation gave 11 g., b. p. 108–112° (16 mm.).

Anal. Calcd. for $C_{10}H_{18}O_3$: C, 64.49; H, 9.74. Found: C, 65.24; H, 9.54.

Ketonic cleavage of 9.3 g. (0.05 mole) of methyl α-butylpropionylacetate in glacial acetatic acid-sulfuric acid mixture[15] gave 4.3 g. (67%) of ethyl *n*-amyl ketone, b. p. 160–166° (mainly 163–165°) (reported, 167–168°).[22] The crude semicarbazone melted at 92–98° and after seven recrystallizations from ether–petroleum ether the pure derivative melted at 116–117°.[23] The 2,4-dinitrophenylhydrazone formed in methanolic hydrochloric acid solution melted at 55–59° (crude) and after two recrystallizations from methanol at 64–65.5°.

Methyl γ,γ,γ-Trimethylacetylacetate.—The anion of pinacolone, prepared at 0° from 19.0 g. (0.19 mole) of pinacolone, was carbonated immediately. γ,γ,γ-Trimethylacetylacetic acid was liberated and esterified as described above. There were obtained 1.6 g. of a fore-run, b. p. 80–82° (17 mm.), and 17 g. (57%) of methyl γ,γ,γ-trimethylacetylacetate, b. p. 82–84° (17 mm.).

Anal. Calcd. for $C_8H_{14}O_3$: C, 60.74; H, 8.92. Found: C, 60.94; H, 8.93.

Ketonic cleavage[16] of methyl γ,γ,γ-trimethylacetylacetate gave a 50% yield of pinacolone, b. p. 104–106°. Semicarbazone, m. p. 154.5–156° (reported, 157–158°).[24] Reaction of the β-keto ester with an equivalent of phenylhydrazine gave a 40% yield of 3-*t*-butyl-1-phenylpyrazolone-5, m. p. 110.5–111°.[25]

Methyl α-Isobutyrylisobutyrate.—The anion of di-isopropyl ketone, prepared from 22.8 g. (0.2 mole) of di-isopropyl ketone at 0°, was carbonated. α-Isobutyrylisobutyric acid was liberated and esterified as described. Distillation gave 1.1 g. of fore-run, b. p. 92–94° (26 mm.), 19 g. (55%) of methyl isobutyrylisobutyrate, b. p. 94–96° (26 mm.), and 10 g. of after-run, b. p. 96–98° (26 mm.).

Anal. Calcd. for $C_9H_{16}O_3$: C, 62.76; H, 9.37. Found: C, 62.75; H, 8.96.

Ketonic cleavage[16] of methyl α-isobutyrylisobutyrate gave a 54% yield of di-isopropyl ketone, b. p. 123–124.5°; m. p. of semicarbazone 157–157.5° (reported, 160°).[26] Acidic cleavage gave isobutyric acid, identified by its anilide, m. p. 104–106°.[27]

Methyl α-Isovalerylisovalerate.—The anion of di-isobutyl ketone, prepared at 0° from 28.4 g. (0.2 mole) of di-isobutyl ketone, was carbonated. Isovalerylisovaleric acid was liberated and esterified as described. There were obtained 0.6 g. of fore-run, b. p. 111–114° (19 mm.), 17 g. (42%) of methyl α-isovalerylisovalerate, b. p. 114–116.5° (19 mm.), and 0.4 g. of after-run, b. p. 116.5–118° (19 mm.).[28]

Anal. Calcd. for $C_{11}H_{20}O_3$: C, 65.97; H, 10.07. Found: C, 65.58; H, 9.47.

Ketonic cleavage[15] of methyl α-isovalerylisovalerate gave a 63% yield of di-isobutyl ketone, b. p. 164–166°. The semicarbazone melted at 121.2–121.8°.[16] Acidic cleavage gave isovaleric acid, identified by its anilide, m. p. 109–111°.[18]

Summary

1. The carbethoxylation of di-isobutyl ketone with diethyl carbonate, which fails in the presence of sodium ethoxide, has been effected by means of sodium triphenylmethide to form ethyl α-isovalerylisovalerate. An attempt to carbethoxylate methyl ethyl ketone using this base in conjunction with ethyl 4-phenylphenyl carbonate has failed.

2. Four ketones, which are not carbethoxylated in the presence of sodium ethoxide, have been carbonated using sodium triphenylmethide and the resulting β-keto acids esterified with diazomethane to form the corresponding methyl β-keto esters.

3. The β-keto esters have been characterized by suitable reactions. The methyl group of methyl ethyl ketone was shown to undergo carbonation.

4. The relative amounts of carbonation and carbethoxylation of ketones that sodium triphenylmethide is capable of effecting is considered in connection with the mechanism of these reactions.

Resin Acids. The Structure of the Lactone of Hydroxytetrahydroabietic Acid[1]

BY RICHARD F. B. COX

The lactonization of dihydroabietic acids derived from abietic and levo-pimaric acids has always led to a single individual lactone melting at 131–132°. No stereoisomeric lactones have yet been produced from these dihydroabietic acids even though acids of rotations −30° to +108° have been investigated. This lactone appears, therefore, to be characteristic of the abietic family of dihydro acids.

Although the lactone has been known for many years[2a] there is very little known about its structure. Hasselstrom[2b] at one time suggested that on the basis of a γ-lactone structure the point of lactonization is probably C-10. Fleck and Palkin[3] then attempted to prove this structure by oxidizing the hydroxytetrahydroabietic acid obtained on saponification of the lactone. Under no conditions were they able to effect an oxidation to a keto acid which would be expected on the basis of Hasselstrom's formula. Moreover, they were unable to esterify the hydroxyl group of the free acid or its methyl ester. They concluded, therefore, that the hydroxyl group must be in a tertiary position which, to fit the molecular models, must be at C-4b.[2a]

It was expected that more concrete evidence in favor of formula I for the lactone might be given by an investigation of the reactions of the dihydroabietic acids produced by dehydration of the hydroxytetrahydroabietic acid. For example, only the Fleck and Palkin formula would be expected to lead to a dihydroabietic acid (4b, 8a) having the  type of double bond which will give a blue nitrosyl chloride derivative.

The stability of the lactone and the ease of lactonization of the hydroxytetrahydroabietic acid under dehydration conditions appeared at first to oppose this method of approach. It was then discovered in the course of our work on resin acids that the lactone underwent a reaction with methylmagnesium iodide which resembled a dehydration in that the product was a mixture of dihydroabietic acids.

The reaction appeared to be an abnormal Grignard reaction as a result of the highly hindered position of the carbonyl group of the lactone. One mechanism to explain the results is shown below.

According to this mechanism, the methylmagnesium iodide first forms a coördination complex (II) with the lactone, as a result of which the carbonyl carbon becomes deficient in electrons. The resulting increased attraction for the oxygen in the bridge then causes the formation of a carbonyl from this oxygen and a shift in the electron deficiency to C-4b. Simultaneously the methyl radical is freed to combine with the activated protons at positions 8a and 5 (III). The end-result of this rearrangement is thus the formation of the dihydroabietic acids as their magnesium salts (IV and V).

Since the gases produced in the reaction included hydrogen, it appears as though the protons at C-5 and C-8a have been displaced completely to combine either with another proton or the methyl radical. Thus the presence of hydrogen leads to the assumption that part of the

liberated methyl radicals combined to form ethane.

Further study of the reaction showed that the yield of the dihydroabietic acids is consistently about 69% of that expected even though a large excess of the methylmagnesium iodide is used. Likewise the ratio of the dextro to the levo acid remains constant at about 65:35 under varying conditions of reaction and ratios of reactants. Further study of the mechanism of this interesting reaction is not contemplated.

The dihydroabietic acids formed by the reaction of methylmagnesium iodide on the lactone differed sufficiently in crystal size when recrystallized from acetone that they were readily separated from each other by a combination of screening and crystallization. The acid of smaller crystal size melted at 185–186° and had a specific rotation −36°. The other dihydroabietic acid melted at 147–148° and had a specific rotation +68°. The properties of these acids are listed in Table I.

Both of these dihydroabietic acids produced from the lactone were stable in boiling acetic acid but lactonized readily in the presence of a little mineral acid. The lactone produced melted at 131–132° and was the same lactone which is produced from all other dihydroabietic acids. In 7.5% alcoholic hydrochloric acid the lactonization at 75°F. (24°C.) could be followed polarimetrically. The data showing the change in rotation during the course of such a lactonization are given in Table II. While the dextrorotatory acid appeared to lactonize the more readily, these data cannot be interpreted exactly without further knowledge of the products. When the lactonization products were isolated after 430 hours and titrated for unlactonized resin acid, the dextrorotatory acid was shown to have lactonized to the extent of 45% and the levorotatory acid to the extent of 35%. The rotations of the unlactonized acids after separation from the lactone showed that the dextrorotatory acid had undergone isomerization while the levorotatory acid was unchanged in rotation. The change in rotation of the dextrorotatory acid from +68° to acids of rotation +22° indicated the possibility that the isomerized acid mixture was 44% levorotatory acid and 56% dextrorotatory acid which is approximately the ratio of these acids as produced in the reaction between the Grignard reagent and the lactone. Apparently the levorotatory acid is more stable toward isomerization.

In regard to hydrogenation, the dextrorotatory dihydroabietic acid absorbed hydrogen the more readily. The rates of hydrogen absorption (Table III) show that after twenty-seven hours the dextrorotatory acid had absorbed 85% of the theoretical amount of hydrogen while the levorotatory acid had absorbed only 53% of the theoretical amount. Under the influence of reduced platinum oxide catalyst, as in hydrogenation conditions but in the absence of hydrogen, neither acid appeared to isomerize even after 60 hours treatment. In line with slower rates of hydrogenation and the higher melting points of related sterols having a double bond common to two rings, it was therefore expected that the levorotatory dihydroabietic acid might have the double bond in the 4b, 8a position and would give a blue nitroso derivative.

When the levorotatory dihydroabietic acid was treated with nitrosoyl chloride in acetic acid solution, it gave a blue solution from which a blue nitroso compound crystallized on the addition of water. This blue nitroso derivative contained no chlorine and was also formed by reaction with butyl nitrite and any mineral acid. Its neutral character and its analyses indicated that it probably was a nitrosolactone. It melted at 91.5–92° and had the unusually high specific rotation $[\alpha]_D$ −925° (2% in alcohol). Such high rotations are unknown in the resin acid field. The nitrosolactone underwent typical reactions such as hydro-

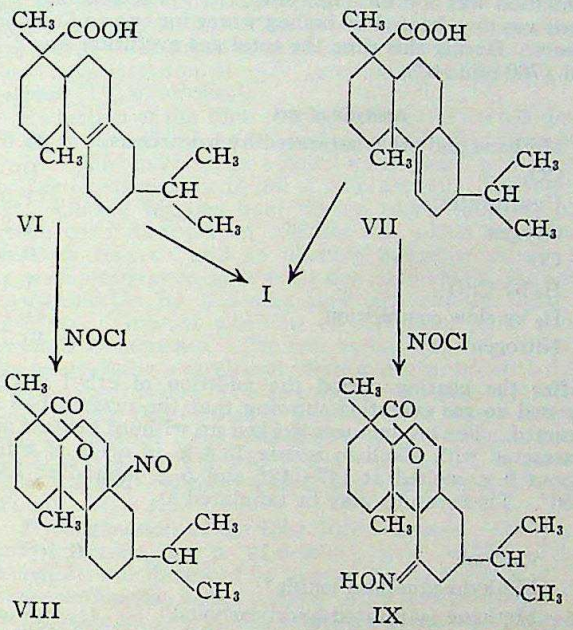
Digitized by Arya Samaj Foundation Chennai and eGangotri

genation to an aminolactone and it lost its nitroso group by hydrolysis in boiling hydrochloric acid with formation of the lactone of hydroxytetrahydroabietic acid, m. p. 131–132°. Based on these characteristics the nitrosolactone is assumed to have formula VIII.

Since the levorotatory dihydroabietic acid is the more stable toward isomerization, has the higher melting point, and gives a blue nitrosyl derivative, it is presumed to be Δ4b,8a-dihydroabietic acid (VI). Support for the Fleck and Palkin formula of the lactone of hydroxytetrahydroabietic acid is thus established.



The dextrorotatory dihydroabietic acid when treated with nitrosyl chloride gave difficultly soluble white crystals in a light-blue mother liquor. These crystals melted at 185–186°, $[\alpha]_D$ −30° (1% in $CHCl_3$) and appeared to be an oximinolactone. Hydrolysis with mineral acids did not remove the oximino group but effected what may have been a Beckman rearrangement.[4] Formula IX has accordingly been assigned to the oximinolactone and Formula VII to the dihydroabietic acid from which it was formed.

Neither the dextro- nor the levo-dihydroabietic acid was found by the nitrosyl chloride reaction to be present in hydrogenated rosin or hydrogenated abietic acid. This is as might be expected in the case of abietic acid because of the position of the double bonds unless hydrogenation were accompanied by isomerization. The specificity of the nitrosyl chloride reaction toward certain dihydroabietic acids also indicates that the nitroso and oximino lactones are probably not the result of isomerization of the resin acids prior to addition of the nitrosyl chloride.

In the case of resin acids with one double bond in the 4b, 5 or 4b, 8a position and another in some other position, the more highly hindered 4b, 5 or 4b, 8a double bonds would be expected to be still present after partial hydrogenation. Thus, if rosin contained such resin acids, hydrogenated rosin would have been expected to give the oximinolactone or nitrosolactone.

Likewise, if abietic acid or levo-pimaric acid contained double bonds in the 4b, 5 or 4b, 8a positions, one of the dihydro acids produced from them would be expected to resemble the new dihydroabietic acids. Since there is no resemblance in physical properties between those dihydro acids reported in the literature and the new dihydroabietic acids, levo-pimaric acid probably does not have Formula X which was favored by Fieser and Campbell,[5] but has instead Formula XI which was favored by Ruzicka.[6]

Experimental

Reaction of Lactone of Hydroxytetrahydroabietic Acid with CH_3MgI.—(a) One mole of methylmagnesium iodide was prepared from 24 g. of magnesium and 145 g. of methyl iodide in 750 ml. of ether. To the reagent was slowly added 304 g. of the lactone of hydroxytetrahydroabietic acid, melting point 131–132° in 1000 ml. of dry benzene. A small amount of heat was given off in the reaction. After standing for one hour, the mixture was warmed on

1330	18.1	27.0
1655	17.9	27.2

the steam-bath under reflux for sixteen hours, during which time much of the ether was lost. At the end of this time all of the reagent had been used up. The mixture was washed with 5% ammonium chloride and then with water. Then the ether and benzene were distilled off to get a brownish residue. This was crystallized from acetone to get three fractions: (1) lactone, melting point 131–132°; (2) an acid, melting point 145–150°; (3) an acid, melting point 185–186°. The acid of melting point 145–150° weighed about twice as much as the higher melting acid. The acids were further purified by conversion to their sodium salts in alcohol followed by dilution with water to allow non-acidic materials to precipitate. After filtering, the acids were again isolated and recrystallized from ethyl acetate. The purified low melting acid melted at 147–148° and had a specific rotation (2% in alcohol) +68.00°. *Anal.* Calcd. for $C_{20}H_{32}O_2$: C, 79.0; H, 10.6; equiv. wt., 304. Found: C, 78.7, 78.9; H, 10.45, 10.47, neut. equiv., 305.5. It was unsaturated to $C(NO_2)_4$ and lactonized readily in sulfuric acid to the lactone melting point 131–132°.

The high melting acid was recrystallized from ethyl acetate to a constant rotation. Its melting point was then 185–186° and its specific rotation −36° (2% in alcohol). It was unsaturated as shown by testing with tetranitromethane and lactonized in sulfuric acid to the lactone, melting point 131–132°. Its neutral equivalent was 304, which is the theoretical for a dihydroabietic acid. *Anal.* Calcd. for $C_{20}H_{32}O_2$: C, 79.0; H, 10.6. Found: C, 78.9, 79.0; H, 10.49, 10.52.

In crystallizing these two acids it was found that the large stubby prisms of the lower melting acid could be separated by screening from the small needles of the higher melting acid. In using this method of separation, purification was achieved quite readily, only three cystallizations being necessary to reach the stage where the properties were constant.

(b) One-tenth mole of methylmagnesium iodide was prepared in the usual manner from 15 g. of methyl iodide and 2.3 g. of magnesium using ether as the solvent for the methyl iodide. To this Grignard solution at room temperature was added 30.4 g. of lactone, melting point 131–132°, in dry benzene. When addition was complete, the ether was distilled and the mixture was heated overnight on the steam-bath. The product was then poured into ice water containing 25 g. of ammonium chloride. The benzene layer was then extracted with 2% sodium hydroxide, extract acidified and the acids recovered, dried and weighed: 21.0 g. (69%), N. E., 295 (trace of HCl still remaining), $[\alpha]_D$ +29° (1% in alcohol), bromine no. 74.5; yield calculated from specific rotation, 62.5% $[\alpha]_D$ +68° acid, 37.5% $[\alpha]_D$ −36° acid.

This run was repeated using the same amount of magnesium and methyl iodide but only 15.2 g. of lactone. The same procedure was followed and the acids extracted, dried and weighed; wt. 8.0 (52%), N. E., 295; $[\alpha]_D$ +32° (1% in alcohol); yield calculated from specific rotation, 65% $[\alpha]_D$ +68° acid, 35% $[\alpha]_D$ −36° acid.

Reaction of the Lactone at Room Temperature with CH_3MgI.—The reaction of 0.1 mole of the lactone with 0.1 mole of Grignard reagent described above was repeated exactly except that the reaction mixture was allowed to stand at room temperature overnight instead of being heated overnight. The product, worked up in the usual manner, weighed 29.6 g. It yielded on extraction with alcoholic alkali, 3 g. of acid mixture. This yield of acids is only about one-quarter the yield obtained at the higher temperature.

Quantitative Study of Reaction between Lactone and Methylmagnesium Iodide.—A solution of methylmagnesium iodide was made by combining 2.5 g. of magnesium and 15.6 g. of methyl iodide in 80 ml. of phenetole. To this reagent in a nitrogen atmosphere in a closed vessel fitted with a gas evolution device was added 30.4 g. of lactone in 100 ml. of dry benzene. Some heat was given off and the temperature accidentally rose to 45°. The gas evolution was 305 ml. (760 mm., 0°). The reaction mixture was then heated by boiling water for one and one-half hours. During this time the total gas evolution was 2100 ml. (760 mm., 0°).

Analysis of gas	Sample 1, %
Methane and other saturated hydrocarbons	25.6
CO_2	0.0
Unsaturates	1.0
Oxygen	11.2
CO	0.0
H_2 by CuO	1.4
H_2 by slow combustion	11.1
Nitrogen	49.7

After the heating period the addition of ethyl alcohol caused no gas evolution showing that the reagent had all reacted. The product was worked up without heating and extracted with alkali to isolate 13.4 g. of acids of which about 9 g. melted at 147–148° and 5 g. melted at 185–186°. These results may be tabulated as

	Moles
Lactone	0.100
Methylmagnesium iodide	.109
Methane (saturated hydrocarbons)	.022
Hydrogen	.010
Dihydroabietic acids	.044

If we assume the formation of one mole of ethane for each mole of hydrogen produced, the gases contain 0.012 mole of methane (from 0.012 mole CH_3MgI). Thus 0.032 mole of CH_3MgI is accounted for in the gases formed and 0.044 mole of CH_3MgI in the dihydroabietic acids produced.

Reaction of the Dihydroabietic Acids with Nitrosyl Chloride.—(a) 0.3 g. of dihydroabietic acid, melting point 185–186° $[\alpha]_D$ −36°, was dissolved in 5 ml. of glacial acetic acid containing 0.2 ml. of butyl nitrite. Then 5 ml. of glacial acetic acid containing 0.2 g. of dry hydrogen chloride was added. After standing overnight at 25°, the solution was a dark greenish-blue. About 5 ml. of water was added dropwise to effect crystallization and the resulting light-blue crystals weighing 0.2 g. were filtered out. These crystals melted at 88–88.5° and were recrystallized from a minimum amount of methanol at −70° to raise the melting point to 91.5–92°. The specific rotation $[\alpha]_D$ was −920° (0.2% in alcohol); −925° (2% in alcohol). *Anal.* Calcd. for $C_{20}H_{31}O_3N$: N, 4.2. Found: N, 4.49; Cl, nil.

(b) 0.3 g. of dihydroabietic acid, melting point 147–148°, $[\alpha]_D$ +68°, was dissolved in 5 ml. of glacial acetic acid containing 0.2 ml. of butyl nitrite and 5 ml. of acetic acid containing 0.2 g. of dry hydrogen chloride was added. The mixture turned dark amber but within two hours was light-blue with white crystals in suspension. The crystals were removed by filtration and were washed with alcohol in which they are very insoluble. The yield was 0.1 g., melting point 169–170°. These crystals were recrystallized from a chloroform–methanol mixture to a constant melting point 184–185°; $[\alpha]_D$ −30° (2% in $CHCl_3$). *Anal.* Calcd. for $C_{20}H_{31}O_3N$: N, 4.2. Found: N, 4.33; Cl, nil.

(c) 42 g. of a mixture of dihydroabietic acids produced by the reaction of methylmagnesium iodide on the lactone of hydroxytetrahydroabietic acid was dissolved in 300 ml. of glacial acetic acid. To this solution was added 30 ml. of butyl nitrite and 450 ml. of glacial acetic acid containing 31 g. of hydrogen chloride. The mixture turned dark and then gradually greenish-blue and crystals separated. The crystals were removed by filtering and were washed once with methanol. They weighed 3 g. and were oximino lactone crystals, melting point 185–186°. The mother liquor was diluted cautiously with water to get 16.3 g. of blue crystals, melting point 91–92°, and 3 g. of white crystals of lactone, melting point 130–131°.

(d) To a solution of 0.3 g. of dihydroabietic acid, melting point 185–186°, $[\alpha]_D$ −36°, in 5 ml. of glacial acetic acid, was added 0.2 ml. of butyl nitrite and then 5 ml. of glacial acetic acid containing 0.2 ml. of concentrated nitric acid (d. 1.42). After two hours at room temperature, water was added to get crystals which were recrystallized from methanol at −70°, melting point 91.5–92°, $[\alpha]_D$ −905° (1% in alcohol).

Reduction of the Blue Nitrosolactone.—To a solution of 2 g. of lactone of hydroxynitrosotetrahydroabietic acid $[\alpha]_D$ −925° in 75 ml. of ethanol was added 2 g. of sodium sulfide (hydrated) in 14 ml. of 70% alcohol. The mixture was refluxed for one hour during which time the blue-green color disappeared. Water was added dropwise to produce crystals and to dissolve inorganic salts. The crystals were taken up in ether and converted to the amine hydrochloride by bubbling hydrogen chloride into the solution. Gradual addition of petroleum ether caused crystals to separate. The free amine was then liberated by neutralizing a methanol solution of the salt with dilute sodium hydroxide. The free amine was then crystallized by diluting the methanol solution with water and was further purified by crystallization from methanol until a melting point of 144–145°, $[\alpha]_D$ ±1° (1.76% in alcohol) was reached. *Anal.* Calcd. for $C_{20}H_{33}O_2N$: N, 4.37. Found: N, 4.27.

Hydrogenation of the Blue Nitrosolactone.—0.268 g. of nitrosolactone, m. p. 91.5–92.5°, $[\alpha]_D$ −925° (2% in ethanol), was dissolved in 10 g. of glacial acetic acid. To this solution was added 0.265 g. of $PtO_2 \cdot H_2O$ (Adams platinum oxide catalyst). The solution was shaken with hydrogen at atmospheric pressure in an apparatus for measuring the volume of hydrogen absorbed. A blank was run on the catalyst in acetic acid at the same time and applied as a correction for the hydrogen absorbed by the catalyst. The corrected volume of hydrogen absorbed was 33.9 ml.

After removal of the catalyst the product was precipitated by adding water. The crystalline aminolactone was then crystallized from methanol. It melted at 146–147° and was shown by mixed melting point to be the same amine which was obtained by reducing the blue nitrosolactone with sodium sulfide.

Hydrolysis of Nitrosolactone —A solution of 1 g. of nitrosolactone, m. p. 91.5–92.5°, in 25 ml. of acetic acid containing 10 ml. of concentrated hydrochloric acid was refluxed. The blue color disappeared in about three hours, but the refluxing was continued forty hours. The product was isolated by adding water and then crystallized from methanol. It amounted to 0.35 g., m. p. 130–131°. It was shown by mixed melting point and microscopic examination to be the lactone of hydroxytetrahydroabietic acid.

Acid Isomerization of Dihydroabietic Acids.—A solution of 0.1000 g. of dihydroabietic acid, melting point 147–148°, $[\alpha]_D$ +68° in 10 ml. of glacial acetic acid was refluxed for thirty minutes. The solvent was evaporated and replaced by 10 ml. of ethanol. The rotation was unchanged by this treatment. Similar treatment of dihydroabietic acid melting point 185–186°, $[\alpha]_D$ −36° did not change the rotation.

A solution of 0.1000 g. of dihydroabietic acid in 5 ml. of ethanol was diluted to 10 ml. with alcoholic hydrogen chloride (15 g. of HCl gas in 100 ml. of solution). The rotation was determined immediately and was followed at 75°F. (29°C.) for twenty days. The change in rotation for both the dextro- and the levo-dihydroabietic acids is given in Table II.

After 430 hours of isomerization, the product was recovered by evaporation and dried over sodium hydroxide pellets *in vacuo*. Titration of these residues indicated that 35% of the levorotatory acid had been converted to the lactone and 45% of the dextrorotatory acid had been converted to the lactone. The lactone was removed from the neutralized solutions by ether extraction and the acids were recovered from the salts. The acid mixture from isomerization of the dextrorotatory acid was +22° indicating the possibility of about 44% levorotatory acid in the mixture. The acid mixture from isomerization of the levorotatory acid was −37° indicating no isomerization to the dextrorotatory acid.

Hydrogenation of Dihydroabietic Acid.—Samples of dihydroabietic acid weighing 0.450 g. were placed in the flasks of a quantitative hydrogenation apparatus, containing 15 ml. of glacial acetic acid. After the resin acid was dissolved, the solution was cooled and 0.401 g. $PtO_2 \cdot H_2O$ catalyst was added. The sample was shaken under a slight pressure of hydrogen for twenty-seven hours. Both dihydroabietic acids $[\alpha]_D$ +68° and $[\alpha]_D$ −36° and a blank on the catalyst were run simultaneously. The data in Table III are corrected for the blank.

After twenty-seven hours, the dextrorotatory acid had absorbed 85% of the theoretical amount of hydrogen and the levorotatory acid had absorbed 53% of the theoretical amount of hydrogen. In both cases the acid mixtures isolated from solution had $[\alpha]_D$ −6°. By lactonizing the remaining dihydroabietic acid and removing the tetrahydroabietic acids, it was found that the tetrahydroabietic acid in each case had zero rotation. By correcting the crude acid mixtures −6° for the rotation of the tetrahydroabietic acid present the unhydrogenated acid from the dextrorotatory acid had $[\alpha]_D$ −40° and that from the levorotatory acid had $[\alpha]_D$ −12°. This is indicative that the hydrogen absorption of the dextrorotatory acid was decreased by isomerization of the original acid to a levorotatory acid.

In order to determine whether the catalyst caused either or both of the acids to isomerize, 0.45-g. samples of each were added to freshly reduced catalyst and acetic acid and were shaken for sixty hours. After this treatment the levorotatory acid had $[\alpha]_D$ −37° and the dextrorotatory acid had $[\alpha]_D$ +66°, which showed no change from the original acid.

Acknowledgment.—The author wishes to acknowledge the skillful assistance of Mr. Thomas F. Sanderson in carrying out the experimental work reported here.

Summary

The lactone of hydroxytetrahydroabietic acid melting at 131–132° has been converted by the reaction with methylmagnesium iodide into two dihydroabietic acids, m. p. 147–148°, $[\alpha]_D$ +68° and m. p. 185–186°, $[\alpha]_D$ −36°, respectively.

Both of these dihydroabietic acids lactonize readily to give only the original lactone, m. p. 131–132°.

The dextrorotatory dihydroabietic acid reacts with nitrosyl chloride to form an oximino lactone. The levorotatory dihydroabietic acid under the same conditions forms a blue nitroso lactone.

The levorotatory dihydroabietic acid absorbs hydrogen in the presence of a platinum catalyst more slowly than does the dextrorotatory acid. In the process of lactonization, the levorotatory acid lactonizes more slowly and does not isomerize while the dextrorotatory acid lactonizes more

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

rapidly and at the same time isomerizes to the levorotatory acid.

All of these data support the formula for the lactone of hydroxytetrahydroabietic acid in which the point of lactonization is at C-4b.

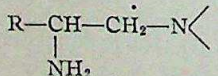
Amino Ketones. II. The Synthesis of α,β-Diamines from α-Amino Ketones*

BY NORMAN H. CROMWELL AND HERMAN HOEKSEMA

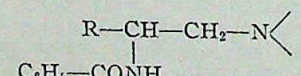
In a previous investigation[1] the synthesis of α,γ-diamines from β-amino ketones was reported. It seemed of interest to investigate similar synthesis of α,β-diamines from α-amino ketones to compare the relative yields in the two series.

Several investigations[2] by other workers have been concerned with the conversion of α-amino ketones to α-amino alcohols in order that the two series of compounds could be studied for their relative values as pressor agents. A similar comparison of the α-amino ketones with their corresponding α,β-diamino compounds should also prove to be interesting. Furthermore, such α,β-diamino compounds might be converted to the benzamides. It has been shown previously that compounds containing the grouping  often possess local anesthetic activity.[3]

Thus a series of diamines (A) and the corresponding benzamides (B) might prove to be of considerable interest, pharmacologically.



(A)

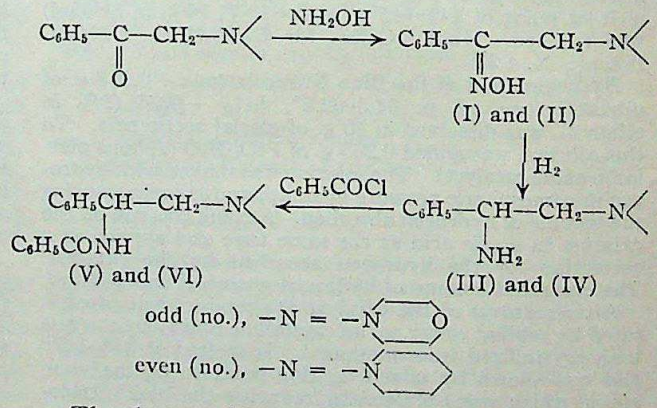


(B)

Attempts were made to obtain in good yields the oximes of ω-N-methylbenzylaminoacetophenone,[4] ω-tetrahydroisoquinolinoacetophenone[5] and ω-tetrahydroquinolinoacetophenone,[6] without success.

The oximes of ω-morpholino-[2b] and ω-piperidinoacetophenone[7] were both obtained in good yields. An extensive investigation was made of the reduction of one of these, (I), to the corresponding α,β-diamine. Sodium and alcohol was found to be the most efficient of the reagents tried. It was interesting to find that α-amino ketoximes are reduced to give better yields of the α,β-diamines by catalytic hydrogen, than were the β-amino ketoximes to give α,γ-diamines.[1] In the latter case it was shown that β-amino ketoximes lost the β-amino group on such treatment, probably because of the tendency to form an α,β-unsaturated ketoxime. The absence of such a tendency with α-amino ketoximes accounts for their greater yields of diamines on catalytic reduction.

The general low yields of α,β-diamines experienced even with sodium and alcohol were caused by condensation of the diamine with itself, through loss of ammonia during distillation. This was shown by the detection of ammonia in the forerun of such distillations and by treating the crude diamine ether solution with benzoyl chloride, and determining the yield of benzamide obtained.



The benzamides (V) and (VI) were readily prepared in good yields from the corresponding α,β-diamines (III) and (IV).

These benzamides have been found to be strong local anesthetics. The various compounds reported in this paper are being fully investigated for various pharmacological activities by L. W. Rowe and others of the Parke, Davis and Company Laboratories. A detailed pharmacological report will be published by them in another journal.

Experimental[8]

ω-Morpholinoacetophenone Oxime (I).—A cooled solution of 200 g. (4.35 mole) of potassium hydroxide in one liter of methanol was mixed with a solution of 61 g. (0.88

mole) of hydroxylamine hydrochloride in 150 ml. of water at 20°. To this basic solution was added a solution of 46 g. (0.19 mole) of ω-morpholinoacetophenone hydrochloride[2b] in 70 ml. of water at 20°. The well-stoppered mixture was allowed to stand at room temperature for two days. The potassium chloride was filtered from the solution and the methyl alcohol evaporated *in vacuo* until only a sirupy residue remained. This residue was then mixed with 150 ml. of water and the solution neutralized with 300 ml. of 6 *N* hydrochloric acid. The white precipitate so obtained was filtered and washed with cold water until no trace of chloride could be detected in the washings. Recrystallization from methanol and water gave soft, white needles, m. p. 147–149°, weighing 38 g. (91% yield).

Anal. Calcd. for $C_{12}H_{16}N_2O_2$: C, 65.43; H, 7.32. Found: C, 65.48; H, 7.42.

This product was soluble in both dilute mineral acids and bases, hot methyl or ethyl alcohol, and warm ether.

ω-Piperidinoacetophenone Oxime (II).—This preparation was carried out in a similar manner to that used for (I), starting with 10 g. (0.043 mole) of ω-piperidinoacetophenone hydrochloride.[7] The white crystalline product weighed 7.9 g. (70% yield), m. p. 111–115°. By fractional crystallization from methyl alcohol, two products were obtained, m. p. 117–118.5° and m. p. 136–138.5°. A mixture of these two isomers melted at 111–115°.

Anal. Calcd. for $C_{13}H_{18}N_2O$: C, 71.40; H, 8.31. Found: m. p. 118°, C, 71.23; H, 8.40; m. p. 138°, C, 71.08; H, 8.37.

Both of these compounds dissolved readily in dilute mineral acids or bases and were soluble in ether and in methyl and ethyl alcohols.

α-Phenyl-β-morpholinoethylamine (III).—This diamine was obtained by the reduction of the corresponding oxime using various procedures.

A. By Catalytic Hydrogenation: (1) Using Raney Nickel.—Five grams (0.023 mole) of (I) was dissolved in 125 ml. of absolute alcohol and shaken with 1.0 g. of Raney nickel for a short time. The catalyst was filtered off and 1.0 g. of Raney nickel again added to the filtrate and the mixture shaken with hydrogen for six hours under a pressure of 50 lb./sq. in. Removal of the catalyst and evaporation *in vacuo* of the alcohol left a yellow oily residue which was dissolved in ether and washed several times with dilute sodium hydroxide and several times with a saturated salt solution. The ether solution was dried over anhydrous sodium sulfate and evaporated to give an oil which was further dried for several days over solid sodium hydroxide. Distillation gave 0.5 g. (10% yield) of a pale yellow oil, b. p. 134° (2 mm.). Considerable residue remained in the distilling flask and ammonia was detected in the forerun.

Anal. Calcd. for $C_{12}H_{18}N_2O$: C, 69.67; H, 8.74; N, 13.58. Found: C, 69.44; H, 8.90; N, 13.43.

When cooled to 0° this diamine solidified. It is slightly soluble in water and very soluble in quite dilute mineral acids.

Reduction of the oxime was inhibited when a similar reduction mixture, to which had been added 0.374 g. of ammonia, was subjected to the same treatment. Almost one-half of the starting oxime was recovered.

(2) Using Palladium on Charcoal.—Ten grams (0.046 mole) of (I) was dissolved in 50 ml. of glacial acetic acid and one-half gram of 30% palladium on charcoal added. Isolation of the product as in the previous experiment gave 1.4 g. (15% yield), b. p. 134° (2 mm.) and the product solidified on cooling to 0°. A similar experiment with 5 g. of (I) dissolved in 100 ml. of absolute alcohol to which had been added 3.3 g. of dry hydrogen chloride gas gave 0.5 g. (10% yield) of the diamine (III).

B. With Sodium and Alcohol.—Ten grams (0.046 mole) of (I) was dissolved in 120 ml. of absolute alcohol and 13.5 g. (0.59 mole) of cut sodium added over a period of three hours to the refluxing solution. Water (25 ml.) was added to destroy the sodium ethoxide, the solution neutralized with conc. hydrochloric acid at 0°, and the precipitated sodium chloride filtered off. The filtrate was then acidified and the solvent removed by vacuum distillation. The residue was mixed with 50% sodium hydroxide, with cooling, and the precipitated oil separated, purified and distilled as before, b. p. 150–152° (3 mm.), wt. 2.5 g. (26% yield). This product also solidified on cooling to 0°.

α-Phenyl-β-piperidinoethylamine (IV).—This diamine was prepared by a sodium–alcohol reduction of (II). It was necessary to use carefully dried absolute alcohol as the reduction medium. Because this diamine was somewhat soluble in water and dilute sodium hydroxide, 40% alkali was used in the purification step to remove any unchanged oxime. The product was a light yellow oil obtained in 24% yield, b. p. 128° (3 mm.). Considerable residue remained in the distilling flask and ammonia was detected in the forerun. The diamine became very viscous on cooling to 0° but did not solidify.

Anal. Calcd. for $C_{13}H_{20}N_2$: C, 76.45; H, 9.86; N, 13.70. Found: C, 76.62; H, 10.07; N, 13.54.

α-Phenyl-β-morpholino-N-benzoylethylamine (V) and α-Phenyl-β-piperidino-N-benzoylethylamine (VI).—These benzamides were prepared by treating a dry ether solution of the diamine with an equal molar quantity of benzoyl chloride at 0°. After allowing the mixture to stand at 0° for three hours the white hygroscopic hydrochloride was removed and mixed with dilute sodium bicarbonate and allowed to stand for twelve hours more in the ice-chest. The white gummy precipitate was recrystallized from alcohol and water. A 95% yield of (V), m. p. 143–144°, was obtained.

Anal. Calcd. for $C_{19}H_{22}N_2O_2$: C, 73.52; H, 7.15; N, 9.09. Found: C, 73.79; H, 7.42; N, 9.05.

A 94% yield of (VI), m. p. 135–136°, resulted.

Anal. Calcd. for $C_{20}H_{24}N_2O$: C, 77.87; H, 7.85; N, 9.03. Found: C, 77.99; H, 8.20; N, 9.07.

Both (V) and (VI) were soluble in dilute mineral acids and insoluble in water.

The preparation of (VI) was repeated using an ether solution of the undistilled diamine (IV) (theoretically containing 2.15 g.). A yield of 2.0 g. of (VI), m. p. 135–136°, resulted. Assuming a 94% yield on benzoylation, this indicates a 65% yield of the diamine (IV) from the sodium and alcohol reduction of (II).

Summary

1. The conversion of α-amino ketones to the corresponding diamines via the reduction of the oximes of the amino ketones has been investigated.

2. Some interesting α,β-diamines and their corresponding benzamides have been prepared.

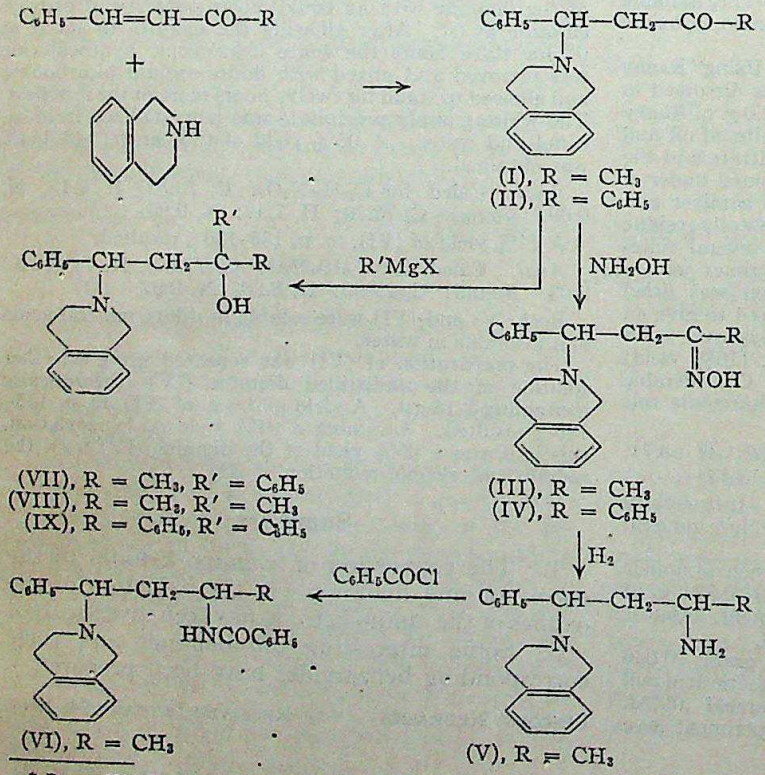
Amino Ketones. III.* β-Tetrahydroisoquinolino Ketones and Derivatives. Reaction with Grignard Reagents[1]

BY NORMAN H. CROMWELL AND JOHN S. BURCH

While extending our investigations of the chemistry of β-amino ketones,[2] it seemed important to introduce the interesting base tetrahydroisoquinoline into these molecules. Buck and Ide[3] reported N-alkyl tetrahydroisoquinolines to show slight depressor action and to be strong sympatholytics. Allewelt and Day[4] reported that 1-phenyl-2-tetrahydroisoquinolino ethanol hydrochloride showed mild local anesthetic activity.

Tetrahydroisoquinoline was found to add readily to benzalacetone and benzalacetophenone to give the β-amino ketones (I) and (II), respectively. The oxime (III) of (I) was reduced with sodium and alcohol to 1-phenyl-1-tetrahydroisoquinolino-3-aminobutane, (V). This reduction was accompanied by some cleavage of the tetrahydroisoquinolino nitrogen to β-carbon bond, thereby reducing the yield of diamine. (V) reacted with benzoyl chloride to give low yields of 1-phenyl-1-tetrahydroisoquinolino-3-benzamidobutane (VI).



Apparently the only previous study of the reaction of a β-amino ketone with a Grignard reagent is the addition of methylmagnesium iodide to diacetone amine, reported by Kohn.[5] Since the β-amino ketones (I) and (II) could be obtained in a pure dry state it was of interest to compare their reactivities with Grignard reagents. Moreover, the resulting amino alcohols should be of interest pharmacologically.

Phenylmagnesium bromide and methylmagnesium iodide both added readily to (I) to give good yields of the corresponding amino alcohols (VII) and (VIII), respectively. Only a very slow and incomplete reaction was experienced in adding phenylmagnesium bromide to (II). This might be expected because of the hindering and electron attracting effect of the phenyl group attached to the carbonyl group, along with the similar effect of the tetrahydroisoquinolino group in the beta position. However, methylmagnesium iodide added readily to this same amino ketone (II) to give a good yield of the amino alcohol (VII).

The pharmacological investigations of these compounds will be reported elsewhere.

Experimental[6]

β-Tetrahydroisoquinolinobenzylacetone (I).—To a solution of 60.8 g. (0.416 mole) of benzalacetone in 100 ml. of 95% ethyl alcohol was added 58.2 g. (0.437 mole) of tetrahydroisoquinoline.[7] This solution was heated to boiling and then allowed to stand at room temperature for two days and in an ice-chest four days. The white crystalline product was filtered and washed with a 70% alcohol solution; yield 69.0 g. (59%); m. p. 71–72°. Recrystallization from low boiling petroleum ether or methyl alcohol and water solutions did not change the melting point of the white product.

Anal. Calcd. for $C_{19}H_{21}NO$: C, 81.68; H, 7.58. Found: C, 81.70; H, 7.83.

Attempts to prepare this amino ketone in a petroleum ether solution gave a mixed product that resisted purification.

β-Tetrahydroisoquinolinobenzylacetone Oxime (III).—To a solution of 11.2 g. (0.162 mole) of hydroxylamine hydrochloride and 16.6 g. (0.202 mole) of sodium acetate in 180 ml. of methyl alcohol and 40 ml. of water was added 29.0 g. (0.104 mole) of (I), dissolved in 300 ml. of methanol. This mix-

ture was heated to boiling and allowed to stand one day at room temperature and two days in the ice-chest. The white, needle-shaped crystals were filtered and washed with 50% methyl alcohol and recrystallized from 95% alcohol, wt. 25.8 g. (84% yield), m. p. 155–157°.

Anal. Calcd. for $C_{19}H_{22}N_2O$: C, 77.51; H, 7.53. Found: C, 77.52; H, 7.68.

β-Tetrahydroisoquinolinobenzylacetophenone (II).—To 100 ml. of 95% alcohol were added 26.8 g. (0.129 mole) of benzalacetophenone and 17.8 g. (0.134 mole) of tetrahydroisoquinoline. Using the same procedure as with (I), the yield was 36.7 g. (83%), recrystallized from an alcohol-ether mixture, m. p. 90–91°.

Anal. Calcd. for $C_{24}H_{23}NO$: C, 84.42; H, 6.79. Found: C, 84.24; H, 7.04.

The oxime (IV) of (II) was prepared by the procedure used for (III); yield 10%, recrystallized from absolute alcohol, m. p. 173–175°.

Anal. Calcd. for $C_{24}H_{24}N_2O$: C, 80.86; H, 6.79. Found: C, 80.82; H, 6.87.

1-Phenyl-1-tetrahydroisoquinolino-3-aminobutane (V).—The oxime (III) was reduced in boiling ethanol with sodium and the diamine isolated by the method outlined in the first paper of this series.[2] The product was a thick, pale-green oil that flowed only when warm and refused to solidify or crystallize, b. p. 178–180° (1 mm.), yield 32%.

Anal. Calcd. for $C_{19}H_{24}N_2$: C, 81.38; H, 8.63; N, 9.99. Found: C, 80.95; H, 8.73; N, 10.06.

From this reduction mixture was also isolated tetrahydroisoquinoline identified as its benzene sulfonamide, m. p. 154°,[8] benzalacetone oxime, m. p. 113–116°,[9] and benzylacetone oxime, m. p. 85–88°.[10]

The benzamide (VI) of (V) was prepared by the method outlined in the first paper in this series.[2] The yield was comparatively low, however (30%); recrystallized from 95% alcohol, m. p. 159–161°.

Anal. Calcd. for $C_{26}H_{28}N_2O$: C, 81.21; H, 7.34. Found: C, 80.89; H, 7.32.

4-Tetrahydroisoquinolino-2,4-diphenylbutanol-2 (VII).—To an ethereal solution of phenylmagnesium bromide, prepared from 3.5 g. (0.144 mole) of magnesium, was added as rapidly as possible, a solution of 10 g. (0.036 mole) of (I) in 75 ml. of dry ether. The solution was stirred during addition and refluxed for four hours thereafter, a white precipitate forming during this time. The reaction mixture was decomposed by pouring it onto ice and 10 g. of ammonium chloride. The product was separated from the water layer with ether–benzene extractions. This ether–benzene layer was washed with four 50-ml. portions of 0.03 *N* hydrochloric acid to remove any free tetrahydroisoquinoline.

Evaporation of the solvent and recrystallization of the residual oil from low boiling petroleum ether gave 5.5 g. (43% yield) of white crystals, m. p. 115–116°.

Anal. Calcd. for $C_{25}H_{27}NO$: C, 83.99; H, 7.61. Found: C, 83.94; H, 7.64.

This same amino alcohol (VII) was obtained in 45% yields by adding methylmagnesium iodide to the β-amino ketone (II).

4-Tetrahydroisoquinolino-2-methyl-4-phenylbutanol-2 (VIII).—This carbinol was prepared from (I) by the method outlined for (VII), using methylmagnesium iodide. The mixture was refluxed for three hours even though an addition product had precipitated in ten minutes. The ether–benzene extractions containing the product were freed of tetrahydroisoquinoline by adding a small amount of acetic anhydride. After standing at room temperature for twelve hours this acetic anhydride reaction mixture was extracted with ten 60-ml. portions of 0.2 *N* hydrochloric acid. The combined acid extracts were made basic with sodium hydroxide and the liberated amino alcohol extracted with benzene. Evaporation of the benzene left a brown oil which was crystallized from low-boiling petroleum ether, yield 46%, m. p. 95–96°. This product was considerably more soluble in dilute hydrochloric acid than was (VII).

Anal. Calcd. for $C_{20}H_{25}NO$: C, 81.31; H, 8.53. Found: C, 81.25; H, 8.60.

3-Tetrahydroisoquinolino-1,1,3-triphenylpropanol-1 (IX).—The amino ketone (II) was refluxed for seven hours with phenylmagnesium bromide. Only a small amount of white addition product was precipitated. The product was isolated in the manner outlined for (VII). Only a small amount of the amino alcohol was obtained (5% yield), recrystallized from absolute alcohol, m. p. 78–80°. A mixed melting point experiment with (II) gave m. p. 73–78°.

Anal. Calcd. for $C_{30}H_{29}NO$: C, 85.88; H, 6.97. Found: C, 85.82; H, 7.20.

Summary

1. β-Tetrahydroisoquinolinobenzylacetone and the corresponding benzylacetophenone have been prepared and their reactions with Grignard reagents compared.

2. 1-Phenyl-1-tetrahydroisoquinolino-3-aminobutane and the benzamide have been prepared starting with the β-amino ketone.

Sulfides and Sulfones Derived from *p*-Mercaptophenylarsonic Acid[1]

BY JACK F. MORGAN AND CLIFF S. HAMILTON

Although numerous ethers derived from *p*-hydroxyphenylarsonic acid have been described in the literature, very little is known of the corresponding thioethers or sulfides derived from *p*-mercaptophenylarsonic acid. Only four such compounds, *p*-methyl-,[2a,b] *p*-ethyl-,[3] *p*-benzylmercaptophenylarsonic acid[4] and *p*-arsonophenylmercaptoacetic acid,[2] are described in the literature. In each case they were prepared by means of the Bart[5] or Scheller[6] reactions. *p*-Arsonophenylmercaptoacetic acid has also been produced from diazotized arsanilic acid by treatment with potassium xanthate followed by basic hydrolysis and reaction with monochloroacetic acid.[7]

In the present work one sulfide, *p*-β-hydroxyethylmercaptophenylarsonic acid, was prepared by means of the Bart reaction. Several other sulfides containing substituted aliphatic, heterocyclic and aromatic groups attached to the sulfur atom of *p*-mercaptophenylarsonic acid were synthesized by a more convenient method. *p*-Thiocyanophenylarsonic acid was obtained in 30–45% yields by the method of Barber.[8] Basic hydrolysis of the thiocyano derivative gave an intermediate acid. This intermediate was readily condensed with active aliphatic, heterocyclic and aromatic halides in basic solution to form the desired sulfides. The intermediate is apparently either composed principally of *p*-mercaptophenylarsonic acid or readily yields this arsonic acid when dissolved in alkaline solution.

In general, sulfones are obtained readily from organic sulfides by oxidation with hydrogen peroxide. In this manner both *p*-methyl-[2a] and *p*-ethylsulfonylphenylarsonic acid[3] have been prepared. In addition *p*-methylsulfonylphenylarsonic acid has been synthesized by means of the Bart reaction on *p*-aminophenylmethylsulfone.[9] No other mention is made in the literature of sulfones derived from *p*-sulfophenylarsonic acid.

Ten sulfides derived from *p*-mercaptophenylarsonic acid were, with one exception, readily converted to the corresponding sulfones by treatment with hydrogen peroxide. 2′-Amino-4′-pyrimidyl-4-arsonophenylsulfide decomposed when warmed in perhydrol.

Experimental

***p*-Aminophenyl-β-hydroxyethylsulfide (I).**—*p*-Nitrophenyl-β-hydroxyethylsulfide was prepared by the method of Waldron and Reid.[10] By means of hydrogen and Raney nickel, 100 g. of the nitro compound was reduced in acetone solution. Removal of the acetone yielded (I) (84 g., 99%), m. p. 43–44°, b. p. 232–235° (38 mm.) (dec.). The product consisted of a light tan wax-like crystalline mass, soluble in the usual organic solvents and hot water, but almost insoluble in cold water. For analysis a sample of the amine was converted to its hydrochloride.

***p*-Aminophenyl-β-hydroxyethylsulfide Hydrochloride (II).**—An ether solution of (I) was treated with dry hydrogen chloride. The precipitated hydrochloride (II) was removed by filtration, washed with ether and recrystallized from ethanol–petroleum ether, m. p. 170°.

Anal. Calcd. for $C_8H_{12}ClNOS$: N, 6.81; Cl, 17.24. Found: N, 6.61; Cl, 16.92.

***p*-β-Hydroxyethylmercaptophenylarsonic Acid (III).**—This arsonic acid was readily prepared in yields of 46–48% from the corresponding amine by the method of Bart.[5] The compound was purified by two recrystallizations from water. The white dimorphous solid may be obtained either as leaflets melting at 120.5–121° or as needles melting at 132–133°. Either crystalline form could be obtained from aqueous solution by seeding with the appropriate crystals.

Anal. Calcd. for $C_8H_{11}AsO_4S$: As, 26.93. Found: needles, As, 26.93; leaflets, As, 26.90.

***p*-Thiocyanophenylarsonic acid** was prepared by the method of Barber[8] in 30–45% yields.

Intermediate Acid (IV).—A solution of *p*-thiocyanophenylarsonic acid (50 g.) in 500 ml. of 10% sodium hydroxide was refluxed for six hours, cooled and slowly treated with 4 *N* hydrochloric acid. The small amount of red gum, which first separated, was removed and the acidification continued (congo red) to obtain a nearly white precipitate of (IV); yield, 35 g. (78% calcd. as *p*-mercaptophenylarsonic acid). This product does not melt below 250°, is insoluble in boiling water but readily dissolves in dilute sodium hydroxide.

Sulfides Derived from (IV).—The intermediate acid (IV) (11.7 g., 0.05 mole calcd. as *p*-mercaptophenylarsonic acid) and dissolved in an aqueous or dilute alcohol solution of sodium hydroxide (6 g., 0.15 mole) and treated with the appropriate halide (0.1 mole). The mixture was refluxed for a period of four to sixty hours depending on the reactivity of the halide. The crude product which separated on acidification (congo red) was purified by two recrystallizations from water, the hot solution being treated with activated charcoal.

Dilute ethanol (25–30%) was used as solvent when halides of low solubility were employed, *i. e.*, ethyl chloroacetate, *p*-nitrochlorobenzene or 2-amino-4-chloropyrimidine. Because *p*-[β-(β′-hydroxyethoxy)-ethylmercapto]-phenylarsonic acid existed as an oil it was isolated as its sodium salt from ethanol solution.

Sulfones.—The appropriate sulfide (2 g.) was treated with 10 ml. of 27.5% hydrogen peroxide solution and warmed a short time. The resulting solution was allowed to stand overnight and cooled in the refrigerator for several hours. The white crystalline sulfone was removed by filtration, washed with a small amount of water and dried. In a few cases no solid separated and the compounds were isolated by slow evaporation of the peroxide solutions at room temperature. Some of the sulfones were further purified by recrystallization from water.

9	4′-Amino-4-arsonodiphenylsulfone[b]	52	229–230 (dec.)	$C_{12}H_{12}AsNO_5S$	20.97	21.00

[a] Isolated by evaporation because of high solubility. [b] Prepared by reduction of (8) with hydrogen and Raney nickel in aqueous sodium bicarbonate.

Melting Point Determination.—Organic arsonic acids normally are converted to their anhydrides by heat; the temperature and time required to complete the dehydration depends on the acid involved and may be a function of the relative acidity of that acid. The dehydration is illustrated by the equation

$$RAsO_3H_2 \xrightarrow{\Delta} RAsO_2 + H_2O$$

If an arsonic acid is heated slowly to its normal melting point, any of three observations may be made depending on the ease of dehydration of the compound. These observations will be: for no dehydration, the normal melting point; partial dehydration, lowered melting point or partial melting; complete dehydration, no melting until melting point of anhydride is reached. In general the anhydrides melt at considerably higher temperatures than the corresponding arsonic acids and frequently decompose at temperatures above 250° without melting.

Melting points of the compounds described in this paper were accurately determined by inserting a sample in a preheated bath at a temperature which was 0–5° below the melting point and slowly raising the temperature of the bath. The shortened time allowed for dehydration allows the observation of melting points which otherwise might be overlooked.

A Bureau of Standards certified thermometer was used in all melting point determinations and stem corrections were calculated to obtain corrected readings.

(11) Cislak and Hamilton, THIS JOURNAL, **52**, 638 (1930).

Summary

1. Two general methods were used to synthesize a number of new sulfides derived from *p*-mercaptophenylarsonic acid.

2. *p*-β-Hydroxyethylmercaptophenylarsonic acid was prepared from the corresponding amine by means of the Bart reaction.

3. *p*-Thiocyanophenylarsonic acid was hydrolyzed in alkaline solution to yield an intermediate acid. This intermediate was readily condensed with substituted aliphatic, heterocyclic and aromatic halides to yield sulfides derived from *p*-mercaptophenylarsonic acid.

4. Sulfides derived from *p*-mercaptophenylarsonic acid were oxidized with hydrogen peroxide to obtain eight new sulfones.

Hydrogenation of Basic Nitriles with Raney Nickel

BY WOLFGANG HUBER

According to von Braun[1] the hydrogenation of a nitrile is expressed by the following series of reactions

$$RCN + H_2 \longrightarrow RCH{=}NH \quad (1)$$

$$RCH{=}NH + H_2 \longrightarrow RCH_2NH_2 \quad (2)$$

$$RCH{=}NH + RCH_2NH_2 \longrightarrow RCH(NH_2)NHCH_2R \quad (3)$$

$$RCH(NH_2)NHCH_2R + H_2 \longrightarrow RCH_2NHCH_2R + NH_3 \quad (4)$$

Numerous procedures have been described in the literature to minimize the formation of secondary amines according to equations 3 and 4. Thus, Carothers[2] hydrogenated benzonitrile to benzylamine with platinum oxide in good yields using acetic anhydride as solvent, and attributed the high yield to the fact that the primary amine is quickly acetylated and therefore protected against interaction with the intermediate imine. Hartung[3] used alcohol containing one mole of hydrochloric acid and palladized charcoal in the hydrogenation of aromatic nitriles, and Kindler[4] used glacial acetic acid containing one mole of concentrated sulfuric acid and palladium sponge to hydrogenate nitriles to the corresponding β-arylethylamines. The high yield of primary amines in these reactions is attributed to the removal of the base from the reaction equilibrium by salt formation, thus preventing the possible interaction with the intermediary imine according to equation 3.

In connection with other work it was of interest to develop a method for the reduction of basic heterocyclic nitriles to the corresponding primary amines exclusively. It was found that such nitriles, and for that matter basic nitriles in general, cannot be hydrogenated in good yields to the corresponding primary amines by any of the aforesaid methods. It is obvious that basic nitriles in the presence of acids or acetic anhydride will undergo salt formation or acetylation, the latter products being considerably less soluble than the parent nitriles in the non-aqueous solvents generally used in hydrogenations. The resulting heterogeneous reaction mixture slows the hydrogenation speed and the subsequent coating of undissolved nitrile salt with primary amine salt, precipitating from the solution, tends to slow further and eventually inhibit the reduction. The poisoning effect of anhydrous mineral acids on catalysts such as platinum oxide, palladized charcoal and palladium on zirconium oxide is an additional factor which tends to slow the smooth and speedy reduction of basic nitriles.

(1) von Braun, Blessing and Zobel, *Ber.*, **56**, 1988 (1923).
(2) Carothers and Jones, THIS JOURNAL, **47**, 3051 (1925).
(3) Hartung, *ibid.*, **50**, 3370 (1928).
(4) Kindler, Peschke and Brandt, *Ber.*, **68**, 2241 (1935).

In the hydrogenation of 2-methyl-4-aminopyrimidine-5-nitrile with either one of the aforesaid catalysts the formation of secondary amine is thus always considerable or even predominant, the reduction time is markedly increased and often, due to catalyst poisoning, the hydrogenation is incomplete. Data illustrating this behavior are listed in Table I.

The hydrogenation of basic nitriles to the corresponding primary amines, however, can be carried out smoothly and with excellent yields with Raney nickel in organic solvents and in the presence of ammonia. Schwoegler and Adkins[5] were the first to use Raney nickel and ammonia in the hydrogenation of aliphatic nitriles, thus obtaining *n*-pentyl- and *n*-heptylamine in excellent yields. The results of this study seem to confirm their assumption that it is the ammonia rather than the primary amine which will react with the imine formed according to equation 1 of the von Braun scheme, thus giving rise to the formation of additional primary amine according to the equations

$$RCH{=}NH + NH_3 \longrightarrow RCH(NH_2)_2 \quad (5)$$

$$RCH(NH_2)_2 + H_2 \longrightarrow RCH_2NH_2 + NH_3$$

The yields, in all reactions studied, were found to be nearly quantitative. Secondary amines, if found at all, were rarely present in excess of 5%. The presence of ammonia, however, is essential since reduction with Raney nickel alone always leads to the formation of large amounts of secondary amines. Indeed, a rather high concentration of ammonia is desirable; generally 3-4 moles of ammonia were used per mole of nitrile. Using less than 2.5 moles of ammonia per mole of nitrile seems to cause a competitive reaction between ammonia-imine and primary amine-imine in equation 5, thus increasing the formation of secondary amine. With all compounds investigated, the reduction proceeded smoothly at room temperature with hydrogen pressures ranging from 60 to 200 lb./sq. in. Vigorous shaking of the autoclave seems to be essential for a smooth reduction at these pressures, since it was found that in slowly shaking autoclaves considerably higher hydrogen pressures were necessary to insure a smooth hydrogenation. A variety of organic solvents has been used including methanol, ethanol, 2-propanol, butanol, dioxane, *n*-butyl ether and formamide. For all practical purposes methanol was found to be an excellent solvent, whereas in water or in aqueous solvents the amounts of secondary amines present were always considerable. The hydrogenation proceeds very quickly, the average time for 0.5 mole

.1	Pt_2O Adams catalyst	EtOH–H_2SO_4	60	29	14	44	43	87

[a] The % of primary amine present was determined by condensation of the free base wtih potassium dithioformate (see Huber, THIS JOURNAL, 65, 2225 (1943)) and subsequent weighing of the precipitated 2-methyl-4-amino-5-thioformylaminomethylpyrimidine. [b] The % of secondary amine present was determined from the weight of the 2-methyl-4-amino-5-hydroxymethylpyrimidine obtained by the treatment of the secondary amine salt with dilute alkali. For details see experimental part. [c] In the case of very slow hydrogen uptake fresh catalyst was always added; generally, however this had no lasting beneficiary effect. [d] Addition of small amounts of a 5% aqueous $PdCl_2$ solution did not improve the rate or the speed of the hydrogenation.

TABLE II

HYDROGENATION OF BASIC NITRILES

Nitrile	Product	B. p., °C. (mm.)	M. p., °C.	Yield, %	Reduction time, min.	Batch size, mole	Average pressure, lb.	Amount of catalyst, g.
2-Methyl-4-aminopyrimidine-5-nitrile[7]	2-Methyl-4-amino-5-aminomethylpyrimidine.[7] As Dihydrochloride.		262, dec.	93.3	80	2.0	125	50
	Di-(2-methyl-4-amino-5-pyrimethyl) amine.[a]			4.2	80	2.0	125	50

4-Diethylaminobutyronitrile[11]	4-Diethylamino-butylamine[12]			97	65	2.0	100	55
	Di-(4-diethylaminobutyl)-amine			2	65	2.0	100	55
Furan-2-nitrile[b]	2-Furyl-methylamine	49–50 (10)		84	76	1.0	125	45
	Di-(2-furylmethyl)-amine	126–28 (10)		11	76	1.0	125	45

[a] Determined as 2-methyl-4-amino-5-oxymethylpyrimidine. [b] Although not a basic nitrile, this method gave excellent yields of the primary amine which were considerably in excess of those reported in the literature.[5,13]

batches being from thirty to eighty minutes. Compounds hydrogenated include pyrimidine, piperidine, pyridine, thiazole, furan and aliphatic basic nitriles. In each reduction the corresponding primary amine was obtained in excellent yields. A summary of the results is found in Table II. The description of the apparatus and a detailed procedure are given in the experimental part.

It is believed that in the preparation of primary amines from basic nitriles in general and from heterocyclic basic nitriles in particular the hydrogenation with Raney nickel in the presence of ammonia will often suggest itself as the method of choice.

Experimental

Apparatus.—The reduction vessel was an ordinary steel cylinder, 9 × 6 inches with rounded bottom and flanged top with lead gasket. A pressure gage and an inlet valve were welded onto the side wall of the vessel, the valve being connected with a copper spiral to a hydrogen tank. The necessary agitation was provided by a Schaerr type shaker into which the reduction vessel was placed. The total capacity of the vessel was 4 liters. After calibration the hydrogen consumption was measured by the pressure drop as indicated by the pressure gage. The copper spiral between reduction vessel and hydrogen tank was made flexible enough to stay on during the shaking to facilitate quick recharging in cases where the size of the batch required hydrogen in excess of the volume available.

Method.—Average pressures as given in Table II were calculated as the mean between highest and lowest pressure

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

as indicated by the side wall gage. For example, if the pressure at the beginning of the hydrogenation was 200 lb./sq. in. and dropped during the course of the reduction to 150 lb./sq. in., to be recharged then to 200 lb./sq. in. again, the average pressure was taken as 175 lb./sq. in.

The Raney nickel was prepared according to the method of Covert and Adkins.[14] The catalyst was washed with water till free of alkali, the water replaced by methanol and the catalyst kept under methanol till ready for use. In none of the experiments had the Raney nickel been stored for more than three weeks. Although the same catalyst can be used several times, it is better to use fresh Raney nickel each time in order to insure a good reduction speed.

The hydrogen was the ordinary commercial product which gave satisfactory results without purification.

The nitriles, prepared according to the literature, were purified until their physical characteristics were constant.

In a typical experiment anhydrous ammonia (4 moles) was incorporated with cooling into anhydrous methanol (35 moles) and the solution filled into the reduction vessel. Nitrile (1 mole) and Raney nickel (1.5 moles)[15] were then added with final attachment of gasket and flange to give a pressure tight seal. The size of the reaction vessel and the volume of the charge were adjusted so that a pressure drop of 50 lb. was equivalent to an uptake of 0.33 mole of hydrogen. The vessel was charged with hydrogen to the maximum pressure necessary and shaking started thereafter. After the uptake of hydrogen equivalent to a 50 lb. pressure drop, fresh hydrogen was charged up to the initial pressure level. This operation was repeated until the calculated amount of hydrogen had been consumed. In all the experiments in this study the hydrogenation stopped after two moles of hydrogen had been consumed, indicating that reduction under these conditions is limited to the nitrile group. The spent catalyst was removed by filtration, washed with methanol and the filtrate decolorized with charcoal, if necessary. After removal of the solvent the residue was freed from unchanged nitrile, if any, and the primary amine purified by distillation, recrystallization, or via its salts. Secondary amine, when present, was isolated by fractional distillation or crystallization.

N-Benzyl-4-phenyl-4-(aminomethyl)-piperidine.—One hundred thirty-one grams of N-benzyl-4-phenylpiperidine-4-nitrile[16] in 560 cc. of methanol containing 34 g. of anhydrous ammonia and 29 g. of Raney nickel took up the calculated amount of hydrogen in ninety minutes at an average pressure of 125 lb./sq. in. From the oily residue, obtained after removal of the solvent, N-benzyl-4-phenyl-4-(aminomethyl)-piperidine was secured by vacuum distillation; b. p. 224–26° (1 mm.); yield, 121 g. or 91%; m. p. 71–72°.

Anal. Calcd. for $C_{19}H_{24}N_2$: N, 10.00. Found: N, 9.84.

On titration the base consumed two moles of hydrochloric acid. The dihydrochloride was recrystallized from acetone–ethanol; m. p. 202–204° (dec.).

Anal. Calcd. for $C_{19}H_{24}N_2Cl_2$: Cl, 20.11. Found: Cl, 19.68.

The dipicrate melts at 229–30°.

Di-(2-methyl-4-amino-5-pyrimethyl)-amine.—Seven grams of 2-methyl-4-aminopyrimidine-5-nitrile was dissolved in 150 cc. of water containing two mols of hydrochloric acid and 100 mg. of moderately active palladized charcoal. The reduction was performed in a Parr–Burgess hydrogenator and the theoretical amount of hydrogen had been taken up after sixteen hours of shaking at room temperature under a pressure of 60 lb./sq. in. After removal of the catalyst, the filtrate was concentrated to a small volume and the reduction product precipitated with excess ethanol containing some hydrochloric acid. The di-(2-methyl-4-amino-5-pyrimethyl)-amine tetrahydrochloride thus obtained was purified by recrystallization from 85% ethanol. Small amounts of 2-methyl-4-amino-5-aminomethylpyrimidine dihydrochloride which were present stayed in solution due to the greater solubility of this compound in 85% ethanol. The tetrahydrochloride melted at 357° (dec.).

Anal. Calcd. for $C_{12}H_{21}N_7Cl_4$: N, 24.19; Cl, 35.06. Found: N, 24.25; Cl, 35.20.

The picrate as obtained from the hydrochloride crystallizes from water; m. p. 269–70° dec.

The free secondary amine is unstable. Even on addition of the calculated amount of dilute alkali to a chilled solution of the tetrahydrochloride the carbon–nitrogen bond is broken with evolution of ammonia and formation of 2-methyl-4-amino-5-hydroxymethylpyrimidine. The latter proved to be identical in all respects with an authentic sample prepared according to the literature.[17] Table III shows the respective data of the two specimens and their derivatives. This instability of the carbon–nitrogen linkage to hydrolysis is not uncommon[18] and accounts also for the fact that the small amounts of di-(2-methyl-4-amino-5-pyrimethyl)-amine formed during the reduction of 2-methyl-4-aminopyrimidine-5-nitrile with Raney nickel in the presence of ammonia are often not found as such but in the form of 2-methyl-4-amino-5-(hydroxymethyl)-pyrimidine.

TABLE III

	M. p., °C.	M. p. (lit.), °C.	Mixed m. p., °C.
Alcohol	192–193	194	191–193
Hydrochloride	220–222	224	223–224
Picrate	194–195	194–196	194–196

Anal. Calcd. for $C_6H_{10}ON_3Cl$: N, 23.93; Cl, 20.22. Found: N, 23.76; Cl, 20.37.

Di-(4-diethylaminobutyl)-amine.—This secondary amine was obtained by vacuum fractionation of the still foots from the preparation of 4-diethylaminobutylamine. If the primary amine is prepared by the reduction of the corresponding nitrile with Raney nickel in the presence of ammonia the amount of secondary amine does not usually exceed 2–3%; b. p. 125–26° (2 mm.).

Anal. Calcd. for $C_{16}H_{37}N_3$: N, 15.49. Found: N, 15.36.

The hydrochloride as obtained with ethanolic hydrogen chloride and precipitated with ether is very hygroscopic and cannot be conveniently purified.

A crystalline, non-hygroscopic picrate was obtained from an alcoholic solution of the base with alcoholic picric acid in the presence of two moles of hydrochloric acid, m. p. 90–93°.

Anal. Calcd. for $C_{24}H_{43}O_{14}N_9$: C, 42.27; H, 6.36. Found: C, 42.51; H, 6.19.

Summary

Basic nitriles cannot be hydrogenated to the

corresponding primary amines in good yields by methods involving the use of acidic solvents and palladium or platinum type catalysts.

The hydrogenation with Raney nickel in the presence of ammonia, however, results in the formation of primary amines in nearly quantitative yields. Compounds hydrogenated include pyrimidine, piperidine, pyridine, thiazole and aliphatic basic nitriles.

Tris-(hydroxymethyl)-aminomethane Derivatives. I. Polyhydroxyamines[1,2]

BY J. STANTON PIERCE AND JOHN WOTIZ[3]

Polyfunctional compounds are of particular interest as they afford opportunities for the synthesis of substances with varied properties, many of which are of practical importance. The ethanolamines have been found to be particularly useful, due to their solubility properties, ease of preparation and low cost. A large and interesting field for the synthesis of more highly polar amino alcohols than the ethanolamines was opened by the recent commercial synthesis of tris-(hydroxymethyl)-aminomethane, $(HOCH_2)_3CNH_2$,[4] (A). In 1897, Piloty and Ruff[5] prepared (A) by the reduction of tris-(hydroxymethyl)-nitromethane which had been prepared two years previously by Henry,[6] by the reaction of nitromethane and formaldehyde.

Various investigators have combined two primary or secondary amino groups by reaction with epichlorohydrin,[7] α,ω-dihalohydrins[8] or α,ω-dihalogenalkanes.[9] This paper takes up the synthesis of polyhydroxyamines by the union of two molecules of (A), mainly through methylene or methylene and hydroxymethylene groups, by the union of (A) with other amino alcohols through methylene and hydroxymethylene groups, and by the alkylation of (A) with chlorohydrins. A subsequent paper will take up the preparation of alkyl and alkaryl derivatives of (A).

The symmetrical polyhydroxydisecondary amines described in this paper usually were prepared by heating (A) with an α,ω-dihalide, in most cases the bromide. The reactions were carried out under reflux, with no solvent or with alcohol as solvent, and in sealed tubes, with alcohol as solvent. The asymmetrical diamines, all of which are derivatives of 2-propanol, were prepared by treating a secondary amine with epichlorohydrin at a temperature not exceeding 30° and by the reaction of the product thus formed with (A) at elevated temperature, with alcohol as solvent. Also, two molecules of (A) reacted with epichlorohydrin, to form a symmetrical derivative. Monoalkylation products of (A) were prepared by reaction with halohydrins.

The greatest difficulty in the preparation of the polyhydroxyamines described in this paper was their isolation and purification. Since the free bases, as obtained, showed no tendency to crystallize, they were converted to hydrobromides or hydrochlorides for identification and analysis. A typical mixture in the preparation of a symmetrical disecondary amine likely contained dihalide, (A), the monoalkylation product of (A) and the desired disecondary amine, the latter three compounds being present both as the free bases and as the halogen acid salts. Usually, excess halogen acid was added to convert all of the free bases to their salts. The unreacted alkylene dihalide was removed by evaporation or extraction with ether. Finally, purification was effected by fractional crystallization or by selective extraction with two solvents, evaporation of the solvent, if necessary, and trituration of the oily residue with alcohol or acetone or a mixture of the two solvents. Since this purification involved so much loss of material, the yield is given only in the case of 1,3-bis-[tris-(hydroxymethyl)-methylamino]-2-propanol, the compound which was studied most fully.

The polyhydroxyamines described in this paper are characterized by their very high water solubility, both as the free bases and in the form of their salts with hydrochloric or hydrobromic acid. Some of these derivatives of (A) have a great tendency to hold ferric hydroxide, bismuth hydroxide and some other metallic hydroxides in solution. The solubilizing action of the derivatives of (A) is being studied with the view to technical and pharmaceutical applications and will be reported elsewhere. Each of these compounds has one or two secondary amino groups. The high proportion of hydroxyl groups and likely their spatial arrangement makes difficult some of the reactions

of amino nitrogens. However, in some cases it is possible to get an amino group to react and a study is being made to utilize these polyhydroxyamines for the preparation of various polyfunctional compounds.

Experimental

1,3-Bis-[-tris-(hydroxymethyl)-methylamino]-propane Dihydrobromide, $(HOCH_2)_3CNHCH_2CH_2CH_2NHC(CH_2OH)_3 \cdot 2HBr$.—A solution of 24 g. of (A) (0.2 mole) and 10 g. of trimethylene bromide (0.05 mole) in 150 ml. of alcohol was heated under reflux on a water-bath for six hours. On standing overnight, needle-like crystals of (A)·HBr were formed. These crystals were filtered off and the filtrate was made distinctly acidic with hydrobromic acid. The acidic solution was evaporated to low volume to remove most of the water. The gummy residue was dissolved in hot absolute alcohol and the solution was treated with an equal volume of anhydrous acetone. Two layers were formed. The lower layer was separated and triturated with a mixture of equal volumes of absolute alcohol and anhydrous acetone, until crystalline. The solid, 1,3-bis-[tris-(hydroxymethyl)-methylamino]-propane dihydrobromide, on three recrystallizations from alcohol, melted at 170–171°.

1,2-Bis-[tris-(hydroxymethyl)-methylamino]-ethane Dihydrobromide, $(HOCH_2)_3CNHCH_2CH_2NHC(CH_2OH)_3 \cdot 2HBr$.—This product was made and purified by practically the same procedure as the compound above.

1,6-Bis-[tris-(hydroxymethyl)-methylamino]-hexane Dihydrobromide, $(HOCH_2)_3CNH(CH_2)_6NHC(CH_2OH)_3 \cdot 2HBr$.—A mixture of 48.4 g. of (A) (0.4 mole) and 24.4 g. of hexamethylene bromide (0.1 mole) was refluxed with mechanical stirring until a homogeneous mixture was obtained. The brown glue thus formed was dissolved by refluxing with 300 ml. of 95% alcohol. The alcoholic solution was made strongly acidic with hydrobromic acid and most of the alcohol was evaporated. The residue was treated with absolute alcohol and anhydrous acetone to yield crystals of impure (A)·HBr, melting at 128–132°. The filtrate was treated with three volumes of anhydrous acetone. An oily layer was formed. This lower layer was triturated with absolute alcohol and anhydrous acetone, yielding a solid melting at 150–155°. On recrystallization from 95% alcohol and anhydrous acetone, the product melted at 160.5–162°.

1,3-Bis-[tris-(hydroxymethyl)-methylamino]-2-propanol Dihydrochloride, $(HOCH_2)_3CNHCH_2CHOHCH_2NHC(CH_2OH)_3 \cdot 2HCl$.—Glyceroldichlorohydrin was heated with two molar quantities of (A) at 100° for three hours with no solvent and with frequent stirring. The yellow glue formed was dissolved in hot alcohol and the solution was acidified with hydrochloric acid. The precipitate which formed, on cooling, was recrystallized from aqueous alcohol.

Better results were obtained by the following procedure: 242 g. of (A) (2.0 moles) and 92.5 g. of epichlorohydrin (1.0 mole) were mixed with 200 ml. of alcohol and heated on a boiling water-bath under reflux for five hours. The viscous brown liquid was treated with 100 ml. (appreciable excess) of concentrated hydrochloric acid, with stirring. The reaction mixture was cooled and filtered with suction. On one recrystallization from an alcohol–water solution, there was obtained 190 g. (51%) of the dihydrochloride of 1,3-bis-[tris-(hydroxymethyl)-methylamino]-2-propanol, m. p. 185–187°.

1,3-Bis-[tris-(hydroxymethyl)-methylamino]-2-propanol, $(HOCH_2)_3CNHCH_2CHOHCH_2NHC(CH_2OH)_3$.—The free base, mixed with a little sodium chloride, was prepared by treatment of the dihydrochloride, in methyl alcohol, with the calculated quantity of sodium methylate, refluxing, filtering and evaporating the methyl alcohol solution. Also, the free base, free of inorganic impurities, was obtained from the dihydrochloride by prolonged heating of an aqueous solution with excess silver carbonate, removal of dissolved silver with hydrogen sulfide and removal of colored impurities by repeated solution in absolute alcohol and treatment with anhydrous acetone. Finally, by evaporation of the oily lower layer, the free base was obtained as an oil. Calcd. for $C_{11}H_{27}O_7N_2$: nitrogen, 9.40. Found: N, 9.41.

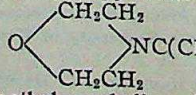
1-Diethanolamino-3-tris-(hydroxymethyl)-methylamino-2-propanol Dihydrochloride, $(HOCH_2CH_2)_2NCH_2CHOHCH_2NHC(CH_2OH)_3 \cdot 2HCl$.—A mixture of 10.5 g. of diethanolamine (0.1 mole) and 9.5 g. of epichlorohydrin (0.1 mole) was stirred well, the temperature being kept around 30°. After the initial exothermic reaction ceased, the mixture was left overnight at room temperature. The clear viscous liquid was extracted with ether. The ether insoluble product was added to 12 g. of (A) (0.1 mole) and 50 ml. of alcohol and the mixture was heated under reflux for six hours on a water-bath. The reaction mixture was acidified with concentrated hydrochloric acid. An oil was thrown out by the addition of absolute alcohol, acetone and ether. This oil was converted to a semi-solid by solution in aqueous alcohol, treatment with anhydrous acetone and by allowing the lower layer, after evaporation, to stand in a vacuum desiccator. Finally, purification was effected by extraction with hot absolute alcohol.

1,3-Di-(diethanolamino)-2-propanol Dihydrochloride, $(HOCH_2CH_2)_2NCH_2CHOHCH_2N(CH_2CH_2OH)_2 \cdot 2HCl$.—The condensation product of diethanolamine and epichlorohydrin was prepared to compare it with the product formed by the reaction of epichlorohydrin with one molecule each of diethanolamine and (A).

10.5 g. of diethanolamine (0.1 mole) and 9.3 g. of epichlorohydrin (0.1 mole) were mixed by shaking and cooling below 30°. After the exothermic reaction ceased, a clear viscous liquid resulted. An additional 10.5 g. of diethanolamine was added and the liquid was heated on a water-bath for eight hours. The product then was acidified with concentrated hydrochloric acid and was extracted with acetone. The lower layer was recrystallized from absolute alcohol.

1-Ethylethanolamino-3-tris-(hydroxymethyl)-methylamino-2-propanol Dihydrochloride, $HOCH_2CH_2(C_2H_5)NCH_2CHOHCH_2NHC(CH_2OH)_3 \cdot 2HCl$.—Ethylaminoethanol was treated with an equimolar quantity of epichlorohydrin at a temperature below 30°. After the exothermic reaction ceased, the viscous liquid was left at room temperature overnight. The condensation product thus formed was heated with an equimolar amount of (A) for eight hours on a water-bath and the mixture was acidified with hydrochloric acid. Repeated attempts to recrystallize from alcohol failed to yield a solid but the light pink colored glue analyzed satisfactorily.

γ,γ′-Bis-[tris-(hydroxymethyl)-methylamino]-propyl Ether Dihydrochloride, $(HOCH_2)_3CNHCH_2CH_2CH_2OCH_2CH_2CH_2NHC(CH_2OH)_3 \cdot 2HCl$.—A mixture of 17 g. of γ,γ′-dichloropropyl ether (0.1 mole) and 24 g. of (A) (0.2 mole) in 100 ml. of alcohol was heated in a sealed tube overnight at 110°. The alcoholic solution was acidified with hydrochloric acid and the precipitated (A)·HCl was filtered off. Repeated evaporations, solution in absolute alcohol, treatments with anhydrous acetone and finally treatments with anhydrous ether were necessary to remove all of the (A)·HCl. The oil finally obtained analyzed slightly low for γ,γ′-bis-[tris-(hydroxymethyl)-methylamino]-propyl ether dihydrochloride.



$NC(CH_2OH)_3 \cdot HCl$, **4-Tris-(hydroxymethyl)-methylmorpholine Hydrochloride.**—Fourteen grams of β,β′-dichloroethyl ether (0.1 mole) and 24 g. of (A) (0.2 mole) were heated with 100 ml. of alcohol in a sealed tube overnight at 150°. On cooling, snow-white crystals of (A)·HCl were formed. The crystals were filtered off and the filtrate was acidified with hydrochloric acid. On partial evaporation, a solid was obtained. On recrystallization from alcohol, the 4-tris-(hydroxymethyl)-methylmorpholine hydrochloride melted at 184–185°. Calcd. for $C_8H_{18}O_4NCl$: Cl, 15.57. Found: Cl, 15.59.

A further concentration of the original filtrate yielded other crops of crystals, likely mainly (A)·HCl, judging

from the melting points. No β,β'-bis-[tris-(hydroxymethyl)-methylamino]-ethyl ether was isolated.

1,2-Dihydroxy-3-tris-(hydroxymethyl)-methylaminopropane Hydrochloride, $HOCH_2CHOHCH_2NHC(CH_2OH)_3\cdot HCl$.—A mixture of 24 g. of (A) (0.2 mole) and 11 g. of glycerol monochlorohydrin (0.1 mole) was heated under reflux with 50 ml. of alcohol for five hours. The resulting liquid was acidified with hydrochloric acid, while hot. On cooling, crystals of (A)·HCl were obtained and filtered off. More (A)·HCl was obtained by concentration of the filtrate and treatment with dry acetone. This process was repeated until no crystals were obtained. The solution then was concentrated to a sirup which was completely miscible with absolute alcohol and dry acetone. The sirup, while hot, was placed in a vacuum desiccator. After two days of drying, a satisfactory analysis for chloride was obtained.

Similar procedures were used for the reaction of ethylene chlorohydrin and trimethylene bromohydrin with (A) and for purification of the products formed.

Summary

A series of highly polar polyhydroxyamines have been made from tris-(hydroxymethyl)-aminomethane.

RICHMOND, VA. RECEIVED JANUARY 18, 1944

The Cleavage of (Dialkylvinyl)-alkylcyanoacetic Esters by Sodium Alkoxides[1]

BY ELIZABETH M. OSMAN AND ARTHUR C. COPE

More or less extensive cleavage of (dialkylvinyl)-alkylcyanoacetic esters to unsaturated nitriles has been observed to occur as a side reaction during condensation of the esters with urea in the presence of sodium alkoxides.[2] This paper reports an investigation of the cleavage reaction, and its use in the preparation of certain α,β-unsaturated nitriles. The hydrolysis of the nitriles to acids has also been studied.

The products of cleavage are ethyl carbonate and an α,β-unsaturated nitrile

$$R''CH{=}C(R')\underset{R}{\overset{CN}{\underset{|}{C}}}\underset{I}{\overset{}{}}COOC_2H_5 + C_2H_5OH \xrightarrow{NaOC_2H_5} CO(OC_2H_5)_2 + R''CH_2C(R'){=}C(R)CN$$

Similar cleavage of other cyanoacetic and malonic ester derivatives has been observed by several investigators.[3] The reaction proceeds readily at moderate temperature with disubstituted esters such as I which contain an α,β-unsaturated (electron attracting, or negative) group. Malonic ester derivatives which are not labilized by electron attracting substituents are cleaved in a similar manner at higher temperatures.[3c]

Kandiah and Linstead[4] have proposed a reaction mechanism for the cleavage in which the carbethoxyl group is removed by combination with ethoxide ion as ethyl carbonate, forming the anion of the nitrile. This ion acquires a proton from the solvent alcohol, producing the nitrile and reforming ethoxide ion. α,β- and β,γ-unsaturated nitriles are equilibrated rapidly in the presence of sodium ethoxide,[4] so that

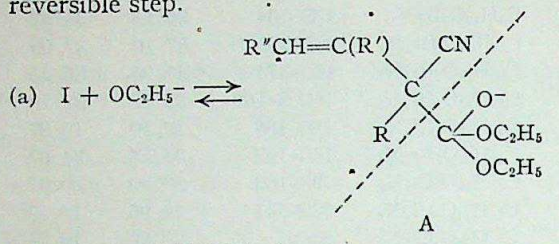
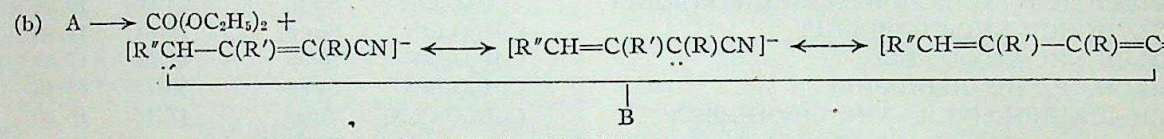
either form or an equilibrium mixture can be the final product. Our results are in accord with this mechanism, which we would expand to include the addition of ethoxide ion as a discrete, reversible step.



(a) $I + OC_2H_5^- \rightleftharpoons A$



(b) $A \longrightarrow CO(OC_2H_5)_2 + [R''CH{-}C(R')=C(R)CN]^- \longleftrightarrow [R''CH=C(R')C(R)CN]^- \longleftrightarrow [R''CH=C(R')-C(R)=C=N:]^-$

B

(c) $B + C_2H_5OH \longrightarrow OC_2H_5^- + R''CH_2C(R')=C(R)CN$

The relative ease with which a number of ethyl (dialkylvinyl)-alkylcyanoacetates are cleaved was determined as follows. The esters (Table I, also ref. 5) were treated with a molecular equivalent of sodium ethoxide in absolute alcohol for one-half hour at a constant temperature. Temperatures were chosen at which partial cleavage occurred. The extent of the reaction was determined in each case by fractional distillation and determination of the yield of ethyl carbonate, unsaturated nitrile, and recovered ester. The data obtained are summarized in Table II.

The susceptibility to cleavage of four esters with the structure $C_2H_5CH=C(CH_3)C(R)(CN)COOC_2H_5$ decreased in the following order: R = methyl > ethyl and *n*-propyl > isopropyl (esters 2, 7, 8 and 9, Table II). This is the order of increasing size and capacity for electron release of the alkyl groups. The relative rates of cleavage of six esters in which R in general formula I was methyl, while the substituted vinyl group was varied, were also determined (esters 1 to 6, Table II). All of these esters were cleaved to a similar extent, 35 to 49%, on treatment with one molar equivalent of alcoholic sodium ethoxide at 30° for thirty minutes.

The reason for the unusual ease with which (substituted vinyl)-alkylcyanoacetic esters are cleaved, according to the sequence of reactions outlined above, is the electron attraction of the substituted vinyl group. Esters are known to undergo ester interchange (step a) in the presence of sodium alkoxides. In this case the intermediate adduct, A, contains the electron attracting nitrile and substituted vinyl groups, while the carbethoxyl group has acquired an integral negative charge from the ethoxide ion and has become electron repelling. If the central methylene carbon atom acquires the electron pair corresponding to the bond at the point of the dotted line in formula A as a result of these forces, ethyl carbonate is formed and process (b) is completed. The normal reaction under mild conditions for esters in which the α-carbon atom is not attached to electron attracting groups is the reversal of (a). Large or branched alkyl groups on the central methylene carbon atom (R in formula I) would be expected to slow the cleavage by steric hindrance to the addition step (a), and by electron release opposed to the cleavage step (b). Modification of R′ and R″ would produce relatively minor effects, since the influence of the substituted vinyl group is due primarily to its unsaturation.

Much more drastic conditions were required to produce partial cleavage of similarly substituted malonic ester and malononitrile derivatives (10 and 11, Table II). Treatment with an equivalent quantity of alcoholic sodium ethoxide for thirty hours at 80° resulted in approximately 30% cleavage of the malonate, while the malononitrile was cleaved to the extent of 50% in one hundred and twenty hours at about 90°. The relatively slow cleavage of the malonate (10) compared to the corresponding cyanoacetate (1) is explained by the fact that the carbethoxyl is less electron attracting than the nitrile group. Consequently, there is less tendency for the cleavage step (b) to occur in the malonic ester series. The substituted malononitrile (11) apparently is converted by addition of an ethoxide ion into an iminoether derivative, $CH_3CH=C(C_2H_5)C(CH_3)(CN)C(OC_2H_5)=NH$, which resists cleavage.

The cleavage of alkyl (1-methyl-1-butenyl)-ethylcyanoacetates, $C_2H_5CH=C(CH_3)C(C_2H_5)(CN)COOR$, by solutions of sodium in methyl, ethyl, isopropyl and *n*-butyl alcohols was also investigated, to determine the relation of the nature of the alkoxide ion to the rate of cleavage. The data obtained are listed in Table III. The cleavages proceeded at approximately equal rates in each of the alcohols except methanol. Cleavage was somewhat slower in methyl alcohol, and it was possible to convert the ethyl ester into the methyl ester by treatment with sodium methoxide in methyl alcohol at a temperature (50°) too low to produce cleavage. Previous investigation[5] of the alkylation of alkylidene cyanoacetic esters has shown that much poorer yields are obtained when the esters are converted into their enolates by sodium methoxide in methyl alcohol than when sodium ethoxide or sodium isopropoxide is employed. According to the present results, the defects of methanol as an alkylation medium cannot be explained by rapid cleavage of the products by methoxide ion. They probably are due to the higher acidity of methyl alcohol, which could lead to an unfavorable

Completion of the cleavage of (substituted vinyl)-alkylcyanoacetic esters by refluxing with alcoholic sodium ethoxide affords a good synthesis for certain α,β-unsaturated nitriles. The properties of a number of nitriles which were prepared by this method are summarized in Table IV. An equilibrium mixture of α,β- and β,γ-unsaturated nitriles should be formed under the conditions of cleavage. The exaltation in molecular refraction of each of the nitriles, and the results of ozonization of two of them (outlined in the Experimental Part) indicate that they are very largely or completely in the α,β-unsaturated form.

The inert character and in particular the resistance to hydrolysis of conjugated unsaturated nitriles has been noted by many investigators.[3b,6] It was found to be possible to hydrolyze the nitriles listed in Table IV by employing drastic conditions. The nitriles were refluxed for forty-eight hours with a solution of potassium hydroxide in diethylene glycol containing a small amount of water. Unsaturated acids were obtained in this manner in yields of 49 to 81% (Table V). The available evidence (see the Experimental Part) indicates that the acids obtained were mixtures of the α,β- and β,γ-unsaturated isomers. The conditions of hydrolysis favor the establishment of equilibrium between the two forms.

One reaction in addition to hydrolysis which was completed successfully with 2-ethyl-3-methyl-2-hexenenitrile was conversion into the amidine by reaction with sodamide. The amidine was not very stable, and decomposed on standing into ammonia and the original nitrile. It was characterized by analysis and conversion into the picrate.

Experimental Part[7]

Substituted Vinylalkylcyanoacetic Esters.—Alkylidene cyanoacetic esters were prepared by the methods described recently.[8] They were alkylated in the alcohol corresponding to the ester alkoxyl group, to prevent ester interchange, by a general procedure previously employed for preparing homologous esters.[5] The yields and properties of esters not previously described in ref. 5 are recorded in Table I.

(1-Ethylpropenyl)-methylmalononitrile.—1-Ethylpropylidene malononitrile (40.2 g.) was added to a solution of 6.9 g. of sodium in 300 cc. of dry isopropyl alcohol and treated with 51 g. of methyl iodide under conditions used for synthesis of the ethyl homolog.[9] After purification by distillation, shaking with sodium bisulfite solution and redistillation, the alkylation product was obtained in yield of 41.6 g. (93%); b. p. 105–108° (17–18 mm.); $n^{25}D$ 1.4458; d^{25}_{25} 0.9182; MD calcd. 42.95; found 43.15.

Anal. Calcd. for $C_8H_{12}N_2$: N, 18.90. Found: N, 18.83.

Cleavages in Ethyl Alcohol: Substituted Vinylalkylcyanoacetic Esters.—Each of the esters was treated with an equivalent quantity of sodium ethoxide in alcohol solution for exactly thirty minutes at 30, 50, or 80 ± 2°. The data in Table II show the extent of cleavage in each case. The following typical example is cited to illustrate the experimental procedure.

Sodium (4.6 g., 0.2 mole) was dissolved in 100 cc. of absolute alcohol in a 500-cc. three-necked flask equipped with a stirrer, a reflux condenser connected through a drying tube to a source of nitrogen, a dropping funnel and a thermometer. A nitrogen atmosphere under slight positive pressure was maintained throughout the reaction. The solution of sodium ethoxide was cooled to 30°, and ethyl (1-methyl-1-hexenyl)-methylcyanoacetate (44.7 g., 0.2 mole) was forced into the flask from the dropping funnel. The mixture was stirred at 30 ± 2° for thirty minutes, and then poured, with stirring, into a mixture of 40 cc. of 6 *N* hydrochloric acid and 100 g. of ice. The non-aqueous layer was removed, and the aqueous layer was extracted with three 50-cc. portions of benzene, which were combined with the non-aqueous layer and washed once with 30 cc. of water. The benzene was distilled through a small Widmer column at atmospheric pressure, and the residue was fractionated slowly and carefully through the column. The following fractions were separated: 3.5 g., b. p. 90–112°, $n^{25}D$ 1.4080; 2.2 g. (9.3%) of ethyl carbonate, b. p. 112–115°, $n^{25}D$ 1.3842; 1.3 g. of intermediate (5.5% calculated as ethyl carbonate), b. p. 115 (atm. p.)–100° (14 mm.), $n^{25}D$ 1.3969; 9.9 g. (32.7%) of 2,3-dimethyl-2-octenenitrile, b. p. 100–110° (14 mm.), $n^{25}D$ 1.4521; 1.3 g. intermediate (4.3% calculated as nitrile), b. p. 110–125° (13 mm.), $n^{25}D$ 1.4510; 23.9 g. (53.7%) of the original ester, b. p. 125–133° (11 mm.), $n^{25}D$ 1.4484; 3.0 g. (6.7% calculated as recovered ester) obtained by evacuating the column to a pressure of 1 mm., $n^{25}D$ 1.4512. The object of the distillation was to provide as accurate an analysis as possible of the reaction mixture; physical properties of the pure esters and nitriles are recorded elsewhere (ref. 5 and Table I and IV). The same molar concentrations of reactants were employed in each cleavage.

Ethyl (1-Methyl-1-propenyl)-methylmalonate.—This ester[10] was treated with a molecular equivalent of alcoholic sodium ethoxide for thirty minutes in the manner outlined

[a] A related malonic ester and malononitrile derivative are included in the table. [b] The first figures in each case represent the purest fraction, while the figures in parentheses include the intermediate fractions in the manner indicated in the detailed example in the Experimental Part. [c] Average from two similar cleavages in which the deviation in yield averaged 4% and the extreme deviation was 7%.

above at temperatures of 30, 50 and 80°, and also for five hours at 80°. In each case no monocarboxylic ester could be isolated, and 84 to 98% of the original ester was recovered. When the reaction mixture was kept at 80° for thirty hours, partial cleavage occurred as indicated in Table II. In order to identify the cleavage product, the fractions resulting from partial cleavage were combined and refluxed with alcoholic sodium ethoxide for seven days. This treatment resulted in complete cleavage. The properties of the monocarboxylic ester fraction were: b. p. 69–75° (16 mm.); $n^{25}D$ 1.4355. This index of refraction lies between the values ($n^{20}D$) of 1.4453 and 1.4298 given by Kon, Linstead and Maclennan[11] for ethyl 2,3-dimethyl-2-pentenoate and ethyl 2,3-dimethyl-3-pentenoate, respectively. An equilibrium mixture of these two esters should be formed in the presence of sodium ethoxide.

(1-Ethyl-1-propenyl)-methylmalononitrile.—No appreciable cleavage resulted from treatment of this malononitrile derivative (0.2 mole) with an equivalent quantity of alcoholic sodium ethoxide for thirty hours at 80°. Approximately 25% of the malononitrile derivative was recovered, while a higher boiling fraction was obtained, which according to analytical evidence was composed principally of $CH_3CH{=}C(C_2H_5)C(CH_3)(CN)C(OC_2H_5){=}NH$, the corresponding imino-ether (25 g., 64% calculated as the imino-ether, b. p. 120–129° (16 mm.), $n^{25}D$ 1.4560). Repetition of this experiment with a reaction time of one hundred and twenty hours at the boiling point (which dropped from 94 to 87° during this time) gave 50% cleavage to 3-ethyl-2-methyl-2-pentenenitrile, as indicated in Table II. Nitrogen and ethoxyl determinations on the higher boiling fraction were in accord with values for a mixture of the malononitrile derivative, the imino-ether formulated above, and the cyanoacetic ester derivative which could be formed from the latter in the process of isolation.[12]

(11) Kon, Linstead and Maclennan, *J. Chem. Soc.*, 2459 (1932).

(12) Similar mixtures have been obtained previously by reaction of malononitrile derivatives with sodium alkoxides; see ref. 9 and references cited therein.

Cleavages in Methyl, Isopropyl and *n*-Butyl Alcohols.—Ethyl (1-methyl-1-butenyl)-ethylcyanoacetate (0.2 mole) was added to a solution of 4.6 g. of sodium in 200 cc. of each of the anhydrous alcohols named above, and allowed to react for exactly thirty minutes at a constant temperature. More dilute solutions were employed than in the cleavages in ethyl alcohol in order to avoid crystallization of the least soluble sodium alkoxides. The cleavage of

[a] By the semi-micro Kjeldahl method unless otherwise indicated. The reason for the consistently low values is believed to be the stability and volatility of the compounds. [b] Micro-Dumas analysis by the Arlington Laboratories. Kjeldahl analyses were low.

this ester with sodium ethoxide in ethyl alcohol was repeated at the same concentration in order to obtain directly comparable data. In isolating the products, the reaction mixtures were poured into 40 cc. of 6 *N* hydrochloric acid and 200 g. of ice. After adding 200 cc. of water, the non-aqueous layer was separated and the aqueous layer was extracted with three 80-cc. portions of benzene. Two 40-cc. portions of sodium chloride solution were used to wash the combined extracts. Otherwise, the conditions of reaction and the method of separating the products corresponded to the procedure outlined for cleavages in ethyl alcohol. The corresponding isopropyl ester was also subjected to cleavage in ethyl and isopropyl alcohol under these conditions, and the methyl ester was treated with sodium methoxide in methyl alcohol, in order to determine the effect of the ester alkoxyl group on the rate of cleavage. Table III contains the data obtained. The yields of alkyl carbonates are not included, since mixtures were formed in the instances where the ester and alcohol alkoxyl groups were different.

A cleavage of the ethyl ester in methyl alcohol in which the quantities and concentrations of the reactants cited above were used was completed by refluxing the mixture for eight hours. The yield of 2-ethyl-3-methyl-2-hexenenitrile was 24.1 g. (88%).

Preparation and Characterization of Nitriles Produced by Cleavage.—The nitriles which are described in Table IV were prepared by completing the cleavages summarized in Table II. The products of partial cleavage were combined with any of the ester which was available and refluxed with an equivalent quantity or slight excess of sodium ethoxide in absolute alcohol for one to five hours. For example: sodium (10 g., 0.43 mole) was dissolved in 200 cc. of absolute alcohol. Ethyl (1,3-dimethyl-1-butenyl)-methylcyanoacetate (44 g., 0.2 mole) and the products from partial cleavage of 0.2 mole of this ester were added, and the solution was refluxed for one hour. The mixture was cooled, poured into ice and hydrochloric acid, extracted and distilled as described above. The yield of 2,3,5-trimethyl-2-hexenenitrile (Table IV) was 50.3 g. (89%). Yields were approximately 90% in the case of each nitrile prepared.

The carbon skeleton of 2-ethyl-3-methyl-2-hexenenitrile, chosen as representative of the nitriles listed in Table IV, was confirmed by hydrogenation followed by hydrolysis to a known derivative. The nitrile (27.4 g.) in alcohol solution absorbed a molar equivalent of hydrogen on shaking at room temperature in the presence of 1 g. of palladinized charcoal for sixty hours. After removal of the solvent, the product was washed with dilute hydrochloric acid to remove basic by-products and distilled through a small Widmer column. The yield of 2-ethyl-3-methylhexanenitrile was 16 g., b. p. 71–72° (7 mm.); $n^{25}D$ 1.4232; d^{25}_{25} 0.8181; MD calcd. 43.60, found 43.48.

Anal. Calcd. for $C_9H_{17}N$: N, 10.06. Found: N, 9.95.

The above nitrile (6.5 g.) was hydrolyzed by refluxing for twelve hours with a solution of 2.8 g. of potassium hydroxide in 40 cc. of ethylene glycol and approximately 1 cc. of water. The mixture was poured into water, extracted with ether, and separated into acidic and neutral fractions by reëxtraction with sodium hydroxide. The acid fraction on distillation yielded 1.9 g. of 2-ethyl-3-methylhexanoic acid,[30] b. p. 230°, $n^{25}D$ 1.4332. The neutral fraction was steam distilled, and yielded as a volatile fraction 0.5 g. of the original nitrile. A solid (3.6 g.) was obtained from the residue, and on recrystallization yielded 3.4 g. of 2-ethyl-3-methylhexaneamide, m. p. 96–97°.[13]

The exaltation in molecular refraction exhibited by the group of nitriles in Table IV (0.75 to 1.02 units) is good evidence that each of the compounds is α,β-unsaturated, although small amounts of the β,γ-unsaturated isomers could be present. von Auwers[14] observed exaltations of 0.9 to 1.0 for conjugated unsaturated nitriles. Two of the unsaturated nitriles were cleaved by ozonization, following a procedure outlined previously.[10] The volatile product obtained by hydrolysis of the ozonide from 2-ethyl-3-methyl-2-hexenenitrile was methyl propyl ketone, identified as the 2,4-dinitrophenylhydrazone, m. p. and mixed m. p. with a known sample 143–144°. 2,3-Dimethyl-2-pentenenitrile yielded methyl ethyl ketone, m. p. and mixed m. p. of the 2,4-dinitrophenylhydrazone with a known sample 114–115°. These ketones are the products expected from the α,β-unsaturated structures in each case.

Hydrolysis of Unsaturated Nitriles.—The nitriles listed in Table IV were hydrolyzed by a general procedure which is illustrated by the following example. 2,3-Dimethyl-2-octenenitrile (17.8 g., 0.12 mole) was added to a solution of potassium hydroxide pellets (13.4 g.) and water (2.4 cc.) in 60 cc. of diethylene glycol. The solution was boiled under reflux for forty-eight hours, cooled and diluted with 120 cc. of water. The solution was extracted three times with benzene, acidified with 60 cc. of 6 *N* hydrochloric acid, and again extracted with three 50-cc. portions of benzene. The benzene extracts of the acid solution were washed with dilute sodium chloride solution and distilled through a small Widmer column, yielding 12 g. of 2,3-dimethyloctenoic acid (Table V). The acids obtained by hydrolysis have the properties of mixtures of the α,β- and β,γ-unsaturated isomers. The indices of refraction of 2,3-dimethylpentenoic acid, 3-ethyl-2-methylpentenoic acid and 2-ethyl-3-methylhexenoic acid lie between the values reported by Kon, Linstead, *et al.*, for the pure α,β- and β,γ-unsaturated forms (see footnotes to Table V). Two of the acids, 2-methyl-3-propylhexenoic acid and 2,3,5-trimethylhexenoic acid, were ozonized. Only products derived from the β,γ-unsaturated forms of these acids could be isolated, indicating that this form probably predominated in each case. From the former the 2,4-dinitrophenylhydrazone of ethyl propyl ketone was isolated, m. p. 145–146°, and from the latter the 2,4-dinitrophenylhydrazone of methyl ethyl ketone, m. p. 110–111°.

Ethyl (1-Methylbutylidene)-acetamidine.—2-Ethyl-3-methyl-2-hexenenitrile (41.9 g.) was added slowly to a

suspension of sodamide (freshly prepared from 6.9 g. of sodium) in 100 cc. of dry boiling benzene in a 500-cc. three-necked flask, with stirring. After the exothermic reaction subsided, the mixture was refluxed for one-half hour. It was cooled to room temperature, and poured, with stirring, into 100 cc. of concd. hydrochloric acid and 100 g. of ice. The benzene layer was separated and washed with a little water, and the combined aqueous layers were washed twice with ether. The aqueous solution was covered with ether, cooled in an ice-bath and made alkaline by the slow addition from a dropping funnel of 180 cc. of 25% sodium hydroxide, with stirring. The ether layer was separated and the aqueous layer was extracted twice with small volumes of ether. The combined ether layers were washed once with water and distilled through a small Widmer column. Ethyl (1-methylbutylidene)-acetamidine was obtained in yield of 12.5–24.4 g. (27–53%); b. p. 99–101° (1 mm.); $n^{25}D$ 1.4932; d^{25}_{25} 0.9050; MD calcd. 48.68; found 49.70 (exaltation 1.02).

Anal. Calcd. for $C_9H_{18}N_2$: N, 18.16. Found: N, 18.09.

It was necessary to analyze the amidine derivative immediately after distillation, because of fairly rapid decomposition into the original nitrile and ammonia, each of which could be detected by odor. Nitrogen analyses made after three hours or more were approximately 0.5% low.

Ethyl (1-methylbutylidene)-acetamidine was converted into the picrate by reaction with an equivalent quantity of picric acid in boiling alcohol. It was precipitated by the addition of water and recrystallized from dilute alcohol; m. p. 136.5–137.5°.

Anal. Calcd. for $C_{15}H_{21}O_7N_5$: N, 18.27. Found: N, 18.14.

Summary

The cleavage of a number of (dialkylvinyl)-alkylcyanoacetic esters by sodium alkoxides has been investigated from the standpoint of the relation of structure to ease of cleavage, and also as a synthetic method for α,β-unsaturated nitriles. The hydrolysis of these nitriles to acids also has been studied.

A Simultaneous Condensation–Reduction Method for the Preparation of Ethyl Monoalkylcyanoacetates

BY ELLIOT R. ALEXANDER AND ARTHUR C. COPE

A method for condensing aliphatic and aromatic ketones with ethyl cyanoacetate was described recently[1] in which the reactants are refluxed in benzene solution with an ammonium acetate and acetic acid catalyst. The equilibrium reaction

$$R_2CO + CH_2(CN)COOC_2H_5 \rightleftharpoons R_2C{=}C(CN)COOC_2H_5 + H_2O$$

is displaced to the right by removing the water formed during the condensation with a constant water separator. Another possible method of displacing this equilibrium is to remove the unsaturated ester as it is formed by catalytic hydrogenation. This possibility has been investigated and experimental conditions have been developed for a practical synthetic method for condensing a number of aldehydes and ketones with ethyl cyanoacetate and simultaneously reducing the products to the corresponding ethyl monoalkylcyanoacetates.

In addition to the reduction of alkylidene cyanoacetic esters in the presence of palladinized charcoal[1] and with aluminum amalgam,[2] there are two general methods of preparing ethyl alkylcyanoacetates directly: the sodium enolate of ethyl cyanoacetate may be alkylated with alkyl halides, or ethyl carbonate may be condensed with nitriles in the presence of sodium ethoxide.[3] Both of these methods give poor yields of the lower members of the series of monoalkylcyanoacetates.

In the alkylation procedure it is impossible to prevent dialkylation, and the lower molecular weight monoalkylcyanoacetates are difficult to separate from the dialkylcyanoacetates by distillation.[4] Pure products have been obtained in good yield by the condensation–reduction method described in this paper. All of the reactants are commercially available and it is unnecessary to prepare intermediate halides or nitriles, or to work in an anhydrous medium with sodium ethoxide or metallic sodium.

The optimum experimental conditions for the reaction vary slightly according to the type of carbonyl compound used. Piperidine acetate and acetic acid were employed as the condensing agents with aldehydes, and ammonium acetate and acetic acid with ketones. Alcohol was found to be the most satisfactory solvent for the condensation–reduction of ethyl cyanoacetate and ketones; dioxane for higher aldehydes (isobutyraldehyde, isovaleraldehyde, heptaldehyde and benzaldehyde); and glacial acetic acid for low molecular weight aldehydes (acetaldehyde, propionaldehyde, and butyraldehyde). The preferred procedure for carrying out the reaction for each of the three classes is given in the Experimental Part. Palladinized charcoal was found to be a suitable hydrogenation catalyst under these conditions. In the presence of platinum oxide partial reduction of the nitrile group occurred, while Raney nickel was deactivated by the acetic acid present in the reaction mixture. The properties and yields of ethyl monoalkylcyanoacetates prepared by the condensation–reduction procedure are listed in Table I.

(4) Hessler, *Am. Chem. J.*, **22**, 169 (1899).

The method seems particularly well adapted for use with aldehydes and methyl ketones not branched at the α-carbon atom, which gave yields ranging from 63 to 98% of ethyl monoalkylcyanoacetates. When dipropyl ketone was used the yield dropped to 39%, and a pure product could not be isolated from the reaction with diisobutyl ketone.

Condensation–reduction of acetophenone and propiophenone with ethyl cyanoacetate in alcohol or dioxane solution at temperatures up to 90° in the presence of ammonium acetate, acetic acid, and palladinized charcoal yielded mixtures, apparently due to incomplete hydrogenation of the condensation products. Under similar conditions, a pure sample of ethyl (1-phenylethylidene)-cyanoacetate[1] was not completely hydrogenated. When aldol was employed in the reaction, the product proved to be ethyl *n*-butylcyanoacetate.

Ethyl alkylmalonates could not be prepared by the condensation–reduction of butyraldehyde, isobutyraldehyde, or benzaldehyde with ethyl malonate in dioxane solution in the presence of ammonium acetate, acetic acid, and palladinized charcoal at temperatures up to 100°. No hydrogen was absorbed and the starting materials were recovered. Similar results were obtained with butyraldehyde and ethyl malonate in glacial acetic acid.

Experimental[5]

The following methods were used to prepare the compounds listed in Table I:

(5) All melting and boiling points are uncorrected. We are indebted to Mr. Saul Gottlieb for microanalyses.

A. Lower Molecular Weight Aliphatic Aldehydes with Ethyl Cyanoacetate.—A mixture of ethyl cyanoacetate[6] (56.6 g., 0.5 mole), the freshly distilled aldehyde (0.6 mole), 1.0 g. of palladinized charcoal[7] and 80 ml. of glacial acetic acid was placed in a 500-ml. Pyrex bottle later to be used for the reduction. To this was added a solution of piperidine (2.0 ml., 0.02 mole) in 20 ml. of glacial acetic acid and hydrogenation at a pressure of 1 to 2 atmospheres was begun immediately.[8] Reduction was rapid and exothermic. In one to three hours the theoretical amount of hydrogen (0.5 mole) was taken up, and absorption ceased.

The ethyl alkylcyanoacetates were purified readily by distillation. The reaction mixture was filtered, 50 ml. of benzene was added, and the solution was washed with two 50-ml. portions of 10% sodium chloride solution followed by three 25-ml. portions of water. If emulsions were formed at this point, they were broken by the addition of a few ml. of ether. The washings were extracted with two small portions of benzene and the combined benzene solutions were distilled through a Widmer column under reduced pressure. No ethyl cyanoacetate was recovered in the forerun, and only a small distillation residue remained.

When aldol was the aldehyde used, 0.7 mole of hydrogen was absorbed (calcd., 0.5 mole) and 55.5 g. (66%) of ethyl *n*-butylcyanoacetate was obtained. The identity of this ester was established by analysis (*Anal.* Calcd. for $C_9H_{15}O_2N$: C, 63.98; H, 8.94. Found: C, 64.29; H, 8.88), and conversion into the amide, m. p. and mixed m. p. with a known sample 125.5–126.5°.[9]

B. Branched Chain, Higher Molecular Weight Aliphatic Aldehydes, and Benzaldehyde.—A mixture of ethyl cyanoacetate (56.6 g., 0.5 mole), the aldehyde (0.6 mole), glacial acetic acid (6.0 g., 0.05 mole) and 150 ml. of dioxane[10] was placed in a 500-ml. Pyrex bottle later to be used for the reduction and cooled in an ice–salt mixture to 4°. Piperidine (2.0 ml., 0.02 mole) was added dropwise to this solution during approximately ten minutes with occasional swirling. The temperature rose to 20° and the solution became turbid. When the addition was complete, 1.0 g. of palladinized charcoal was added and the mixture was hydrogenated as before. With the aliphatic aldehydes, heat was evolved and reduction was complete in about four hours. With benzaldehyde, hydrogen absorption was very slow even when the reaction was carried out at 60°. The esters were purified as in method A. In the reactions employing aliphatic aldehydes, no ethyl cyanoacetate was recovered and only small distillation residues were left. With benzaldehyde there was a forerun of ethyl cyanoacetate (8.0 g.) and considerable residue (35 g.).

C. Aliphatic Ketones with Ethyl Cyanoacetate.—Ethyl cyanoacetate (56.6 g., 0.5 mole), the ketone (0.55 mole), ammonium acetate (3.9 g., 0.05 mole), glacial acetic acid (6.0 g., 0.1 mole), 100 ml. of 95% ethanol and 1.0 g. of palladinized charcoal were placed in a 500-ml. Pyrex bottle and hydrogenated as before. These reductions were exothermic but to a lesser degree than those mentioned under methods A and B. The esters were purified as in method A.

Summary

Experimental conditions are described whereby a number of aldehydes and aliphatic ketones can be condensed with ethyl cyanoacetate and simultaneously hydrogenated in the presence of palladinized charcoal to obtain pure ethyl monoalkylcyanoacetates in good yield. Ammonium acetate and acetic acid were employed as the condensing agents with ketones, and piperidine acetate and acetic acid with aldehydes.

(6) Obtained from the Dow Chemical Company, Midland, Michigan.

(7) Hartung, THIS JOURNAL, **50**, 3372 (1928), subsequently modified by Dr. Hartung as follows. Ten ml. of a commercial palladium chloride solution containing 0.1 g. of palladium and approximately 0.05 g. of hydrogen chloride per ml. (obtained from the J. Bishop Company, Malvern, Pennsylvania) is added to a solution of 27 g. of sodium acetate trihydrate in 100 ml. of water. Norite (9 g.) is added and the mixture is hydrogenated until absorption ceases. The catalyst (10 g.) is filtered on a Büchner funnel, washed with water, dried by drawing air through the funnel for about thirty minutes and stored in a desiccator over calcium chloride.

(8) With propionaldehyde the yield of ethyl *n*-propylcyanoacetate dropped from 94 to 61% when the solution was allowed to stand for one hour before reduction was commenced. The yield of ethyl *n*-butylcyanoacetate was 87% when the reaction mixture stood for three hours before hydrogenating.

Some Derivatives of Phenothiazine

BY HENRY GILMAN AND DAVID A. SHIRLEY

The first attempt to apply a phenothiazine derivative as an antimalarial agent was made by Guttman and Ehrlich[1] in 1891, when they showed that methylene blue was an active chemotherapeutic agent against human malaria, and later work[2,3] substantiated this claim. As a part of the extensive antimalarial research carried out by the I. G. Farbenindustrie, Schuleman[4] modified the structure of methylene blue by replacing an N-methyl group with alkylaminoalkyl groupings. More recently Holcomb and Hamilton[5] prepared 3,7-di-(6′-methoxy-2′-methyl-4′-quinolyl)-thionine as a possible antimalarial, but no report is available of its pharmacological value.

These prior studies have been concerned with the oxidized or methylene blue types of phenothiazine. It seemed of interest to prepare some appropriately substituted, non-oxidized phenothiazines for testing in avian malaria. Phenothiazine and some of its simple derivatives have a significantly low toxicity for animals. The toxicity is still further reduced by the introduction of

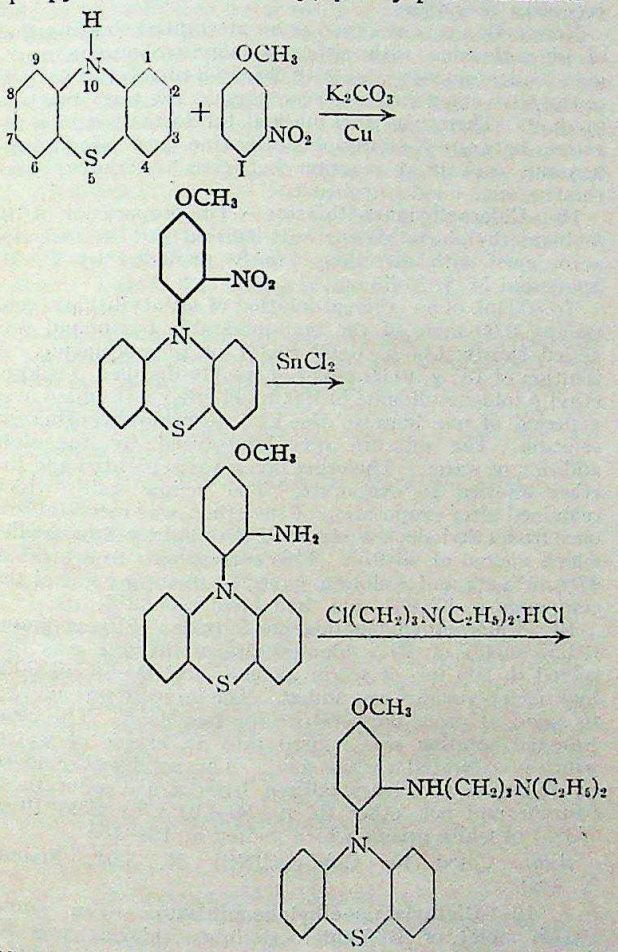
substituents in the 10-position.[6] For this reason, and also because of the opportunity of introducing some nuclear substituents like chlorine and methoxy groups which are present in atabrine, some substituted 10-phenylphenothiazine derivatives were prepared. Some of these had the generally desirable dialkylaminoalkylamino group, and the following typical series of reactions illustrates the synthesis of 10-(2′-γ-diethylaminopropylamino-4′-methoxy)-phenylphenothiazine



None of these compounds showed antimalarial activity with the exception of 10-(4′-γ-diethylaminopropylamino)-phenylphenothiazine, which had a doubtful activity at a daily dosage of twelve and one-half milligrams.

A series of phenothiazine derivatives was prepared which contained a basic alkylaminoalkyl group attached to the nitrogen of phenothiazine. These compounds were prepared by the following reactions in which the synthesis of 10-γ-diethylaminopropylphenothiazine is an illustration (RN- is the phenothiazyl radical).

$$\text{RNH} \xrightarrow[\text{(2) } p\text{-}CH_3C_6H_4SO_3(CH_2)_3Cl]{\text{(1) } n\text{-}C_4H_9Li} \xrightarrow[\text{(3) } H_2O]{} \text{RN—}(CH_2)_3Cl \xrightarrow{(C_2H_5)_2NH} \text{RN—}(CH_2)_3N(C_2H_5)_2$$

(6) Schaffer, Haller and Fink, *J. Econ. Entomol.*, **30**, 361 (1937).

There were also prepared two derivatives of this type which contained a methoxyl group in the 3-position. These compounds were prepared by the same series of reactions shown above, starting with 3-methoxyphenothiazine which was prepared from 4-methoxydiphenylamine by ring closure with sulfur. None of these derivatives showed any activity.

In addition, tests were carried out on a miscellany of phenothiazine derivatives which were prepared either during the course of the investigation on the metalation of phenothiazine[7] or as intermediates in the synthesis of the compounds containing groups likely to impart or increase antimalarial action. This group of compounds, listed in the Experimental Part, was also without activity.

Experimental

10-(2′-Nitro)-phenylphenothiazine.—Twenty grams (0.1 mole) of phenothiazine, 37 g. (0.15 mole) of *o*-iodonitrobenzene, 100 ml. of xylene, 15 g. of potassium carbonate, and 1 g. of copper bronze were refluxed with stirring for ten hours. The mixture was cooled, filtered and the residue extracted with water. The residue was recrystallized from a mixture of benzene and petroleum ether (b. p. 80–110°) to give 14 g. (44%) of yellow-brown prisms which melted at 156–157°.

Anal. Calcd. for $C_{18}H_{12}O_2N_2S$: N, 8.75. Found: N, 8.66.

10-(2′-Amino)-phenylphenothiazine.—Five grams (0.015 mole) of 10-(2′-nitro)-phenylphenothiazine, 10 g. of granulated tin, and 20 ml. of water were stirred and refluxed for one-half hour during which 75 ml. of concd. hydrochloric acid was added. The mixture was stirred and heated for an additional one-half hour. The organic matter was removed by filtration and recrystallized from alcohol. Another recrystallization from petroleum ether (b. p. 80–110°) gave 4.5 g. (95%) of light yellow needles melting at 139–139.5°.

Anal. Calcd. for $C_{18}H_{14}N_2S$: N, 9.65. Found: N, 9.66.

γ-Diethylaminopropyl Chloride Hydrochloride.—The general procedure for the preparation of γ-diethylaminopropyl chloride hydrochloride was kindly furnished by Dr. R. R. Burtner and represents a modification of the procedure of Slotta and Behnisch.[8]

A mixture of 1200 ml. of chloroform and 290 g. (2.43 moles) of thionyl chloride was immersed in an ice-bath, and to this was added (one hour) a solution of 157 g. (1.20 moles) of γ-diethylaminopropanol in 260 ml. of chloroform. The mixture was refluxed for three hours, after which the solvent and excess thionyl chloride were removed by distillation. The residue was treated cautiously with 300 ml. of 40% sodium hydroxide solution and extracted with 2 liters of ether. The ethereal solution was dried over anhydrous sodium sulfate and then evaporatively distilled. The residue distilled as a colorless oil at 73–75° (20 mm.). The yield was 131 g. (73%).

The hydrochloride is a white, extremely hygroscopic powder which melts at 66–68°. Magidson and Strukov[9] reported the compound to melt at 62–64°.

10-(2′-γ-Diethylaminopropylamino)-phenylphenothiazine.—Four grams (0.013 mole) of 10-(2′-amino)-phenylphenothiazine and 2.5 g. (0.014 mole) of γ-diethylaminopropyl chloride hydrochloride were heated for fifteen hours in a test-tube immersed in a metal bath at 130–140°. The dark red viscous product was extracted with hot 2% hydrochloric acid. The acidic extracts were made alkaline

with concentrated sodium hydroxide solution and extracted with ether. The ethereal extract was dried over anhydrous sodium sulfate and evaporatively distilled. The residual oil was distilled at less than 0.5 mm. pressure. It boiled at 215–230° and was a yellow-green, fluorescent, highly viscous oil. The yield was 2.7 g. or 49%.

Anal. Calcd. for $C_{25}H_{29}N_3S$: N, 10.41. Found: N, 10.54.

TABLE I

10-(γ-DIETHYLAMINOPROPYLAMINO)-PHENYLPHENOTHIAZINES AND THEIR PRECURSORS

10-Substituent	M. p., °C.	Yield, %	N Analyses, % Calcd.	Found
-(4′-nitro)-phenyl-[a]	157	33	8.75	8.77
-(4′-amino)-phenyl-[b]	132–133	85	9.65	9.41
-(4′-γ-diethylaminopropyl amino)-phenyl	[c]	42	10.41	10.50
-(2′-nitro-4′-methyl)-phenyl-[d]	179.5–180	36	8.40	8.47
-(2′-amino-4′-methyl)-phenyl-[e]	140–140.5	81	9.20	9.45
-(2′-γ-diethylaminopropyl-amino-4′-methyl)-phenyl	[f]	45	10.08	10.09
-(2′ nitro-4′-methoxy)-phenyl-[g]	184–186	26	8.00	7.85
-(2′-amino-4′-methoxy)-phenyl[h]	180–181	57	8.75	8.74
(2′-γ-diethylaminopropyl-amino-4′-methoxy)-phenyl	[i]	47	9.70	9.60
-(2′-methoxy-4′-nitro)-phenyl-[j]	159–160	36	8.00	8.06
(2′-nitro-4′-chloro)-phenyl-[k]	185–186.5	21	7.90	8.10
-(2′-amino-4′-chloro)-phenyl-[l]	125.5–126	38	8.65	8.45
-(2′-γ-diethylaminopropyl-amino-4′-chloro)-phenyl-	[m]	47	9.61	9.62

[a] Prepared from phenothiazine (0.1 mole) and *p*-iodonitrobenzene (0.15 mole); crystallized first from ethanol, then from benzene; yellow prisms. [b] The nitro compound was reduced by tin and hydrochloric acid. Crystallization from petroleum ether (b. p., 80–110°) gave yellow prisms; yield in first run was 46%. [c] The product was distilled at less than 0.5 mm. with a bath temperature of 350°, and was a yellow "glass." [d] Prepared from phenothiazine (0.1 mole) and 3-nitro-4-iodotoluene (0.12 mole). The 3-nitro-4-iodotoluene was prepared in 88% yield by treating the diazotized 3-nitro-4-aminotoluene with potassium iodide in accordance with some general directions of Beilstein and Kuhlberg, *Ann.*, **158**, 344 (1872). The brownish crystals of the product were obtained from glacial acetic acid, and a mixed m. p. with phenothiazine (m. p. 180–181°) was below 150°. [e] Reduction was effected by adding a hot solution of stannous chloride in concd. hydrochloric acid to a hot glacial acetic acid suspension of the nitro compound. Crystallization was from petroleum ether (b. p., 80–110°). [f] The product distilled at a bath temp. of 270° under a pressure of less than 0.5 mm., and was a yellow oil with a green fluorescence. [g] Prepared (first in 24% and then in 26% yield) from phenothiazine (0.1 mole) and 3-nitro-4-iodoanisole (0.12 mole). The latter was prepared in 92% yield from diazotized 3-nitro-4-aminoanisole in general accordance with the directions of Reverdin, *Ber.*, **29**, 2595 (1896). [h] Reduction was effected by stannous chloride and concd. hydrochloric acid; the yield in a first preparation was 53%. Crystallization from benzene gave small olive-green prisms. [i] The product distilled at 220–235° at a pressure less than 0.5 mm., and was a yellow-red oil. [j] Prepared from phenothiazine (0.1 mole) and 2-iodo-5-nitroanisole (0.15 mole). The orange-red plates were obtained by first crystallizing from acetic acid and then from a mixture of benzene and petroleum ether (b. p., 80–110°). The m. p. of 5-nitro-2-iodoanisole (prepared by diazotization) was 130–131° instead of 127–128° reported previously by Meldola and Eyre, *Proc. Chem. Soc.*, **17**, 131 (1901). An attempted reduction of 10-(2′-methoxy-4′-nitro)-phenylphenothiazine by stannous chloride gave a mixture which has not been resolved by crystallization. [k] Prepared from phenothiazine (0.1 mole) and 2-nitro-4-chloroiodobenzene (0.125 mole). Crystallization from acetic acid gave brown prisms. The 2-nitro-4-chloroiodobenzene was obtained in 96% by the procedure of Körner, *Gazz. chim. ital.*, **4**, 381 (1874). [l] Reduction was by stannous chloride, and there was appreciable tar formation. Crystallization was from benzene and then from pet. ether (b. p., 80–110°). [m] The product distilled over the range 270–280° (2 mm.) as a yellow oil.

Preparation of 10-(γ-Diethylaminopropylamino)-phenylphenothiazines.—The nitro-, the amino- and the γ-diethylaminopropylamino-phenylphenothiazines described in Table I were prepared in general accordance with the directions just given for the preparation of 10-(2′-γ-diethylaminopropylamino)-phenylphenothiazine and its necessary precursors.

No reaction was observed in an attempted condensation of phenothiazine with either *m*-iodonitrobenzene or 2-iodo-5-nitrotoluene; and with 2-iodo-3-nitrotoluene, 24% of the nitro compound was recovered in the tarry reaction product. There was also marked tar formation in a reaction between 3-methylphenothiazine and *o*-iodonitrobenzene, and in a reaction between 3-methoxyphenothiazine and *o*-iodonitrobenzene.

10-β-Chloroethylphenothiazine.—The preparation of 10-β-chloroethylphenothiazine was carried out in essential accordance with directions kindly provided by S. M. Spatz and M. J. Kolbezen.

To 600 ml. of an ethereal solution of *n*-butyllithium containing 0.69 mole of the organometallic compound was added slowly 137 g. (0.69 mole) of phenothiazine. A solution of 151 g. (0.69 mole) of freshly distilled β-chloroethyl *p*-toluenesulfonate in 100 ml. of ether was added over a period of one hour to the iced 10-lithiophenothiazine solution. The mixture was hydrolyzed by the slow addition of water. The ether layer was separated and the ether allowed to evaporate. The yellow solid, which remained after evaporation of the ether, was recrystallized once from ethyl alcohol to give 85 g. of light yellow needles which melted at 96–97°. This corresponds to a yield of 47%. Spatz and Kolbezen gave the melting point of the compound as 97–98°, and their yield was 62%.

10-β-Chloroethylphenothiazine-5-oxide.—Fifteen grams (0.057 mole) of 10-β-chloroethylphenothiazine was dissolved in 500 ml. of warm alcohol, and 50 ml. of 30% hydrogen peroxide[10] was added. The mixture was allowed to stand at room temperature for two days. The clear wine-red solution was poured into an excess of water, which precipitated a white solid. This solid was removed by filtration and recrystallized from a 1:1 mixture of benzene and pet. ether (b. p., 80–110°) to yield 10 g. (63%) of white prisms which melted at 154–155°.

Anal. Calcd. for $C_{14}H_{12}OClNS$: N, 5.04. Found: N, 4.80.

10-β-Diethylaminoethylphenothiazine.—Ten grams (0.038 mole) of 10-β-chloroethylphenothiazine was refluxed with 30 ml. of diethylamine in the presence of 1.0 g. of copper bronze for sixty hours. The reaction mixture was dissolved in dilute hydrochloric acid and this solution was made strongly alkaline with sodium hydroxide. The mixture was extracted with ether and the combined extracts dried over sodium sulfate. Evaporative distillation of the dried ethereal solution followed by a vacuum distillation of the residue gave a yellow oil boiling at 161–165° at a pressure of less than 0.5 mm. The yield was 7.6 g. (67%).

Anal. Calcd. for $C_{18}H_{22}N_2S$: N, 9.40. Found: N, 9.46.

Table II lists other 10-β-aminoethylphenothiazines prepared in an analogous manner.

The condensation of β-chloroethylphenothiazine (0.038 mole) and 8-amino-6-methoxyquinoline (0.114 mole) was effected by heating with 1.0 g. of copper powder for five hours in a nitrogen atmosphere at 140–150°.

10-γ-Chloropropylphenothiazine.—10-γ-Chloropropylphenothiazine was prepared in a manner analogous to the preparation of 10-β-chloroethylphenothiazine from 10-lithiophenothiazine and γ-chloropropyl *p*-toluenesulfonate.

TABLE II

10-(β-AMINOETHYLPHENOTHIAZINES)

10-Substituent	B. p., °C.	Yield, %	N Analyses, % Calcd.	Found
-β-dipropylaminoethyl-[a]	225–230 (1 mm.)	77	8.59	8.50
-β-morpholinoethyl-[b]	198–201 (< 0.5 mm.)	71	8.97	8.95
-β-(6′-methoxy-8′-quinolyl)-aminoethyl-	[c]	12	10.53	10.82

[a] The product was a light yellow oil. [b] The light yellow, viscous oil solidified to a white crystalline mass which melted at 74.5–75.5°. [c] The red, viscous oil distilled over the range 310–330° at a pressure less than 0.5 mm. This oil was extracted several times with pet. ether (b. p., 80–110°), and evaporation of the solvent gave a mixture of oil and yellow crystals. Recrystallization from a mixture of benzene and pet. ether, and then from pet. ether (b. p., 80–110°), gave light yellow prisms melting at 118.5–119.5°.

The product crystallized from methanol in the form of white prisms melting at 60°. The yield was 32%.

Anal. Calcd. for $C_{15}H_{14}ClNS$: N, 5.08. Found: N, 5.23.

10-γ-Diethylaminopropylphenothiazine.—The reaction of 10-γ-chloropropylphenothiazine and diethylamine was carried out as previously described under the preparation of 10-β-diethylaminoethylphenothiazine. The product was a yellow oil boiling at 170–182°/< 0.5 mm. and was obtained in a yield of 68%.

Anal. Calcd. for $C_{19}H_{24}N_2S$: N, 8.97. Found: N, 9.18.

The *dipicrate* derivative separated from the alcohol as yellow prisms which melted at 103–104°.

Anal. Calcd. for $C_{31}H_{30}O_{14}N_8S$: N, 14.56. Found: N, 14.80.

It was attempted to prepare 10-γ-diethylaminopropylphenothiazine by the condensation of γ-diethylaminopropyl chloride or its hydrochloride with phenothiazine, but only unchanged phenothiazine or tarry product was isolated in two attempts. Also unsuccessful was an attempt to use γ-diethylaminopropyl bromide hydrobromide in the preparation of this compound.

Table III lists other 10-γ-aminopropylphenothiazines prepared by a corresponding procedure.

TABLE III

10-(γ-AMINOPROPYLPHENOTHIAZINES)

10-Substituent	B. p., °C.	Mm.	Yield, %	N Analyses, % Calcd.	Found
-γ-dipropylaminopropyl-[a]	257–262	2	57	8.25	8.17
-γ-diallylaminopropyl-[b]	245–260	1	53	8.34	8.57
γ-piperidylpropyl-[c]	255–265	1–2	33	8.65	8.90

[a] Reaction was effected by refluxing, in the presence of copper powder, for twenty hours. The product was a light yellow oil. [b] The reflux period was twenty-six hours, and the product was a yellow oil. [c] The reflux period for this condensation with piperidine was fifty hours, and the product was a dark yellow, viscous oil.

3-Methoxyphenothiazine.—This compound was prepared by the action of sulfur on 4-methoxydiphenylamine.

4-Methoxydiphenylamine was prepared by treating acetyl-*p*-anisidine with excess bromobenzene in the presence of sodium carbonate and copper powder, followed by treatment with dilute hydrochloric acid in order to remove the acetyl group. The yields in two runs were 31 and 48%. The product was separated as steel-gray needles which melted at 106°. Wieland and Wecker[11] gave 105° as the melting point.

An intimate mixture of 37.5 g. (0.189 mole) of 4-methoxydiphenylamine, 12.5 g. (0.378 g. atom) of sulfur, and 1 g. of iodine as a catalyst was placed in a distilling flask immersed in a metal bath. The temperature of the bath was raised to 140–150°. Evolution of hydrogen sulfide began at this temperature and continued for thirty minutes. The reaction mixture was then heated to 175° over a period of fifteen minutes as the evolution of hydrogen sulfide slackened. The black fluid was poured into a mortar and allowed to solidify. The solid cake was then ground up to a yellow powder, which was placed in a Soxhlet extractor and extracted with pet. ether (b. p., 80–110°) for fifty hours. Nineteen and one-half grams of yellow powder melting at 158–159° separated from the pet. ether, which corresponded to a yield of 45%. A second run gave a yield of 51%. Pummerer and Gassner[12] gave 163° as the melting point of 3-methoxyphenothiazine; however, Kehrmann,[13] who later prepared the same compound, reported the melting point as 159°.

3-Methoxy-10-γ-di-*n*-propylaminopropylphenothiazine.—Four grams (0.0131 mole) of crude 3-methoxy-10-γ-chloropropylphenothiazine[14] was refluxed with 15 ml. of di-*n*-propylamine and 0.2 g. of copper bronze for eight hours. The reaction mixture was treated as previously described under the preparation of 10-γ-diethylaminopropylphenothiazine. The product distilled over the range 250–265° (2 mm.). The yield of red oil was 3.2 g. (66%).

Anal. Calcd. for $C_{22}H_{30}ON_2S$: N, 7.56. Found: N, 7.72.

3-Methoxy-10-γ-diethylaminopropylphenothiazine.—Eight grams (0.0262 mole) of the crude 3-methoxy-10-γ-chloropropylphenothiazine was refluxed for ten hours with 30 ml. of diethylamine and 0.2 g. of copper bronze. The product distilled at 220–225° at a pressure of less than 0.5 mm. as a dark yellow oil with a strong green fluorescence. The yield was 4.4 g. (49%).

Anal. Calcd. for $C_{20}H_{26}ON_2S$: N, 8.20. Found: N, 8.46.

3-Methoxy-10-acetylphenothiazine.—Two grams (0.0087 mole) of 3-methoxyphenothiazine was refluxed for four and one-half hours with 50 ml. of acetic anhydride. The solution was poured into excess water, which precipitated a white solid. The solid was removed by filtration and refluxed with enough petroleum ether (b. p. 80–110°) to effect solution. Cooling the petroleum ether solution precipitated two crops of oil from which the clear supernatant solution was decanted. The solution then deposited 0.5 g. (22%) of white rosets which melted at 121–121.5°.

Anal. Calcd. for $C_{15}H_{13}O_2NS$: N, 5.16. Found: N, 5.24.

3-Methylphenothiazine.—3-Methylphenothiazine was prepared by the action of sulfur on 4-methyldiphenylamine.

The preparation of 4-methyldiphenylamine was carried out by the method of Weston and Adkins,[15] in yields of 27 and 28%.

For the conversion of 4-methyldiphenylamine to 3-methylphenothiazine, an intimate mixture of 72 g. (0.394 mole) of 4-methyldiphenylamine, 25.3 g. (0.788 g. atom) of sulfur, and 1 g. of iodine were heated to a temperature of 280° over a period of twenty minutes. The liquid melt was allowed to solidify before being ground up in a mortar to a green powder. This material, which was obtained in a quantitative yield, melted at 160–162°. Two recrystallizations from benzene raised the melting point to 166–168°.

Anal. Calcd. for $C_{13}H_{11}NS$: N, 6.57. Found: N, 6.66.

3,7-Dinitro-10-acetylphenothiazine-5-oxide.—10-Acetylphenothiazine was prepared according to Bernthsen.[16]

(11) Wieland and Wecker, *Ber.*, **43**, 708 (1910).

(12) Pummerer and Gassner, *ibid.*, **46**, 2325 (1913).

(13) Kehrmann, *ibid.*, **48**, 327 (1915).

(14) This was prepared from the 3-methoxy-10-lithiophenothiazine and γ-chloropropyl *p*-toluenesulfonate as a viscous orange oil which was intractable to both distillation and crystallization.

Digitized by Arya Samaj Foundation Chennai and eGangotri

The nitration of 10-acetylphenothiazine was attempted according to the directions of Bernthsen,[16] and it was found that no reaction occurred under these conditions. The following procedure was found satisfactory for the preparation of 3,7-dinitro-10-acetylphenothiazine-5-oxide.

Fifty grams (0.25 mole) of phenothiazine was suspended in 400 ml. of glacial acetic acid and 125 ml. of concd. nitric acid was added over a period of fifteen minutes. Upon standing the solution precipitated 40 g. (46%) of yellow-tan powder which melted with decomposition at 265–267°. Bernthsen[16] gives no melting point for his nitration product.

Anal. Calcd. for $C_{14}H_9O_6N_3S$: N, 12.03. Found: N, 12.21.

3-Nitro-10-ethylphenothiazine-5-oxide.—Kehrmann and Zybs[17] nitrated 10-methylphenothiazine and obtained 3-nitro-10-methylphenothiazine-5-oxide. 10-Ethylphenothiazine was nitrated using the general procedure developed by these workers. The 10-ethylphenothiazine was prepared by the reaction of ethyl bromide and phenothiazine in a steel bomb.[18]

Ten grams (0.044 mole) of 10-ethylphenothiazine was dissolved in 250 ml. of glacial acetic acid, and to this solution was added 10 ml. of concd. nitric acid dissolved in 40 ml. of glacial acetic acid. The mixture was allowed to stand for two days, and the clear yellow solution was poured into excess water. A bright yellow powder which melted at 202–204° was precipitated in a quantitative yield. One recrystallization of the product from a 1:1 mixture of alcohol and glacial acetic acid gave minute canary-yellow crystals which melted at 204.5–205°. Analysis showed this to be a mononitro-10-ethylphenothiazine-5-oxide, and by analogy to the nitration of 10-methylphenothiazine, it was assumed that nitration had occurred in the reactive 3-position of phenothiazine.

Anal. Calcd. for $C_{14}H_{12}O_3N_2S$: N, 9.72. Found: N, 9.82.

10-Allylphenothiazine.—A mixture of 50 g. (0.25 mole) of phenothiazine, 60 g. (0.50 mole) of allyl bromide, 50 ml. of benzene, 20 g. of sodium carbonate, and 2 g. of copper powder was stirred and refluxed for six hours. The hot mixture was filtered and the filtrate was distilled to remove the benzene and excess allyl bromide. The residual oil was distilled at 187–195° (1 mm.), and 37 g. (62%) of product was collected as a light brown oil.

Anal. Calcd. for $C_{15}H_{13}NS$: N, 5.86. Found: N, 5.91.

10-Decylphenothiazine.—A mixture of 50 g. (0.25 mole) of phenothiazine, 55 g. (0.25 mole) of *n*-decyl bromide, 25 g. of sodium carbonate, and 2 g. of copper powder was stirred and heated in an oil-bath at 170–180° for eleven hours. The cooled reaction mixture was extracted with ether, and the combined ether extracts were dried over anhydrous sodium sulfate and the ether removed by evaporative distillation. The residue was distilled at 1 mm. pressure and 21.5 g. of yellow oil was collected at 225–235°. This was redistilled at less than 0.5 mm. pressure, and 8.0 g. (9.4%) of yellow oil was collected at 183–185°.

Anal. Calcd. for $C_{22}H_{29}NS$: N, 4.13. Found: N, 4.16.

3-Nitro-10-decylphenothiazine-5-oxide.—Ten grams (0.295 mole) of 10-decylphenothiazine was dissolved in 75 ml. of glacial acetic acid and 10 ml. of concd. nitric acid in 75 ml. of acetic acid was added with shaking over a period of ten minutes. The mixture was allowed to stand for two days, and was then poured into excess water. The precipitated yellow solid was recrystallized from pet. ether (b. p. 60–68°) to give 4.0 g. (34%) of bright yellow prisms which melted at 102.5–103°.

Anal. Calcd. for $C_{22}H_{28}O_3N_2S$: N, 7.00. Found: N, 7.34.

(17) Kehrmann and Zybs, *Ber.*, **52**, 130 (1919).

(18) Gilman, Van Ess and Shirley, THIS JOURNAL, **66**, in press (1944).

10-Octadecylphenothiazine.—A mixture of 30 g. (0.09 mole) of *n*-octadecyl bromide, 17.9 g. (0.09 mole) of phenothiazine, 10 g. of anhydrous sodium carbonate, and 1 g. of copper powder was heated at 170–180° for twelve hours. The mixture was extracted with ether. The combined ether extracts were dried over anhydrous sodium sulfate and then evaporatively distilled. The residual oil was distilled at a pressure of less than 0.5 mm., and gave 18 g. of yellow oil boiling at 290–300°. Upon cooling, this oil solidified to a waxy solid which was recrystallized from ethanol to give 8.2 g. (20%) of minute, white needles which melted at 53°.

Anal. Calcd. for $C_{30}H_{45}NS$: N, 3.11. Found: N, 3.06.

10-Octadecylphenothiazine-5-oxide.—Five grams (0.011 mole) of 10-octadecylphenothiazine was dissolved in 600 ml. of hot alcohol and 30 ml. of 30% hydrogen peroxide solution was added to the mixture. The solution was heated to boiling for several minutes, and then allowed to stand at room temperature for two days. Pouring the reaction mixture into water precipitated 4.2 g. of a pink powder which upon recrystallization from pet. ether (b. p. 80–110°) gave 2.7 g. (53%) of light pink to white plates which melted at 98°.

Anal. Calcd. for $C_{30}H_{45}ONS$: N, 3.00. Found: N, 3.07.

10-Phenylphenothiazine-5-oxide.—Two grams (0.0073 mole) of 10-phenylphenothiazine was dissolved in 50 ml. of hot alcohol and treated with 5 ml. of 30% hydrogen peroxide as in the preparation of 10-octadecylphenothiazine-5-oxide. The product melted at 170–171° after recrystallization from a mixture of benzene and pet. ether (b. p. 80–110°) and consisted of white prisms. The yield was 1.5 g. (71%).

Anal. Calcd. for $C_{18}H_{13}ONS$: N, 4.81. Found: N, 4.66.

3-Nitro-10-phenylphenothiazine-5-oxide.—Ten grams (0.036 mole) of 10-phenylphenothiazine was suspended in 75 ml. of glacial acetic acid, and a solution of 10 ml. of concd. nitric acid in 75 ml. of acetic acid was added. The mixture was allowed to stand for two days and then was poured into water. The precipitated yellow solid was recrystallized once from ethanol and once from a mixture of ethanol and acetic acid to yield 8.5 g. (70%) of yellow minute crystals melting at 223.5–224.5°.

Anal. Calcd. for $C_{18}H_{12}O_3N_2S$: N, 8.33. Found: N, 8.51.

Pharmacological Tests.—The authors are grateful to Parke, Davis and Company for arranging for the tests on experimental avian malaria. In addition to the compounds mentioned in the Introduction, the following phenothiazine derivatives were tested, and showed no activity: 10-(4′-carboxy)-phenyl-; 3-methyl-; 1-carboxy-; 3-nitro-10-phenyl-5-oxide; 10-methyl-; 10-β-chloroethyl-; 10-phenyl-; 10-allyl-; 10-decyl-; 10-octadecyl-; and phenothiazine.

In connection with the decrease in toxicity of some derivatives substituted in the 10-position, the following information on the lethal dose for canaries in milligrams (in parentheses) is of interest: phenothiazine (20), 3-methylphenothiazine (50), 10-phenylphenothiazine (>50), and 10-phenyl-3-nitrophenothiazine-5-oxide (100).

The relatively low toxicity of phenothiazine and many of its derivatives suggests an examination of some non-oxidized types containing, in addition to a basic side chain, two nuclear substituents drawn from groups like methyl, methoxyl, chloro, or diethylamino. In particular, a compound patterned somewhat after atabrine and containing a methoxyl and a chlorine might help provide more decisive information on the possibilities of effective non-oxidized phenothiazine types.

Summary

The relatively low toxicity of phenothiazines suggested an examination in avian malaria of a miscellany of non-oxidized phenothiazine derivatives containing a basic side-chain and, parti-

Zinc Alkyls from Secondary Alkyl Halides

BY HAROLD SOROOS AND MORLEY MORGANA

Of zinc alkyls derived from secondary alkyl halides, the literature reports the preparation of only one, diisopropylzinc.[1] In the reported preparations of this compound, isopropyl iodide was added all at once to zinc or zinc–copper couple, and heat was applied. The yields were low, and mainly gaseous products were obtained. Recent attempts to repeat and confirm this work, by methods known to be successful for the preparation of zinc alkyls from primary halides, were unsuccessful.[2]

Recently, in studies conducted in this Laboratory, it was found that both diisopropylzinc[3] and di-*s*-butylzinc could be obtained in essentially as good yields as the zinc alkyls derived from primary alkyl halides, by a modification of Noller's procedure.[2] The method consists simply of adding a mixture of the secondary alkyl bromide and iodide slowly with stirring under controlled temperature conditions to an excess of zinc–copper couple, followed by distillation of the reaction mixture at as low a temperature and pressure as possible.

In contrast to the preparation of zinc alkyls from primary alkyl halides, the reaction with the secondary halides starts easily and proceeds smoothly if properly controlled. Only a trace of gas is formed, and the reaction mixture consists of a clear oily liquid[4] and the excess couple. Distillation of the reaction mixtures under reduced pressure gives the zinc alkyls in good yield.

Both compounds are spontaneously inflammable and somewhat less stable than the primary analogs, decomposing slowly in diffused daylight with the deposition of metallic zinc.

(1) Bohm (*J. Russ. Phys.-Chem. Soc.*, **31**, 46 (1899); *Chem. Zentr.*, **70**, I, 1067 (1899)) reports obtaining diisopropylzinc in 25% yield from isopropyl iodide and zinc; Gladstone and Tribe (*J. Chem. Soc.*, **26**, 961 (1873)) obtained the compound in 13% yield from isopropyl iodide and zinc-copper couple; Ragosin (*J. Russ. Phys.-Chem. Soc.*, **24**, 549 (1892); *Ber.*, **26** (Ref.), 380 (1893)) obtained the compound by interaction of isopropyl iodide in ether with zinc and a small amount of sodium–zinc alloy.

(2) Noller, THIS JOURNAL, **51**, 594 (1929).

(3) The preparation of this compound was investigated in a study sponsored and supported by the National Advisory Committee for Aeronautics.

(4) The oily liquid is apparently the RZnX compound, which on subsequent heating disproportionates to R_2Zn and ZnX_2. It was necessary to heat the reaction mixtures at 1 mm. to considerably higher temperatures than required for distillation of the zinc alkyls alone before the latter distilled from the reaction mixtures. Also, the liquid was observed to be considerably more stable toward oxidation on exposure to air than the zinc alkyls.

Experimental

Zinc–Copper Couple.—A wrought-iron alloy pot, flushed with nitrogen, was charged with 3319 g. (51 g. atoms) of zinc and 369 g. (3.55 g. atoms Cu, 2.11 g. atoms Zn) of Tobin bronze brazing rod, and loosely covered. The mass was heated to 600° with an oxy-acetylene torch and shaken vigorously for five minutes, maintaining the temperature at 600°. The melt was discharged into a one-inch iron pipe mold, cooled in air, and finally quenched in water. The rod was machined into turnings without the use of cutting oil. *Anal.*[5] Zn, 94.5; Cu, 5.86.

Diisopropylzinc.—To a 500-ml., 3-neck flask, equipped with a reflux condenser, an efficient stirrer, and a Hershberg dropping funnel, was added 104.5 g. (98.9 g. Zn, 1.5 g. atom) of zinc–copper couple turnings. The system was evacuated to 1 mm. while stirring and warming gently with a free flame, and then flushed several times with dry nitrogen. A trap cooled in dry-ice was connected to the outlet of the reflux condenser and a mixture of 61.5 g. (0.5 mole) of isopropyl bromide and 85.0 g. (0.5 mole) of isopropyl iodide was added to the dropping funnel. A water-bath at 50° was raised around the flask and the stirrer started. About 2 ml. of the alkyl halide mixture was added rapidly. Within two minutes, reaction had started as shown by a trace of white fumes, a darkening of the couple, and the oily appearance of the liquid on the walls of the flask. The 50° bath was replaced by a water-bath at 20°, and dropwise addition of the halides was started. The drop rate was adjusted so that addition was complete in five and one-half hours. At this rate not more than 0.5 ml. of liquid collected in the trap; a faster rate caused undue gas formation as shown by liquid in the dry-ice trap. After addition, stirring was continued for 30 minutes. The reaction mixture consisted of a clear, colorless, liquid and the almost black excess zinc–copper couple.

For distillation of the diisopropylzinc, one neck of the three-neck flask was stoppered, the other was equipped with a simple distillation head and thermometer, and the rubber sleeve of the stirrer was wired to the shaft. Three traps were placed in series, the first two being equipped with Vaseline-lubricated stopcocks, all being large enough so that freezing of the distillate would not cause plugging. With the first two traps at room temperature and the third in liquid nitrogen, the system was slowly evacuated to 1 mm. Low-boiling material was collected in the cold trap until ebullition ceased in the flask. The first two traps were then cooled in a dry-ice mixture at −65° and an oil-bath, placed around the flask, was heated rapidly to about 100°. The oil-bath was maintained at 90–140° for forty-five minutes until distillation was almost complete, at the end of which time it was raised to 200° to remove the last trace of product. It was necessary to maintain the oil pump on the system throughout, owing to some pyrolytic decomposition. Without the liquid nitrogen trap, an oil pump would not maintain a pressure of 1 mm. and the yield was lowered. The residue was a

(5) Spectrographic analysis of the zinc used in this preparation, kindly obtained for us by Dr. F. L. Howard of the National Bureau of Standards, showed the metal to contain trace amounts (less than 0.01%) of Au, Ba, Cd, Cu, Fe, Mg, Mn, Ni, Pb, and Si.

Digitized by Arya Samaj Foundation Chennai and eGangotri

hard, gray cake. The yield of crude product was 64.2 g. (0.42 mole), or 85% based on the isopropyl halides.

The boiling points of a middle fraction of redistilled material at various pressures were obtained by distillation of a sample through a short Stedman column. The relation between temperature and pressure (in mm.) is given to within ±1.0 mm., which is within the accuracy of the measurements, by the equation $\log P = 7.987 - 1858/(t + 230)$.

Di-*s*-butylzinc.—By a procedure similar to that described above, di-*s*-butylzinc was prepared from 68.5 g. (0.5 mole) of *s*-butyl bromide, 92.0 g. (0.5 mole) of *s*-butyl iodide, and 140 g. (132 g. Zn, 2.0 g. atom) of zinc–copper couple. The starting temperature was 60°, and the reaction temperature 25°. The yield of crude product was 64.5 g. (0.36 mole), or 72%. On redistillation, the material distilled at 56° at 4 mm. *Anal.* Calcd. for $(C_4H_9)_2Zn$: Zn, 36.4. Found: Zn, 36.1.

Summary

Diisopropylzinc and di-*s*-butylzinc have been prepared from zinc–copper couple and secondary alkyl halides in good yield by a modification of the procedure usually used for preparation of the primary analogs.

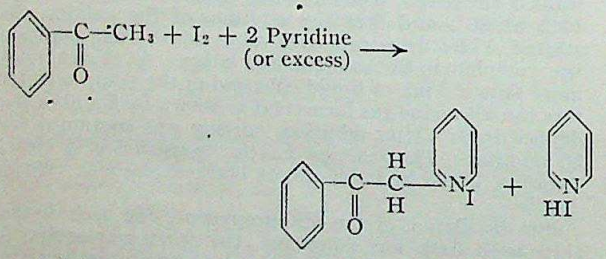
The Reaction of Iodine with Some Ketones in the Presence of Pyridine

BY L. CARROLL KING

In an investigation of the reactions of compounds containing reactive hydrogen atoms with iodine in the presence of a base it was observed that acetophenone, 1-naphthyl methyl ketone, 1-anthryl methyl ketone and propiophenone react directly with one mole of iodine and two moles (or excess) of pyridine to give excellent yields of 1-phenacylpyridinium iodide, 1-(1-naphthoylmethyl)-pyridinium iodide, 1-(1-anthroylmethyl)-pyridinium iodide and 1-(α-methylphenacyl)-pyridinium iodide, respectively, and, in each case, pyridine hydroiodide.

If acetophenone is used as an example the reaction may be formulated as follows



1-Phenacylpyridinium iodide has been reported.[1] It was further characterized by conversion to the known 1-phenacylpyridinium perchlorate.[2,3] 1-(α-Methylphenacyl)-pyridinium iodide was also characterized by conversion to the known 1-(α-methylphenacyl)-pyridinium perchlorate.[4]

It has been demonstrated previously that 1-phenacylpyridinium bromide[2,5] and 1-(α-methylphenacyl)-pyridinium bromide[3] can be cleaved by means of aqueous alkali to give benzoic acid. The 1-phenacylpyridinium iodide and the 1-(α-methylphenacyl)-pyridinium iodide described in this article when treated with aqueous sodium hydroxide also gave excellent yields of this substance.

The characterization of 1-(1-naphthoylmethyl)-pyridinium iodide and of 1-(1-anthroylmethyl)-pyridinium iodide depends on the mode of formation, the analysis, and on the fact that after treatment with aqueous alkali the respective 1-naphthoic and 1-anthroic acids were isolated in good yield from the cleavage products.[6]

In three of the four reactions carried out 74–92% yields (based on the ketones) of the expected substituted β-ketoalkylpyridinium iodides were obtained and in every case 87–95% of the expected yields of pyridine hydroiodide were observed. 1-(α-Methylphenacyl)-pyridinium iodide was obtained in only 41% yield. The low yield in this case was due to the solubility characteristics of this compound. When the 1-(α-methylphenacyl)-pyridinium compound was isolated as the perchlorate a 64% yield was obtained.

When excess pyridine was used as the solvent, the formation of the substituted β-ketoalkylpyridinium iodides, by means of the above reaction, proceeded smoothly with twenty to thirty minutes heating on the steam-bath and the reaction was complete after standing overnight. In most cases a solid began to separate soon after the heating was started. This substance consisted of pyridine hydroiodide and usually contained some of the substituted β-ketoalkylpyridinium iodide. In the four instances discussed in this paper, it was not found advantageous to use solvents other than an excess of the base when effecting this synthesis.

Preliminary experiments indicate that the above reaction is of value for the synthesis of derivatives of various nitrogeneous bases, particularly in those cases where an intermediate halogen compound is difficult to obtain. These experi-

1-(α-Methylphenacyl)-	$C_{14}H_{14}ClNO_5$	141–142	64[d]–90[c]	54.29	4.49		53.94	4.52	

[a] All melting points were observed on a Fisher–Jones melting point apparatus. [b] Based on the ketone. [c] Based on the corresponding substituted β-ketoalkylpyridinium iodide. [d] This yield, based on the ketone, was obtained when the crude reaction mixture was converted directly into the perchlorate salt without preliminary isolation of the iodide.

ments also indicate that this reaction followed by alkaline cleavage, may be adapted to the preparation of acids from certain sensitive methyl ketones, particularly in those cases where the ordinary haloform reaction gives poor yields.

Extension of this reaction to other bases, to other halogens, and to various types of compounds containing active hydrogen atoms is in progress.

Experimental

Preparation of the Substituted β-Ketoalkylpyridinium Iodides.—The procedure was essentially the same for each of the four compounds prepared and was about as follows. To 0.1 mole of the appropriate ketone[7] dissolved in 30–50 ml. of pyridine 0.1 mole of iodine was added. The solution was heated thirty minutes on the steam-bath and let stand overnight. The excess pyridine was then removed and the mixture of pyridine hydroiodide and substituted β-ketoalkylpyridinium iodide separated by means of their solubility characteristics. 1-Phenacylpyridinium iodide, 1-(1-naphthoylmethyl)-pyridinium iodide and 1-(1-anthroylmethyl)-pyridinium iodide were comparatively insoluble in water and in methyl or ethyl alcohol and were easily separated from the more soluble pyridine hydroiodide. 1-(α-Methylphenacyl)-pyridinium iodide is very soluble in the solvents mentioned above but could be obtained pure from the concentrated methyl alcohol mother liquors after removal of most of the pyridine hydroiodide. In each case the substituted β-ketoalkylpyridinium iodide was crystallized from water or from dilute alcohol before analysis. The critical data for each of these compounds are listed in Table I.

The pyridine hydroiodide isolated in each case was identified by the usual procedures.

Preparation of the Substituted β-Ketoalkylpyridinium Perchlorates.—About 1 g. of each of the above substituted β-ketoalkylpyridinium iodides was dissolved in 50–400 ml. of hot water and 60% perchloric acid added until the solutions contained about 3% of it. The substituted β-ketoalkylpyridinium perchlorates separated at once or as the solution was cooled. The critical data for each of these substances are listed in Table I.

Alkaline Cleavage of the Substituted β-Ketoalkylpyridinium Iodides.—The method of cleavage of each of the four compounds was essentially the same. To suspensions of 1–5 g. of each of the substituted β-ketoalkylpyridinium iodides in 50–100 ml. of water or 50% ethyl alcohol, 1–3 g. of sodium hydroxide was added.

TABLE II

Starting iodide	Acid resulting from alkaline cleavage	Yield, %	M. p., °C.
1-Phenacylpyridinium	Benzoic	90	122
1-(α-Methylphenacyl)-pyridinium	Benzoic	88	122
1-(1-Naphthoylmethyl)-pyridinium	1-Naphthoic[a]	90	160–161
1-(1-Anthroylmethyl)-pyridinium	1-Anthroic[b]	80	251–252

[a] This substance was converted to the amide, m. p. 202–203°. [b] This substance was converted to the methyl ester, m. p. 101–102°.

The suspensions were heated one hour on the steam-bath and the acidic fractions isolated from the resulting homogeneous solutions. A summary of the results of this experiment appears in Table II.

Summary

1. It has been demonstrated that acetophenone, 1-naphthyl methyl ketone, 1-anthryl methyl ketone, and propiophenone react directly with one mole of iodine and two moles (or excess) of pyridine to give 1-phenacylpyridinium iodide, 1-(1-naphthoylmethyl)-pyridinium iodide, 1-(1-anthroylmethyl)-pyridinium iodide and 1-(α-methylphenacyl)-pyridinium iodide, respectively, and, in each case, pyridine hydroiodide.

2. Each of the substituted β-ketoalkylpyridinium iodides produced by the above reaction when treated with aqueous alkali was cleaved, and the corresponding carboxylic acid was isolated from the cleavage products.

EVANSTON, ILLINOIS RECEIVED JANUARY 31, 1944

(7) The 1-anthryl methyl ketone, m. p. 108°, was prepared by Mr. Clair J. Collins. The author is also indebted to Mr. Collins for the procedure for purification of 1-anthroic acid, and for the authentic samples of 1-anthroic acid and its methyl ester.

The Assay of Purified Proteins, Enzymes, Etc., for "B Vitamins"

BY ROGER J. WILLIAMS, FRITZ SCHLENK[1] AND MARGARET A. EPPRIGHT[2]

Microbiological assay methods for "B vitamins" have been used extensively in this Laboratory to assay small samples of tissues and foods.[3,4] In the present study the same methods were applied to various purified proteins, etc., as indicated in Table I.

The purpose of the investigation was to gain insight into the possible importance of "B vitamins" as prosthetic groups in proteins known to possess unusual physiological functions. It is common to assume that those B vitamins whose functions are unknown will ultimately be found to have a catalytic role and to be essential parts of specific enzyme systems. The possibility that some of these B vitamins should be constituent parts of already recognized enzymes and other physiologically active substances seemed worth exploring. Obviously in the case of comparatively low molecular weight proteins, a vitamin in order to be a constituent part of the molecule must be present in relatively large amounts, and relatively crude tests may serve to settle the question. It was of additional interest, however, to know in some cases whether specific proteins contained substantial amounts of B vitamins even though the vitamins were not present in amounts sufficient to be integral parts of the protein molecules, and were presumably held only by adsorption.

The results of the assays are given in Table I.

Of the 33 samples tested, the urease, ferritin and two ribonuclease samples were prepared by one of us (F. S.) using published methods[5,6,7,8,9]; the casein samples were obtained commercially. The others are described and their origin indicated in Table I.

The various preparations were not in general assayed for riboflavin because it is a highly colored substance and could hardly be an integral part of a purified protein (except highly colored ones) without revealing its presence visually.

Quantitative determinations on poor sources of B vitamins such as those investigated in this study are, in the nature of the case, subject to large percentage errors. The method for inositol is not on a par with the other methods because the organism (yeast) is far less sensitive to it, and the enzyme preparation used for digestion is comparatively rich and introduces a high correction. For this reason the low values for inositol content are relatively unreliable.

For determination of biotin and *p*-aminobenzoic acid, acid digestion replaced enzyme digestion; hence there was no "enzyme blank" to be used as a correction. The determinations of *p*-aminobenzoic acid were made with slight modifications according to the method of Lewis.[10]

Discussion

Most of the preparations of enzymes, hormones, proteins and other principles assayed contained measurable amounts of the various B vitamins. In most cases, however, the amounts are so small that the vitamins could not constitute an integral part of the molecules concerned.

Two samples yielded results of unusual interest, namely, pancreatic amylase and the yeast carboxylase. The pancreatic amylase preparation was capable of yielding 11,000 times its weight of maltose under standard test conditions. This is as high a potency as has been reported for any amylase preparation. Its inositol content is sufficiently high (4.1 mg. per gram) so that in order to be an integral part of the enzyme, the molecular weight of the latter would need to be no more than 44,000. That this inositol content is real and not due to error is indicated by the fact that a duplicate set of assays using acid extraction instead of enzymatic extraction gave results which were in substantial agreement (4.4 mg. per gram). This interesting observation regarding the amylase will be investigated further in collaboration with Dr. Caldwell.

Both yeast carboxylase preparations yielded an amount of nicotinic acid which was far above that obtained from other proteins. Preparation 1 was approximately 25% pure. The second preparation was "put through the same purification procedure that leads to the purest material recorded in our paper. However, the purity of this preparation is certainly far below what it ought to be. I have no explanation for this discrepancy except to point out that the activity of our starting material was 10% of that we used in England."[11] The possible existence of nicotinic acid in carboxylase will require further investigation, but the results obtained are suggestive.

The fact that for the most part B vitamins are found not to be constituents of the enzymes, etc., tested indicates, assuming that the less known B vitamins are enzyme constituents, that there exists a multiplicity of enzymes which are not at present available in concentrated form.

[a] Symbols stand for the following sources: MB = Max Bergmann, MK = Moses Kunitz, DG = David E. Green, GC = Gerty T. Cori, MC = Mary L. Caldwell, HK = Herman M. Kalckar, JN = J. M. Nelson, EH = Erwin Haas, GS = Gerhardt Schmidt, VV = Vincent du Vigneaud (Eli Lilly product), HE = Herbert M. Evans, IP = Irvine H. Page, TJ = T. H. Jukes (Lederle Labs.), AM = Alfred E. Mirsky, WS = W. M. Stanley. [b] Values obtained were not necessarily zero, but were so low as to be probably negligible. [c] These tests were not entirely satisfactory. In most cases a slight growth inhibition was observed and this makes the result open to some question. [d] Approximately 25% pure, contained about 15 mg. dry wt. protein and approximately 20 units carboxylase activity per cc. [e] Many times recrystallized, washed with potassium chloride, dried *in vacuo*. [f] Highly purified, will produce approximately 11,000 times its weight of maltose under standard conditions. [g] Three to four times less active than material which catalyzes transfer of 5γ P per 1γ protein per minute. [h] From common mushroom; one cc. contains 10,200 Miller–Dawson catecholase units. [i] One mg. of dry enzyme forms 20 mg. of inorganic P within fifteen minutes from glycerophosphate. [j] About ten times more concentrated than preparation 1. [k] Relatively impure, but very potent. [l] N = 18.9% dry wt., ash = 0.08% (sulfate). [m] Purified from calf thymus. [n] Three times recrystallized, then denatured. [o] Partial assays were made of three other viruses, samples of which were kindly furnished by Dr. W. M. Stanley, *e. g.*, tobacco necrosis virus, bushy stunt virus and a centrifugally purified preparation of PR8 influenza virus. In no case did any vitamin appear to be present in substantial amounts; their contents of B vitamins appeared to be of a similar order to those of the tobacco mosaic virus. The small amounts of the other viruses which were available made the assays less satisfactory and less complete. [p] Crystalline, prepared by three differential centrifugative cycles.

The existence of appreciable amounts of the various B vitamins in all forms of living matter which have been investigated suggests the possibility of utilizing the presence or absence of these vitamins as a criterion with regard to the animate and inanimate nature or origin of a material in question. If we accept this criterion and the probability that viruses maintain their identity in the absence of all B vitamins, we must conclude that they are what we call inanimate.

Acknowledgment.—We wish to acknowledge most gratefully the kindness of the numerous

individuals and laboratories referred to in Table I for furnishing us with the samples which made this investigation possible.

Summary

A series of protein, enzyme, hormone, and miscellaneous preparations have been assayed for B vitamins. Only traces have been found in most; however, inositol appears to be a constituent of purified amylase and the impure carboxylase preparations available contained a suggestively high content of nicotinic acid in addition to the thiamin already known to be present. The viruses investigated were found to be nearly devoid of B vitamins, and in this respect they appear to resemble "inanimate" rather than "animate" matter.

Some Experiments on the *in vitro* Formation of Thyroxine from Diiodotyrosine

BY ARCHIE E. BARKDOLL[1a] AND WILLIAM F. ROSS[1b]

Following the report of von Mutzenbecher[1c] that thyroxine is readily formed *in vitro* from diiodotyrosine as well as from iodinated proteins,[2] considerable interest has been expressed in the nature of the reaction. As normally carried out, slightly alkaline digestion of diiodotyrosine over a period of two weeks gives a very small quantity of thyroxine. Block[3] repeated von Mutzenbecher's work using completely synthetic diiodotyrosine in order to eliminate the possibility that a trace of impurity, responsible for the thyroxine formation, had accompanied the tyrosine from its natural source. Johnson and Tewkesbury[4] made a further study of the reaction, obtaining a slight increase in the yield of thyroxine on the addition of hypoiodite to the solution and establishing pyruvic acid and ammonia as further products. As a result of their work, they postulated a mechanism evolved from the work of Pummerer[5] on the oxidation of *o*- and *p*-substituted phenols in alkaline solution. Their paper may be consulted for the proposed mechanism. We have made additional observations on the nature of the reaction, which throw further light on several points.

It appeared plausible that thyroxine may have been formed by the oxidizing action of the iodine solution originally used for the preparation of the diiodotyrosine rather than during the incubation of the diiodotyrosine. This possibility was eliminated when a sample of crude diiodotyrosine, as it was obtained from the iodination reaction, was subjected to butyl alcohol extraction for thyroxine. No thyroxine was found.

It was equally possible that a small amount of precursor was formed during the iodination and that this and not diiodotyrosine was converted into thyroxine during the long incubation period. A quantity of diiodotyrosine was therefore very carefully purified, but the yield of thyroxine after digestion was not altered.

To further eliminate the role of a small amount of accompanying impurity, diiodotyrosine which had already yielded thyroxine by incubation, was recovered, purified and re-incubated. Again thyroxine was formed.

In order to prove or disprove that oxidation, presumably by air, is involved in the formation of thyroxine, a solution of diiodotyrosine was incubated in an oxygen-free system under the usual conditions; it yielded no thyroxine. Whereas diiodotyrosine recovered from experiments carried out in the presence of air contain much brown, amorphous material, the diiodotyrosine recovered from this experiment was crystalline and only slightly darker than the starting material.

Conversely, the yield of thyroxine from a given amount of diiodotyrosine was increased by passing a slow stream of carbon dioxide-free air through the solution during the incubation.

In view of the work of Pummerer, *et al.*,[6] it was thought that incubation in the presence of a small amount of potassium ferricyanide might increase the yield of thyroxine. This appeared to be too drastic an oxidizing agent, however, as no thyroxine whatever was formed and the diiodotyrosine was converted to a dark brown amorphous substance.

A possible intermediate in the formation of thyroxine would be 3,5-diiodo-4-hydroxybenzoic acid, formed through the oxidative degradation of diiodotyrosine. An incubation carried out in the presence of this compound, instead of increasing the yield of thyroxine, completely prevented the conversion.

It was also found that 2,4,6-triiodophenol would not act as an intermediate to increase the

yield. The normal amount of thyroxine was obtained in the presence of this substance.

Experimental

3,5-Diiodotyrosine Dihydrate—This substance was prepared from *l*-tyrosine by the method of Bauer and Strauss.[7] It crystallizes as the dihydrate, which fact was overlooked by these authors but was pointed out by Savitskii.[8] From 32.6 g. of tyrosine, in a typical experiment, 62 g. (66%) of diiodotyrosine dihydrate of m. p. 198° (dec.) was obtained.

Thyroxine from the Alkaline Digestion of Diiodotyrosine.—The procedure of earlier workers[1,3] was adopted for our experiments. This involved digestion of 14 g. of diiodotyrosine in 325 cc. of 0.1 *N* sodium hydroxide at *p*H 8.8 for two weeks at 37.5°, followed by isolation of the thyroxine through its butyl alcohol-soluble potassium salt. From 25 to 40 mg. of thyroxine was normally obtained.

No Thyroxine from Undigested Diiodotyrosine.—A solution of 14 g. of diiodotyrosine dihydrate in 25 cc. of 2 *N* sodium hydroxide was extracted with twelve 25-cc. portions of wet *n*-butyl alcohol. On working up the combined butyl alcohol extracts by the usual procedure none of the potassium salt of thyroxine was obtained.

Digestion of Analytically Pure Diiodotyrosine.—Crude diiodotyrosine (30.2 g.) was dissolved in 175 cc. of 0.85 *N* hydrochloric acid, treated three times with activated carbon and crystallized by the addition of 20 g. of sodium acetate in 30 cc. of water. The dried product weighed 17.7 g. and melted at 202° (dec.).

Anal. Calcd. for $C_9H_9O_3NI_2$: I, 58.62. Found: I, 58.41.

Fourteen grams of this product digested in the usual way yielded 24 mg. of thyroxine; m. p. 228 (dec.).

Digestion of Recovered Diiodotyrosine.—A solution in 180 cc. of 0.12 *N* hydrochloric acid of 41.3 g. of diiodotyrosine recovered from previous runs was filtered free of brown, amorphous material, saturated with sulfur dioxide and treated twice with activated carbon. The diiodotyrosine was crystallized by the addition of 40 cc. of 50% sodium acetate. It was then recrystallized from 0.1 *N* hydrochloric acid by the addition of sodium acetate to give 17.1 g. of light yellow crystals melting at 200°.

Incubation of 14 g. of this recrystallized diiodotyrosine in the customary manner gave 39 mg. of thyroxine.

Digestion of Diiodotyrosine in the Presence of Potassium Ferricyanide.—Ten grams of diiodotyrosine dihydrate and 3.29 g. of potassium ferricyanide were dissolved in 231 cc. of 0.1 *N* sodium hydroxide, and the *p*H of the solution adjusted to 8.8. After the usual incubation period the solution was black. A dark brown amorphous precipitate was thrown out by acidification. This was examined in the usual way for thyroxine, but none was obtained.

A control experiment run simultaneously with the same diiodotyrosine gave a good yield of thyroxine.

Digestion of Diiodotyrosine in the Presence of 2,4,6-Triiodophenol and of 3,5-Diiodo-4-hydroxybenzoic Acid.—A. A mixture of 10 g. of diiodotyrosine dihydrate and 2.28 g. of triiodophenol, prepared by the method of Datta and Prosad,[9] was added to 280 cc. of 0.1 *N* sodium hydroxide. The solution, of *p*H 9.0, was placed in the incubator at 37.5° for fifteen days, although the triiodophenol was not entirely dissolved. The mixture was shaken daily to maintain saturation. After eleven days the *p*H had fallen to 8.7; it was raised to 8.9 and the solution digested five more days. The undissolved triiodophenol (1.68 g.) was filtered off and the solution worked up in the usual way for thyroxine, of which 29 mg. of m. p. 227° (dec.) was obtained.

B. A mixture of 10 g. of diiodotyrosine dihydrate and 1.56 g. of diiodohydroxybenzoic acid,[9] was added to 250 cc. of 0.1 *N* sodium hydroxide. All the diiodotyrosine dissolved but an appreciable amount of the benzoic acid remained undissolved. The system was incubated at *p*H 8.8, 37.5°, for fifteen days with daily shaking. The acids were precipitated by acidification and extracted in the usual fashion for thyroxine with a negative result.

Identification of Thyroxine.—The sample of our synthetic thyroxine employed for analysis and physiological testing was purified[10] by conversion into the potassium salt, followed by regeneration of thyroxine. This procedure was repeated three times. The material was obtained as microcrystalline sheaves and rosets, m. p. 233° (dec.). The sample was dried before analysis over phosphorus pentoxide for one hour at 100° (1 mm.).

Anal. Calcd. for $C_{15}H_{11}O_4NI_4$: I, 65.34. Found: I, 65.10.

The material gave a deep red color with nitrous acid and ammonia,[11] a specific reagent for ortho-iodophenols.

The method of Gaddum[12] for the qualitative assay of thyroxine and thyroid active substances by the use of tadpoles was employed for physiological testing. Our material proved to be fully as active as crystalline thyroxine, obtained from E. R. Squibb and Sons, in producing metamorphosis in tadpoles (*rana sylvatica*).

Summary

Some experiments on the *in vitro* formation of thyroxine from diiodotyrosine are reported.

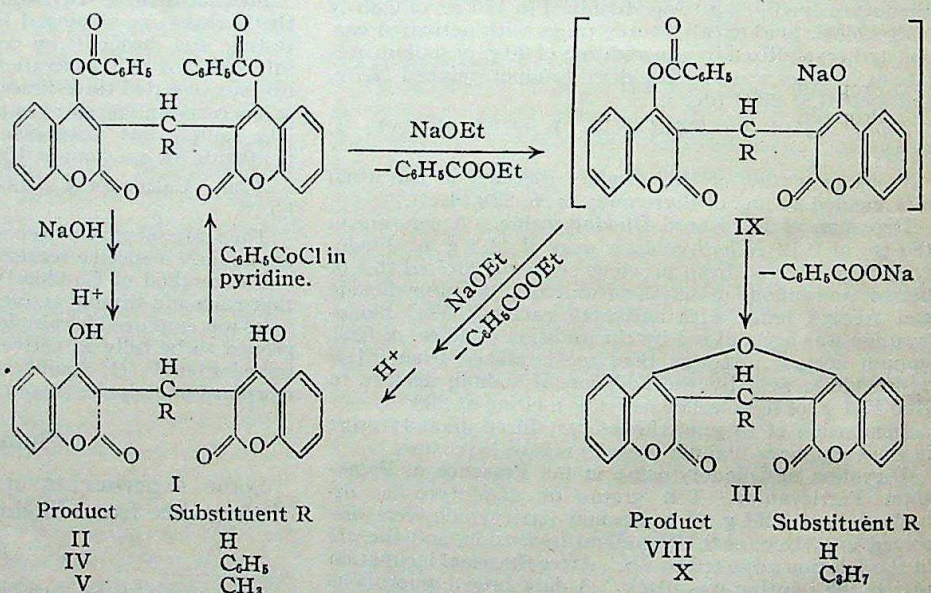
Studies on 4-Hydroxycoumarins. IV. Esters of the 4-Hydroxycoumarins[1]

BY MARK A. STAHMANN, LLOYD H. GRAF, CHARLES F. HUEBNER, SAUL ROSEMAN AND KARL PAUL LINK

The 3,3′-alkylidenebis- and -arylidenebis-(4-hydroxycoumarin)s (I) aldehyde condensation products of 4-hydroxycoumarin, may exist in an enol or keto form. In the enol form they may react with acid halides or acid anhydrides to esterify both enolic hydroxyl groups. This paper discusses the synthesis of some of these diesters, principally those of 3,3′-methylenebis-(4-hydroxycoumarin) (II). Since certain experiments of Link, *et al.*,[2] indicate that the 4-hydroxycoumarins may exert their anticoagulant action after degradation in the body to salicylic acid, salicylic acid esters are included. These compounds were prepared as part of the study dealing with the relation of structure in the 4-hydroxycoumarin group to anticoagulant activity.

II was readily converted to its acetate by treatment with acetic anhydride in pyridine.[3] In this study other diesters of II were prepared by a similar method.

When the methylene carbon atom of I carries a substituent other than hydrogen, treatment with acetic anhydride or acetyl chloride in pyridine does not give the esters. Dehydration occurs between the enolic hydroxyls with the formation 3,3′-alkylidene- or -arylidene-4,4′-epoxydicoumarins (III).[4] IV and V appear to be the most easily dehydrated bis-4-hydroxycoumarins. Both are dehydrated by refluxing with acetic anhydride, the former also being dehydrated by treatment with benzoyl chloride in pyridine. In contrast, VI and VII form stable diacetates when refluxed in acetic anhydride, and stable dibenzoates when treated with benzoyl chloride in pyridine. When a diester of I is treated with one equivalent of sodium ethoxide, a partial conversion to the unesterified parent substance and to the anhydride, III results. Studies with the dibenzoate of II revealed that the acyl residue is removed as sodium benzoate and ethyl benzoate. Since it has been shown that treatment of the monobenzoate and mono-(dimethylphosphate) of II with one mole of sodium ethoxide transforms them to the anhydro compound, 3,3′-methylene-4,4′-epoxydicoumarin (VIII), the conversion of the diesters of II to VIII (and in general the conversion of a diester of I to III) probably proceeds over a mono ester (IX) as an intermediate. This mono ester then loses one mole of acid (as the sodium salt) intramolecularly to form the dehydration product. These reactions can be illustrated by the following transformations of the dibenzoate of I



Product	Substituent R
II	H
IV	C_6H_5
V	CH_3
VI	C_2H_5
VII	C_3H_7

Product	Substituent R
VIII	H
X	C_3H_7

o-Hydroxy substituted salicylates of II were prepared by condensation with the appropriate acid chloride in pyridine. The di-(carbomethoxysalicylate) of II was used in an attempt to prepare the disalicylate, but all efforts to remove the carbomethoxy group (acidic and basic hydrolysis and ammonolysis) resulted in further hydrolysis and loss of the salicylate group. The remarkable lability of the salicylate linkage is illustrated by the conversion of the di-(carbomethoxysalicylate) of II to VIII by as weak a base as sodium acetate. In this reaction some carbomethoxysalicylic acid is formed. This indicates that the salicylate linkage is as labile as the readily hydrolyzed carbomethoxy group. The disalicylate of II was successfully prepared by hydrogenolysis of the di-(*o*-benzyloxybenzoate)

[a] Recrystallized from acetic acid. [b] Recrystallized from amyl alcohol. [c] Recrystallized from dioxane. [d] Recrystallized from β,β′-dichloroethyl ether. [e] Recrystallized from ethyl acetate.

at high pressure over Raney nickel. The crude product is separated from the small quantity of II which is produced in the reaction by repeated recrystallizations from dioxane. The *o*-benzyloxybenzoate of 3-phenyl-4-hydroxycoumarin is converted to 3-phenyl-4-hydroxycoumarin salicylate by hydrogenolysis at atmospheric pressure over palladium. Under these conditions the di-(*o*-benzyloxybenzoate) of II is unchanged. Table I lists the esters prepared.

The anticoagulant activity of the ester is lower than that of the parent 3,3′-alkylidenebis-(4-hydroxycoumarin). It appears that they act as anticoagulants after hydrolysis *in vivo*. A report on their activity will appear elsewhere.

Experimental

Esterification of 3,3′-Methylenebis-(4-Hydroxycoumarin) (I).[5]—All the diesters of II were prepared by slowly adding with vigorous stirring, 4 equivalents (100% excess) of the corresponding acid chloride to an 8% solution of the parent substance (usually about 2 g.) in dry pyridine (25 ml.) at 0°. After a few minutes the diesters usually crystallized from the reaction mixture. The mixture was allowed to stand for six hours at 25°, filtered, and washed with ethanol. In most cases, the crude product was recrystallized from cyclohexanone. The exceptions are noted in Table I.

(5) The 3,3′-alkylidenebis-(4-hydroxycoumarin)s were prepared by condensing 4-hydroxycoumarin with the corresponding aldehyde by the method of Sullivan, *et al.*, THIS JOURNAL, 65, 2288 (1943). 4-Hydroxycoumarin was prepared by the method of Stahmann, *et al.*, *ibid.*, 65, 2285 (1943).

Acetylation of I was accomplished by refluxing the parent substance (usually about 2 g.) with 12.5 parts of acetic anhydride (25 g.) for six hours. In some cases the diacetate crystallized out when the reaction mixture was cooled. When this did not take place the excess anhydride was decomposed by pouring the reaction mixture into six volumes of ice-water. The acetates then separated as crystalline products. IV and V were converted to the anhydrides by this procedure.

Benzoylation of 3,3′-Alkylidenebis-(4-hydroxycoumarin)s.—Benzoates were prepared by adding benzoyl chloride to a pyridine solution of the 3,3′-alkylidenebis-(4-hydroxycoumarin). 3,3′-Benzylidenebis-(4-hydroxycoumarin) underwent dehydration under these conditions, but all the other compounds which were studied formed stable dibenzoates which were recrystallized from cyclohexanone.

Action of Bases on Esters of I.—A mixture of 5 g. of **3,3′-methylenebis-(4-hydroxycoumarin) dipropionate,** and 0.76 g. of sodium ethoxide was suspended in 100 ml. of absolute ethanol and refluxed for twelve hours. The mixture was then filtered while hot, yielding 1.85 g. (49%) of VIII m. p. 317–321°. After recrystallization from cyclohexanone the melting point was 320–323°. II (1.55 g.) was recovered from the filtrate by acidification. Treatment of **3,3′-methylenebis-(4-hydroxycoumarin) diacetate** with sodium ethoxide under these conditions gave a lower yield of the dehydration product. Saponification of the esters of I with aqueous sodium hydroxide gave the unesterified parent substances.

Treatment of **3,3′-butylidenebis-(4-hydroxycoumarin) diacetate** with one equivalent of sodium ethoxide in boiling ethanol for twelve hours gave a 40% yield of X, m. p. 246°.

3,3′-Methylenebis-(4-hydroxycoumarin) di-(carbomethoxysalicylate) (1.0 g.) was dissolved in 45 ml. of boiling dioxane. A solution of 4.70 g. of hydrated sodium acetate in 25 ml. of water was added and the mixture was refluxed for ten hours. The following products were iso-

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

lated: 0.31 g. of VIII (63%); 0.19 g. of II (35%); 0.20 g. of salicylic acid and traces of carbomethoxysalicylic acid. One gram of the ester under the same conditions yielded 0.18 g. of VIII after refluxing for five minutes.

3,3′-Methylenebis-(4-hydroxycoumarin) dibenzoate (1.12 g.) in 12 ml. of absolute ethanol was refluxed with 2 moles of sodium ethoxide for fifteen hours. Two moles of 1 *N* hydrochloric acid was added and the combined precipitate of II and VIII was filtered off and II separated from VIII by means of its solubility in dilute NaOH. VIII (0.13 g.) m. p. 318–320° and II (0.56 g.) m. p. 290° were obtained. One mole of $NaHCO_3$ was added to the filtrate and after concentration to dryness *in vacuo*, the residue was acidified and extracted with ether. The acid fraction yielded 0.12 g. of benzoic acid, m. p. 118–120°, and the neutral solution yielded 0.02 g. of ethyl benzoate, b. p. 206–207°.

3,3′-Methylenebis-(4-hydroxycoumarin) Disalicylate.—The di-(*o*-benzyloxybenzoate) of I (3.9 g.) in 200 ml. of dioxane was hydrogenated at 1900 pounds pressure and 100° for three hours over Raney nickel. The catalyst was filtered off and the filtrate concentrated to dryness *in vacuo*. The residue was taken up in a small volume of hot dioxane and the insoluble residue of II was filtered from the hot solution. This process was repeated three times. After a final recrystallization from acetic acid the disalicylate of II melted at 223–225°, yield 0.7 g.

Anal. Calcd. for $C_{33}H_{20}O_{10}$: C, 68.75; H, 3.47. Found: C, 68.62; H, 3.68.

3-Phenyl-4-hydroxycoumarin Salicylate.—3-Phenyl-4-hydroxycoumarin *o*-benzyloxybenzoate (1.5 g.) was dissolved in 200 ml. of acetic acid–ethyl acetate (1:1) and hydrogenated at 1 atmosphere over palladium on charcoal. In thirty minutes one mole of hydrogen had reacted. The catalyst was filtered off and the filtrate concentrated to dryness *in vacuo*. The residue was recrystallized twice from ethyl acetate and once from benzene, m. p. 185–187°, yield 0.9 g.

Anal. Calcd. for $C_{22}H_{14}O_6$: C, 73.74; H, 3.63. Found: C, 73.72; H, 4.09.

Acknowledgment.—The authors are indebted to Dr. Ivan Wolff for carrying out the high pressure hydrogenation experiments and to Mr. Miyoshi Ikawa for some of the C and H determinations.

Summary

1. A series of diesters of some 3,3′-alkylidenebis-(4-hydroxycoumarin)s and of monoesters of 3-phenyl-4-hydroxycoumarin have been prepared.

2. The *o*-benzyloxybenzoic acid esters have been converted to the corresponding salicylic acid esters by hydrogenolysis.

3. The 3,3′-alkylidenebis-(4-hydroxycoumarin)s yield 3,3′-alkylidene-4,4′-epoxydicoumarins upon treatment with sodium ethoxide.

Studies on 4-Hydroxycoumarins. V. The Condensation of α,β-Unsaturated Ketones with 4-Hydroxycoumarin[1]

BY MIYOSHI IKAWA, MARK ARNOLD STAHMANN AND KARL PAUL LINK

It has been observed by Sullivan, *et al.*,[2] that when salicylaldehyde is condensed with 4-hydroxycoumarin (I), an α,β-unsaturated ketone is formed, which reacts with another molecule of I by a Michael type addition. Accordingly a study of the condensation of other α,β-unsaturated ketones with 4-hydroxycoumarin was undertaken. The Michael type condensation is usually carried out in an alcoholic medium in the presence of an acid[3] or base catalyst. According to Conner and McClellan[4] secondary amines (*e. g.*, piperidine) are the most suitable catalysts in that they seldom cause other than the normal condensation, but they are not as effective as the metallic alkoxides.

The condensation of benzalacetone with 4-hydroxycoumarin under the usual conditions in ethanol with either sodium ethylate, hydrochloric acid, or piperidine as catalyst gives a mixture of products. The mixture contains the normal condensation product and the cyclic ketal formed by reaction with ethanol. However, by carrying out the reaction in pyridine alone, satisfactory yields of the Michael condensation products can be obtained. The condensation of benzalacetone with 4-hydroxycoumarin can also be brought about by refluxing the two components with water without the addition of a catalyst.

The α,β-unsaturated ketones II–VIII which were condensed with 4-hydroxycoumarin (I) are indicated below along with the structures of the resulting condensation products (IX–XV). On treatment of the condensation products (IX–XV) with 4% hydrogen chloride in absolute methanol cyclic ketals (XVI–XXII) are formed. This reaction is rationalized on the basis that the Michael type condensation products are δ-hydroxy ketones and can therefore undergo ring closure to the corresponding cyclic hemi-ketals which are then methylated. An analogous example is the reversible ketal formation of 4-salicyl-butan-2-one.[5] Evidence for the cyclic ketal structure of the benzalacetone product XVIII resides in the following transformations. When XI was methylated with diazomethane, the methyl ether XXIII was obtained, which differed from the isomeric cyclic ketal XVIII. By refluxing XVIII with aqueous methanolic HCl the

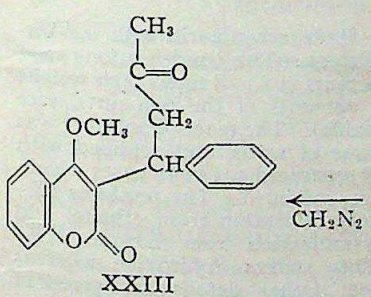
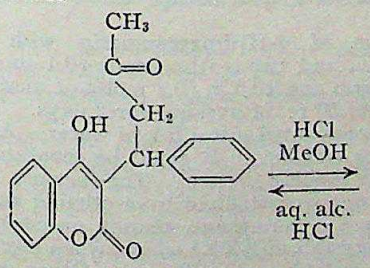
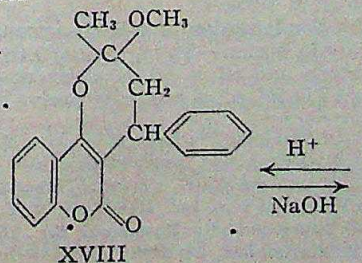
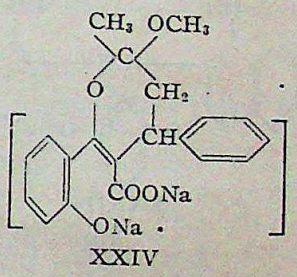
original material XI was recovered. On treatment of XVIII with aqueous methanolic NaOH an alkali soluble product was obtained, which on acidification gave XVIII with no trace of XI. The sodium hydroxide had evidently opened up









the lactone ring (product XXIV), which closed on acidification, without affecting the ketal system.

When α,β-unsaturated ketones derived from salicylaldehyde (XXV–XXVII) are condensed with 4-hydroxycoumarin, the Michael condensation products undergo spontaneous dehydration to give products with high melting points, which are alkali insoluble and have low solubility in ethanol (XXVIII–XXX).

A similar dehydration has been observed by Sullivan, *et al.*,[2] in the condensation of salicylaldehyde with 4-hydroxycoumarin.

Mesityl oxide (III) when condensed with 4-hydroxycoumarin gives rise to two compounds. In addition to the normal condensation product (X) there is obtained an alkali insoluble product. It can easily be separated from X by its solubility in hexane. The properties and elementary analysis indicate XXXI to be the structure for this compound.

The compound XV resulting from the condensation of benzal-*o*-hydroxyacetophenone (VIII) with 4-hydroxycoumarin has also been prepared by degrading 3,3′-benzylidenebis-(4-hydroxycou-

The α,β-unsaturated esters, ethyl cinnamate and ethyl benzalmalonate, as well as phorone, dibenzalacetone, and furfuralacetone, when refluxed in pyridine with 4-hydroxycoumarin failed to yield the Michael products.

The condensation products obtained from 4-hydroxycoumarin and α,β-unsaturated ketones as well as the corresponding cyclic ketals have relatively high anticoagulant properties when compared with 3,3′-methylenebis-(4-hydroxycoumarin). A report on their physiological activity will appear elsewhere.

Experimental

The α,β-Unsaturated Ketones and Esters.—The mesityl oxide (III), benzalacetone (IV), anisalacetone (V), *o*-hydroxybenzalacetophenone (XXVI), furfuralacetone, dibenzalacetone, ethyl cinnamate and phorone were obtained from the Eastman Kodak Company. Ethylideneacetone[7] (II), vanillylalacetone[8] (VI), benzalacetophenone[9] (VII), benzal-*o*-hydroxyacetophenone[10] (VIII), salicylalacetone[11] (XXV), and ethyl benzalmalonate[3] were prepared according to the references cited.

2,2′-Dihydroxybenzalacetophenone (XXVII).—Ten grams of salicylaldehyde and 10 g. of *o*-hydroxyacetophenone were dissolved in 300 cc. of water containing 10 g. of sodium hydroxide and kept at 85° for ten to fifteen hours. Upon acidification of the reaction mixture an oil was obtained which crystallized partially on standing. The product was filtered off and recrystallized from ethanol, m. p. 160° dec., yield 2.4 g. (14%).

Anal. Calcd. for $C_{15}H_{12}O_3$: C, 75.0; H, 5.0. Found: C, 75.0; H, 5.2.

The **dibenzoate** was prepared by heating XXVII with benzoyl chloride in pyridine and was recrystallized from ethanol, m. p. 114°.

Anal. Calcd. for $C_{29}H_{20}O_5$: C, 77.7; H, 4.5. Found: C, 77.5; H, 4.8.

The Condensation of 4-Hydroxycoumarin with α,β-Unsaturated Ketones and Esters.—The condensations were made by refluxing the reactants in 2 to 3 times their weight of pyridine. Equimolar amounts of the reactants were used (except for mesityl oxide). The reaction mixture was poured into a large volume of water and acidified with hydrochloric acid. An oil separated out in all cases which, if condensation took place, solidified. The products IX–XV were purified by recrystallization from ethanol and XXVIII–XXX by recrystallization from dioxane. IX–XV were soluble in dilute sodium hydroxide whereas XXVIII–XXX were not. Other details are given in Table I.

Condensation of 4-Hydroxycoumarin with Mesityl Oxide.—Sixteen and two-tenths grams (0.1 mole) of 4-hydroxycoumarin and 19.6 g. (0.2 mole) of mesityl oxide were refluxed in 50 cc. of pyridine for 2 days. The reaction mixture was poured into 1.5 l. of water. An oil was obtained which solidified. It could be separated into 2 fractions with boiling hexane. The hexane insoluble material (X) was recrystallized from ethanol and melted at 212° (3.3 g.). The hexane solution on concentration yielded large crystals of XXXI which, when recrystallized from hexane, melted at 93° (8.3 g.). Other details are included in Table I.

The Condensation of 4-Hydroxycoumarin with Benzalacetone in Water.—Thirty grams (0.18 mole) of 4-hydroxycoumarin and 27 g. (0.18 mole) of benzalacetone were refluxed in 500 cc. of water for twelve hours. The mixture

[a] Recrystallized from 4% hydrochloric acid in methanol. Should be thoroughly dried before taking a melting point. Gave a melting point depression when mixed with XV.

was cooled to 0° for twelve hours, whereupon a heavy gum separated out. The aqueous phase was decanted off and the gum recrystallized from an acetone–water mixture. The yield of XI was 27.5 g. (48%).

Treatment of the Michael Condensation Products with Methanolic Hydrogen Chloride.—One gram of the condensation products was refluxed with 10 g. of 4% hydrochloric acid in absolute methanol for the times indicated in Table II. The products were obtained either directly from the reaction mixture on cooling or by the addition of water, and were recrystallized from ethanol. Further details are given in Table II.

2-Methyl-2-ethoxy-4-phenyl-5-oxo-dihydropyrano(3,2-C)(1)benzopyran.—Two grams of XI was refluxed with 25 cc. of 3% hydrochloric acid in ethanol for twenty-two hours. Crystals were obtained on cooling (m. p. 135–152°). After two recrystallizations from ethanol 70 mg. of the desired product was obtained melting at 177°. It was also obtained in poor yield when 4-hydroxycoumarin and benzalacetone were refluxed in ethanol + sodium ethylate for two days.

Anal. Calcd. for $C_{21}H_{20}O_4$: C, 75.0; H, 6.0. Found: C, 75.0; H, 6.2.

Methylation of the Michael Condensation Products with Diazomethane.—The methyl ethers of IX, XI, XII, XIV were prepared by distilling an excess of ethereal diazomethane into an ether suspension of the compounds and allowing to stand for several hours. On methylation the solids went into solution. The excess diazomethane was decomposed by adding glacial acetic acid. The ether solutions were concentrated and the products, when solid, recrystallized from ethanol. The ethers of XII and IX could not be crystallized and were therefore distilled under low pressure. Further details are included in Table I.

Treatment of XVIII with Aqueous Methanolic Hydrochloric Acid.—One-half gram of XVIII was refluxed with 50 cc. of 10% hydrochloric acid (in 50% methyl alcohol) for six hours. The methanol was distilled off. The reaction mixture was made alkaline with sodium hydroxide, thoroughly triturated and filtered. The filtrate was acidified with hydrochloric acid and the precipitate obtained recrystallized from ethanol: 170 mg. of a product was obtained which melted at 159–161° and showed no m. p. depression when mixed with XI.

Treatment of XVIII with Aqueous Methanolic Sodium Hydroxide.—One-half gram of XVIII was refluxed with 50

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

cc. of 10% sodium hydroxide (in 50% methyl alcohol) for six hours. The methyl alcohol was distilled off. An oil was obtained which on the addition of water dissolved completely. Upon acidification of the aqueous solution with hydrochloric acid an oil separated which solidified. This acidic solution including the solid was again made alkaline with sodium hydroxide, thoroughly triturated and filtered. This time some insoluble material remained. The filtrate was acidified with hydrochloric acid and 97 mg. of an oily precipitate was obtained from which no XI could be isolated. From the sodium hydroxide insoluble solid the starting material XVIII was isolated.

Acknowledgment.—We are indebted to Mr. Lloyd Graf for some of the C and H determinations and to Dr. Charles F. Huebner for the many valuable suggestions that he contributed to this work.

Summary

1. 4-Hydroxycoumarin has been condensed with the following α,β-unsaturated ketones by the Michael type addition: ethylideneacetone, mesityl oxide, benzalacetone, anisalacetone, vanillylalacetone, benzalacetophenone, benzal-*o*-hydroxyacetophenone, salicylalacetone, salicylalacetophenone, and 2,2′-dihydroxybenzalacetophenone. The condensations were carried out by refluxing in pyridine.

2. The condensation products from salicylalacetone, salicylalacetophenone, and 2,2′-dihydroxybenzalacetophenone undergo spontaneous dehydration to 7-substituted 6-oxo-(1)benzopyrano(4,3-b)(1)-benzopyrans.

3. The other condensation products (not included above) were converted to the corresponding cyclic methyl ketals by refluxing in methanolic hydrogen chloride.

Studies on 4-Hydroxycoumarins. VI. Glucosides of 4-Hydroxycoumarins[1]

BY CHARLES F. HUEBNER, SULO A. KARJALA, WILLIAM R. SULLIVAN AND KARL PAUL LINK

Glucosides of the anticoagulant, 3,3′-methylenebis-(4-hydroxycoumarin)[2] and of related 4-hydroxycoumarins were desired for use in the study of the relationship between chemical structure and hypoprothrombinemia inducing capacity. Glucosides of the keto-enol 4-hydroxycoumarins have heretofore not been prepared. Certain chemical properties of these glucosides are worthy of note. They are readily hydrolyzed by alkali and some of them undergo cleavage to the aglucone when their acetates are subjected to catalytic deacetylation in methanol by metal alkoxides. Because of the uniqueness of this behavior, the deacetylation reaction was studied in detail.

When stable silver salts of the enol aglucones were realizable they were treated with acetobromoglucose to form the acetylated glucosides. A modification of Robertson's method for phenol β-glycosides[3] was applied to the cases in which the silver salts of the enol aglucones were unstable. No reaction occurs between these enols and acetobromoglucose in the presence of silver oxide unless a catalytic quantity of quinoline is included. In all probability quinoline hydrobromide is the first product of the coupling and the excess of silver oxide regenerates the catalyst. If more than a trace of quinoline is used, the reaction proceeds with decomposition and the production of uncrystallizable sirups.

4-Hydroxycoumarin glucoside tetraacetate (I), 4-hydroxy-6-methylcoumarin glucoside tetraacetate (II), 3-phenyl-4-hydroxycoumarin glucoside tetraacetate (III), and 3,3′-methylenebis-(4-hydroxycoumarin) monoglucoside tetraacetate (IV) were prepared by the silver salt method. The modified Robertson method was used in the preparation of 3,3′-methylenebis-(4-hydroxycoumarin) diglucoside octaacetate (V) and 3-[6-oxo(1)benzopyrano(4,3-b)(1)benzopyran-7-yl]-4-hydroxycoumarin glucoside tetraacetate (VI).

Because of the method of preparation and the substantial negative rotation of all except two of these glucosides (IV and V), the β-configuration can be assigned with some confidence.

All the glucosides and glucoside acetates involving the 4-hydroxycoumarins reduce boiling Fehling solution within two minutes. The acidic nature of 4-hydroxycoumarin ($K_a = 2.3 \times 10^{-6}$) probably accounts for this alkaline hydrolysis. Hibbert[4] and co-workers have shown that the rate of alkaline hydrolysis of phenol glycosides increases with the order of acidity of the parent phenol.

The deacetylation of I and II was accomplished by the catalytic barium methoxide procedure. No method was found for effecting simple deacetylation of the glucoside acetates in which there are substituents on position 3 of the coumarin residue. When III was catalytically deacetylated, the rate of mutarotation gradually fell and the rotation became constant after two weeks. At least 80% of the starting compound had been

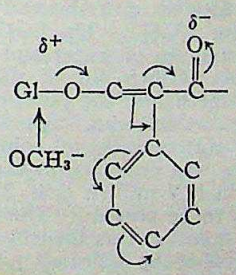
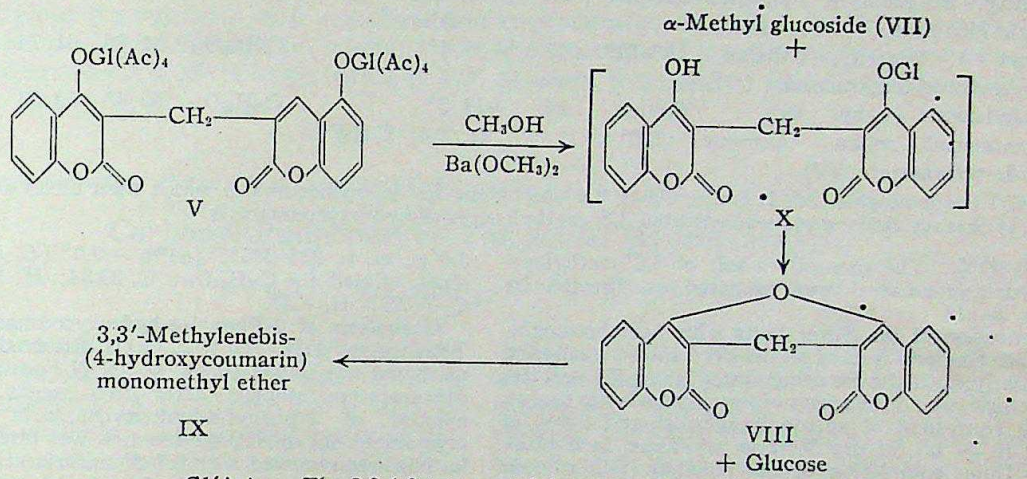
converted to 3-phenyl-4-hydroxycoumarin and α-methyl glucoside (VII).

Isbell[5] has recently pointed out that the cleavage of the sugar-oxygen bond in enol glycosides is favored over fission at the aglucone-oxygen bond. The methanolysis of III furnishes experimental proof for this suggestion. The formation of 3-phenyl-4-hydroxycoumarin rather than 3-phenyl-4-methoxycoumarin and the Walden inversion accompanying the production of VII indicate the point of fission. Conversely, methanolysis of sugar esters usually occurs at the aglycone–oxygen bond with no inversion and formation of the methyl ester of the acid involved in the sugar ester. The presence of the phenyl and carbonyl groups in III favors the indicated electronic shift. The glucosidic carbon is the positive center of this polarized molecule and it is attacked by the methoxyl anion with cleavage of the sugar–oxygen bond.



III

When the catalytic deacetylation of V was attempted, 3,3′-methylene-4,4′-epoxydicoumarin (VIII) and some 3,3′-methylenebis-(4-hydroxycoumarin) monomethyl ether (IX) were obtained instead of the glucoside.[6] Recognizing that III yields 3-phenyl-4-hydroxycoumarin and VII under these conditions, the formation of VIII and IX can be attributed to the following reactions. One glucose residue is liberated initially by alcoholysis yielding VII and 3,3′-methylenebis-(4-hydroxycoumarin) monoglucoside (X). A ring closure of the type noted in mono esters of 3,3′-methylenebis-(4-hydroxycoumarin)[6] then produces VIII and glucose. Part of VIII is then converted to IX by the alkoxide as indicated previously.[6] The production of IX in this manner is preferred over formation by methanolysis of X because the latter reaction would be expected to yield as the methylated component, VII rather than IX.



Gl(Ac)$_4$ = The 2,3,4,6-tetraacetylglucopyranose residue

Additional support for the above mechanism was obtained from a study of the glucose content of the resulting reaction mixture. One half of the theoretical amount was present as free glucose based on the exhibited reducing power. The second half of the reducing power could be liberated by acid hydrolysis, indicating the presence of a methyl glucoside in the reaction mixture. The tetraacetate (IV) of the intermediate (X) was synthesized and it showed the predicted properties. It gave VIII and IX on catalytic deacetylation, and the amount of IX increased as larger amounts of catalyst were used. This further substantiates the mechanism of formation of IX, since in the conversion of VIII to IX the amount of IX produced parallels mole for mole the amount of metal alkoxide used. IV can also be converted to VIII by simply dissolving it in pyridine.

Experimental

Preparation of the Silver Salts of the 3-Substituted-4-Hydroxycoumarins.—The following method was used for the silver salts, with a slight modification in the case of 4-hydroxycoumarin. The 3-substituted-4-hydroxycoumarin was dissolved in one equivalent of 1.5 *N* aqueous sodium hydroxide and one equivalent of silver nitrate plus 2% excess, dissolved in a small amount of water, was added with vigorous stirring. The gelatinous, white silver salt precipitated immediately. It was filtered and resuspended in water, washed thoroughly with water, pressed dry on the funnel and washed once with ethanol. Precautions were taken to work in a feeble light. Since the silver salt of 4-hydroxycoumarin is appreciably soluble in water it was not washed but recrystallized from the minimum volume of water. The salts were dried over calcium chloride *in vacuo*, finely pulverized and dried again at 45° under 0.05 mm. pressure over phosphorus pentoxide.

4-Hydroxycoumarin glucoside	Methanol	201–202	90	−106° (*C*, 16; CH_3OH)	$C_{15}H_{16}O_8$	55.55	55.72	4.94	4.94
4-Hydroxy-6-methylcoumarin glucoside tetraacetate (II)	Ethanol	168–170	36	−24.9° (*C*, 2; C_6H_6)	$C_{24}H_{26}O_{12}$	56.91	57.11	5.14	5.35
4-Hydroxy-6-methylcoumarin glucoside	Pyridine water	223–224	90	−86° (*C*, 0.75) pyridine	$C_{16}H_{18}O_8$	56.80	56.98	5.32	5.32
3-Phenyl-4-hydroxycoumarin glucoside tetraacetate (III)	Ethanol	156–158	47	−58.4° (*C*, 3.2; C_6H_6)	$C_{29}H_{28}O_{12}$	61.35	61.74	4.94	5.12
3,3′-Methylenebis-(4-hydroxycoumarin) monoglucoside tetraacetate (IV)	Dry benzene	Sinters 185[a]	25	+14.0° (*C*, 2.5; C_6H_6)	$C_{33}H_{30}O_{15}$	59.45	59.53	4.50	4.67

[a] At 185° the monoglucoside is converted to 3,3′-methylene-4,4′-epoxydicoumarin which then melts at 290°. This behavior is characteristic of monosubstituted 3,3′-methylenebis-(4-hydroxycoumarin)s.[6]

yields 80–90%. The monosilver salt of 3,3′-methylenebis-(4-hydroxycoumarin) was prepared as directed by Huebner, *et al.*[6]

Condensation of the Silver Salts with Acetobromoglucose.—The condensations of all the silver salts were carried out similarly until the resulting sirupy glucoside acetates were crystallized. Five grams of the silver salt was shaken with 0.9 equivalent of acetobromoglucose and 1.0 g. of Drierite in 50 ml. of dry benzene contained in a black bottle. Upon completion of the reaction (two to four days), the silver salts were centrifuged off and washed with hot benzene. The benzene solution was concentrated *in vacuo* yielding a sirup. These sirups were crystallized from a suitable solvent as indicated in Table I. Deacetylation of I and II was accomplished by the method of Brauns[7] (Table I).

Preparation of 3,3′-Methylenebis-(4-hydroxycoumarin) Diglucoside Octaacetate (V).—A solution of 25 g. of acetobromoglucose in 150 ml. of dry benzene was shaken with 10 g. of 3,3′-methylenebis-(4-hydroxycoumarin), 8 g. of silver oxide, 10 g. of Drierite and 4 drops of quinoline for four days. The silver salts and unreacted 3,3′-methylenebis-(4-hydroxycoumarin) were centrifuged off and washed with cold benzene. The combined benzene fraction was concentrated to half its volume, and cooled. The small amount of 3,3′-methylenebis-(4-hydroxycoumarin) that crystallized was filtered off. The benzene solution was extracted with cold 1% sodium hydroxide, then with cold 1% hydrochloric acid solution, and finally with ice water. It was dried over sodium sulfate and concentrated to a sirup. The sirup was dissolved in a minimum of ethanol, filtered from some 3,3′-methylenebis-(4-hydroxycoumarin) which had crystallized out, and stored at 0°. After seven months, partial crystallization had taken place. These crystals were dissolved in the minimum of hot ethanol, the solution filtered while hot and, on cooling, 1 g. of hair-like crystals, m. p. 160–165°, was deposited. After eight crystallizations from ethanol the rotation and m. p. remained constant, m. p. 167–168°; $(\alpha)^{30}D$ + 58.0° (*C*, 2.5; benzene). *Anal.* Calcd. for $C_{47}H_{48}O_{24}$: C, 56.62; H, 4.84. Found: C, 56.97; H, 4.50.

Preparation of 3-[6-Oxo(1)benzopyrano(4,3-b)(1)benzopyran-7-yl]-4-hydroxycoumarin Glucoside Tetraacetate (VI).—A mixture of 4 g. of 3-[6-oxo(1)benzopyran(4,3-b)(1)benzopyran-7-yl]-4-hydroxycoumarin, 12 g. of acetobromoglucose, 5 g. of silver oxide, 5 g. of Drierite, and 5 drops of quinoline was shaken for twenty-four hours. The procedure for working up the reaction mixture was the same as that given for V. The sirup obtained after concentration was rubbed with a small amount of hot ethanol and crystallization occurred. This crop was recrystallized from pyridine diluted with water; yield 3.0 g., m. p. 234–235°: $(\alpha)^{25}D$ −9.0° (*C*, 8; pyridine). *Anal.* Calcd. for $C_{39}H_{32}O_{15}$: C, 63.24; H, 4.32. Found: C, 63.27; H, 4.38.

Alcoholysis of 3-Phenyl-4-hydroxycoumarin Glucoside Tetraacetate (III).—To 10 g. of III dissolved in 300 ml. of methanol was added 10 ml. of 0.2 *N* barium methoxide. Mutarotation stopped after two weeks. The small amount of 3-phenyl-4-hydroxycoumarin which had crystallized out during the reaction was filtered off. The barium was removed with 0.1 *N* sulfuric acid. An equal volume of water was added, the solution concentrated to 50 ml. and the aglucone that crystallized during the concentration was filtered off; 3.4 g. of 3-phenyl-4-hydroxycoumarin was obtained, (81%), m. p. 233–236°. The filtrate was concentrated to a sirup and dissolved in a minimum of hot ethanol. On cooling 1.2 g. of α-methylglucoside (VII) crystallized, m. p. 165–167°; $(\alpha)^{30}D$ +159° (*C*, 1.2; water).

Alcoholysis of 3,3′-Methylenebis-(4-hydroxycoumarin) Monoglucoside Tetraacetate (IV).—In 10 ml. of dry methanol to which had been added 0.2 ml. of 0.5 *N* sodium methoxide solution, 87.8 mg. of IV was refluxed for one half hour; needles of the anhydride VIII crystallized out in the first minute. VIII, which is practically insoluble in methanol, was filtered on a sintered glass funnel, the yield being 23.2 mg. (55%). The methanol filtrate was poured into two volumes of water and a flocculent precipitate of IX was thrown out of solution. After recrystallizing from methanol, the product melted at 171–172°, yield 24 mg. A reducing sugar determination[8] on an aliquot of the water–methanol solution showed that 20.2 mg. of glucose was produced in the reaction. After hydrolysis at 95° in 1 *N* sulfuric acid, 22.0 mg. of glucose (93%) was shown to be present. The reducing sugar in an aliquot of the solution was identified by the osazone method.[9] If one half of the indicated quantity of $NaOCH_3$ was used the yield of VIII was increased to 86%.

Alcoholysis of 3,3′-Methylenebis-(4-hydroxycoumarin) Diglucoside Octaacetate (V).—In 4 ml. of dry methanol to which had been added 0.1 ml. of 0.2 *N* barium methoxide, 67.8 mg. of V was refluxed for one half hour. The technique of separation was the same as above; 12.7 mg. (59%) of VIII was formed. Before the acid hydrolysis, 13.0 mg. of reducing sugar (as glucose) was present (theoretical for one mole of glucose from V is 12.2 mg.). After acid hydrolysis 24.0 mg. of glucose was present (theoretical for two moles of glucose is 24.4 mg.).

Summary

1. A series of glucosides of the 4-hydroxy-

coumarins has been prepared. The glucoside acetates of 4-hydroxycoumarin, 4-hydroxy-6-methylcoumarin, 3-phenyl-4-hydroxycoumarin and the monoglucoside acetate of 3,3′-methylenebis-(4-hydroxycoumarin) were prepared by treating the enol silver salts with acetobromoglucose.

2. The diglucoside octaacetate of 3,3′-methylenebis-(4-hydroxycoumarin) and of 3-[6-oxo(1)-benzopyrano(4,3-b)(1)benzopyran-7-yl]-4-hydroxycoumarin glucoside tetraacetate were prepared by coupling the aglucone with acetobromoglucose in the presence of catalytic amounts of quinoline and an excess of silver oxide.

3. The two 4-hydroxycoumarin glucoside tetraacetates unsubstituted on position 3 were successfully deacetylated by the catalytic barium methoxide procedure.

4. The 3-substituted-4-hydroxycoumarin glucoside acetates underwent alcoholysis with the removal of the glucose residue involving a Walden inversion. A course of reaction in which both glucoside residues were removed from 3,3′-methylenebis-(4-hydroxycoumarin) diglucoside octaacetate with the formation of 3,3′-methylene-4,4′-epoxydicoumarin, and 3,3′-methylenebis-(4-hydroxycoumarin) monomethyl ether is proposed

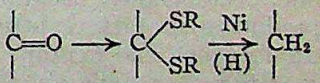
Carbonyl Reduction by Thioacetal Hydrogenolysis

BY M. L. WOLFROM AND J. V. KARABINOS

In connection with another problem being pursued in this Laboratory, we were interested in convenient methods of synthesis for 1- and 2-desoxy sugar alcohols. The present methods are laborious and are not always of general applicability. The reduction of the 2-desoxyaldoses, synthesized through the glycals, constitutes the only present synthesis for the 2-desoxy sugar alcohols.[1] More numerous are the procedures for the preparation of the 1-desoxy sugar alcohols. These may be prepared through the reduction of a terminal halide in a sugar alcohol and special methods exist for obtaining these halides by utilizing the preferential reactivity of the primary alcohol function.[2] The 1-desoxy sugar alcohols are also preparable by reduction of the ω-desoxy-aldoses, either naturally occurring or synthesized[3] from the aldoses by reduction therein of a terminal halide group. In the acyclic sugar derivatives, a diisopropylidene-*aldehydo*-pentose has reacted with methyl Grignard reagent to produce, after hydrolysis of the isopropylidene groups, a 1-desoxy-hexitol.[4] Reduction of the first carbon of the diazomethyl ketones[5] of the acyclic sugar acetates or the reaction of diazomethane with *aldehydo*-sugar esters,[6] led to the synthesis of 1-desoxy-*keto*-sugar acetates which on reduction with subsequent deacetylation, led to the synthesis of a mixture of two 1-desoxy sugar alcohols.[7]

The remarkable discovery of the simultaneous desulfurizing and reducing action of Raney nickel[8] by Bougault, Cattelain and Chabrier[9] and its subsequent extension by Mozingo and co-workers,[10] offered the promise of establishing a simple and direct route to the 1- and 2-desoxy sugar alcohols. The French workers had demonstrated this reaction with the thiocarbonyl compounds, thiols, disulfides and heterocyclic sulfur (thiophene); the latter group had extended the reaction to sulfides, sulfoxides and sulfones; and Richtmyer, Carr and Hudson[11] had ememployed reductive hydrolysis with Raney nickel in their synthesis of polygalitol (1,5-anhydro-(*levo*)-sorbitol) tetraacetate from the acetates of glucothiopyranose and its disulfide. We have now found that this reaction is applicable to thioacetals, leading to easy reduction to the hydrocarbon stage.



The other products of the reaction are presumably sulfide sulfur (verified in the present work) and the hydrocarbon RH. Following the directions of Mozingo and co-workers, we employed dilute ethanol as the solvent. Under these conditions we have noted that acetaldehyde is formed. This is to be expected from the dehydrogenating action of Raney nickel in the liquid phase,[12] but it may play some part in the reaction by furnishing a source of active hydrogen.

D-Galactose diethyl thioacetal (mercaptal) was reduced to L-fucitol but a higher yield (66%) was obtained when the pentaacetate was employed. In view of the ready availability of the aldose thioacetals and their acetates, this procedure gives easy access to the 1-desoxy sugar alcohols. Extension to D-glucose diethyl thioacetal pentaacetate yielded L-gulomethylitol pentaacetate.

The high acidity required for aldose thioacetal formation destroys the acid-sensitive ketoses[13] and thus the thioacetals of the ketoses cannot be obtained directly from the sugars. They are obtainable from the *keto*-acetates[14] and recently a general method for the synthesis of *keto*-acetates has been devised.[15] D-Fructose diethyl thioacetal (mercaptole) pentaacetate was subjected to hydrogenolysis and yielded 2-desoxy-(*levo*)-sorbitol pentaacetate, albeit in rather low yield. Even with this low yield, the present method is preferable to the former procedure[1] and it is possible that future work may lead to better reaction conditions and higher yields. Deacetylation to the parent alcohol, while not carried out in the present work, is a well-known and relatively simple process.

The above-described reduction of a carbonyl to a methylene group by means of neutral Raney nickel in dilute alcohol, offers promise in general organic preparative work. A previous reduction of a mercaptal with zinc dust and alkali is recorded[16] and recently the desulfurizing action of Raney nickel alloy and alkali in the hydrogenolysis of aromatic sulfonic acids has been described.[17] The present general methods for the reduction of a carbonyl group to the methylene stage are the Clemmensen reduction, the Wolff–Kishner method, high-pressure catalytic methods and electrolytic reduction. The thioacetal hydrogenolysis procedure adds an alternative method and descriptions are made of applications to benzaldehyde, benzophenone, acetophenone, heptanal and heptanone-2, producing in turn, toluene, diphenylmethane, ethylbenzene and heptane. The intermediate thioacetals are readily obtained and were used without purification.

Experimental

Preparation of Raney Nickel Catalyst.—The nickel catalyst was prepared from nickel–aluminum alloy (Raney) according to the procedure of Mozingo and co-workers,[18] employing their later-described[10] modifications. The nickel should be washed well to remove all traces of alkali

A. Preparation of Desoxyhexitols

1-Desoxy-D-galactitol (L-Fucitol) Pentaacetate (Procedure A).—To 1.00 g. of D-galactose diethyl thioacetal (mercaptal) pentaacetate[19] was added 100 cc. of 70% ethanol and 15 g. of Raney nickel catalyst and the mixture was refluxed for five hours. At the end of this period a filtered test portion of the solution no longer evolved ethyl mercaptan on acidification with hydrochloric acid and heating. The nickel was removed by centrifugation and was washed several times with hot ethanol by centrifugation followed by decantation, and the centrifugates were combined. (It was noted that the nickel residue evolved hydrogen sulfide (tested with lead acetate paper) on treatment with dilute hydrochloric acid.) These were concentrated under reduced pressure at 40° to a volume of 10–20 cc., whereupon the product crystallized and was collected by filtration after cooling in an ice-bath; yield 0.55 g. (66%), m. p. 118–121°. Pure material was obtained on one recrystallization from ethanol; m. p. 126–127° unchanged on admixture with authentic L-fucitol pentaacetate of m. p. 126–127°, spec. rot. +20.9° (17°, *c* 2.8, $CHCl_3$, D line). The constants recorded[20] for L-fucitol pentaacetate are: m. p. 127°, spec. rot. +20.5° (25°, *c* 3.0, $CHCl_3$, D line).

1-Desoxy-D-glucitol (1-Desoxy-(*levo*)-sorbitol, L-Gulomethylitol) Pentaacetate.—D-Glucose diethyl thioacetal pentaacetate[21] (0.50 g.) was subjected to hydrogenolysis as in the preceding experiment (procedure A) and the reaction product was isolated in the same manner; yield 0.25 g. (60%), m. p. 98–101°. Pure material was obtained on further crystallization from ethanol; m. p. 102–103°, m. p. 102–104° on admixture with authentic L-gulomethylitol pentaacetate of m. p. 103–104°, spec. rot. +22° (17°, *c* 0.7, $CHCl_3$, D line), +20° (20°, *c* 0.5, MeOH, D line). The recorded[4] constants for L-gulomethylitol pentaacetate are: m. p. 105–106°, spec. rot. +21° (21°, *c* 2, MeOH, D line).

2-Desoxy-D-mannitol (2-Desoxy-(*levo*)-sorbitol, 2-Desoxy-D-glucitol) Pentaacetate.—D-Fructose diethyl thioacetal pentaacetate[14] (500 mg.) was subjected to hydrogenolysis as in procedure A except that the time of reaction was decreased to three hours. On concentration of the centrifugate under reduced pressure there was obtained a sirup (300 mg.) which crystallized with some difficulty; yield 82 mg. (20%), m. p. 68–70°, spec. rot. +31° (24°, *c* 2.8, $CHCl_3$, D line). Pure material was obtained on further crystallization from ether–petroleum ether; m. p. 85–87° unchanged on admixture with an authentic specimen of 2-desoxy-(*levo*)-sorbitol of m. p. 86–87°. The constants for this substance are: m. p. 86–87°, spec. rot. +35° (25°, *c* 3, $CHCl_3$, D line).[22]

1-Desoxy-D-galactitol (L-Fucitol) from D-Galactose Diethyl Mercaptal.—D-Galactose diethyl thioacetal[19] (1.00 g.) was subjected to hydrogenolysis as described in procedure A except that the reaction time was decreased to one hour and the nickel residues were washed thoroughly with water. The centrifugate was concentrated under reduced pressure to a thin sirup which was brought to crystallization by the addition of absolute ethanol; yield 140 mg. (24%) in 2 crops, m. p. 149–151°. Pure material was obtained on recrystallization from absolute ethanol; m. p. 152–153° unchanged on admixture with authentic L-fucitol of like m. p., spec. rot. +4.4° (25°, *c* 3, saturated aqueous borax solution, D line). The recorded[23] constants for L-fucitol are: m. p. 153–154°, spec. rot. +4.7° (20°, *c* 3, aqueous borax (1 part borax: 10 parts water) solution).

B. Thioacetal Formation and Hydrogenolysis of Several Simple Aldehydes and Ketones

Thioacetal Formation.—The aldehyde or ketone (0.1 mole) was added slowly with cooling (ice-bath), to a mixture of 20 cc. (*ca.* 2.7 moles) of ethyl mercaptan, 2.5 g. of freshly fused zinc chloride and 2 g. of anhydrous sodium

Digitized by Arya Samaj Foundation Chennai and eGangotri

sulfate, contained in a glass-stoppered bottle. The aldehydes reacted more vigorously than the ketones. The mixture was maintained at 5° for twenty hours and then at room temperature for four hours, whereupon it was poured into 50 cc. of ice and water in a separatory funnel. The water-insoluble layer was washed consecutively with 10% aqueous sodium hydroxide and water, and dried with sodium sulfate. This crude product was used directly for the hydrogenolysis. The yields were nearly quantitative.

Hydrogenolysis of Benzaldehyde Diethyl Thioacetal.—The hydrogenolysis was carried out on 0.01 mole of the thioacetal as described in procedure A. After a reaction period of two hours, the mixture was diluted with 300 cc. of water and distilled until the cessation of ethanol distillation. The process was repeated on the distillate and to the azeotrope distilling over was added sufficient water to separate the toluene which was collected, dried and distilled; yield 0.60 g. (65%), b. p. 110° at 750 mm., $n^{25}D$ 1.498. The generally accepted constants for toluene are: b. p. 111° at 760 mm., $n^{16}D$ 1.4978.

Hydrogenolysis of Acetophenone Diethyl Thioacetal.—The thioacetal (0.01 mole) was treated in the manner described above for the hydrogenolysis of benzaldehyde diethyl thioacetal; yield of ethylbenzene 0.70 g. (66%), b. p. 134° at 750 mm., $n^{25}D$ 1.498. The accepted constants for ethylbenzene are: b. p. 136° at 760 mm., $n^{14.5}D$ 1.4983.

Hydrogenolysis of Heptanone-2 Diethyl Thioacetal.—The hydrogenolysis was carried out on 0.01 mole of the thioacetal as described in procedure A. The reaction product was distilled out of the reaction mixture, the distillate was diluted with a large volume of water and extracted twice with ether. The ether extract was washed with 50% calcium chloride aqueous solution, then with water, dried over sodium sulfate and distilled; yield 0.50 g. (50%), b. p. 96–100° at 750 mm., $n^{25}D$ 1.390. The accepted constants for heptane are: b. p. 98.4° at 760 mm., $n^{23}D$ 1.3867.

Hydrogenolysis of Heptanal Diethyl Thioacetal.—The thioacetal (0.01 mole) was treated in the manner described above for the hydrogenolysis of heptanone-2 diethyl thioacetal; yield of heptane 0.40 g. (40%), b. p. 98–100° at 750 mm., $n^{25}D$ 1.395.

Hydrogenolysis of Benzophenone Diethyl Thioacetal.—The thioacetal (0.01 mole) was subjected to hydrogenolysis as described in procedure A. The sirup obtained on solvent removal from the centrifugate was dissolved in ether, dried with sodium sulfate, and the solvent removed; yield 1.3 g. (77%), b. p. 255° at 740 mm. A boiling point of 261–262° at 760 mm. is recorded for diphenylmethane. Further identification was afforded by the preparation[24] of the 2,4,2′,4′-tetranitro derivative which after two recrystallizations from glacial acetic acid melted at 170–173° (accepted value 172°).

Identification of Acetaldehyde Formed During the Hydrogenolysis.—In one of the experiments (the hydrogenolysis of heptanal diethyl thioacetal) the gases escaping from the top of the condenser during the refluxing were bubbled through 5 cc. of a solution of 2,4-dinitrophenylhydrazine (1 g. of the hydrazine dissolved in 7 cc. of concentrated sulfuric acid, then diluted with 100 cc. of methanol followed by 25 cc. of water). After one hour, crystalline needles separated which after two recrystallizations from ethyl acetate–ethanol were identified as acetaldehyde 2,4-dinitrophenylhydrazone by melting point (161–163°) and mixed melting point (unchanged) with an authentic sample (m. p. 162–164°).

Summary

1. It is shown that the carbonyl group of aldehydes and ketones may be reduced to the hydrocarbon stage by the hydrogenolysis of their thioacetals with Raney nickel in dilute ethanol solution.

2. Examples are cited for the diethyl thioacetals of *aldehydo*-D-galactose (and its pentaacetate), *aldehydo*-D-glucose pentaacetate, *keto*-D-fructose pentaacetate, benzaldehyde, heptanal, heptanone-2, acetophenone and benzophenone.

Pyrolysis of Nicotine to Myosmine

BY C. F. WOODWARD, ABNER EISNER AND PAUL G. HAINES

Two new processes have been developed in this Laboratory for the preparation of nicotinic acid from nicotine. One involves the catalytic, vapor-phase, air oxidation of nicotine to nicotinonitrile,[1b] which is hydrolyzable to either nicotinic acid[2] or nicotinamide,[3] whereas the second employs the catalytic, liquid-phase, sulfuric acid oxidation of nicotine directly to nicotinic acid.[4]

It appeared that an alternative method could be employed for a stepwise conversion of nicotine to nicotinic acid which would utilize a preliminary pyrolysis of the alkaloid to β-alkyl and β-alkenyl pyridines prior to oxidation of these products.

This paper discloses the results obtained in a study of the pyrolytic reaction. Preliminary experiments indicated that the yields of such products as β-picoline, β-ethylpyridine, and β-vinylpyridine were too low to justify the utilization of this reaction in the preparation of nicotinic acid from nicotine. This investigation revealed, however, that myosmine (III) can be produced in fair yields, and most of the data herein reported were obtained in an attempt to determine the optimum pyrolytic conditions for the production of this rare alkaloid.

Brief references to the pyrolysis of nicotine have been made previously by Cahours and Étard,[5] but the two experiments reported were

apparently only incidental to the investigation of the reaction of nicotine with sulfur and selenium. In these procedures, nicotine was passed through an iron pipe filled with porcelain chips while the reactor was "heated to dark red" on one occasion and to "cerise red" in the other experiment. In addition to appreciable quantities of unchanged nicotine, these investigators obtained pyridine, "picoline," and a "collidine," which was later postulated to be "a propyl pyridine," since it was oxidized to the same acid obtained by the oxidation of nicotine. It was further reported that the "propyl pyridine fraction tended to form resinous polymerides." In view of this observation, it appears that the product under consideration contained at least small amounts of a β-alkenyl pyridine.

The present investigation has shown that β-vinylpyridine is produced in the pyrolysis of nicotine (I), but in general the pyrolytic fission of nicotine results in the formation of a variety of products rather than a high yield of any one material. The N-methylpyrrolidine nucleus of the nicotine molecule appears to be the more susceptible to pyrogenic disintegration, since the following pyrolysis products were obtained: ammonia, methylamine, hydrogen cyanide, pyridine, β-picoline, β-ethylpyridine, β-vinylpyridine, 3,2′-nicotyrine (II), myosmine (III), and a high-boiling fraction not yet identified.

The pyrolysis of nicotine over quartz at 570° produced a fair yield of myosmine but only small quantities of other identifiable reaction products. Pyridine was not isolated under these experimental conditions, but it was produced in low yields when the pyrolysis temperature was increased to 700° or when the quartz contact material was replaced by activated alumina at 500°. These latter conditions were too drastic for the obtention of myosmine.

In addition to being the principal pyrolysis product obtained with a quartz contact material at 570°, myosmine was of particular interest from an historical as well as a theoretical viewpoint. This base was first isolated from cigar smoke by Wenusch and Schoeller,[6] and since the alkaloid had never been found in the *Nicotiana* genus it was postulated by these investigators that myosmine was probably formed from nicotine during the smoking process. Although our experiments were conducted in the absence of air, the pyrolysis of nicotine to myosmine lends some credence to this theory.

The myosmine obtained from cigar smoke was assigned formula III by Späth, Wenusch, and Zajic.[7] This structural configuration was later confirmed synthetically by Späth and Mamoli.[8] N-Benzoylpyrrolidone was condensed with ethyl nicotinate, and the resulting 3-nicotinyl-N-benzoylpyrrolidone-2 was heated with concentrated hydrochloric acid. The latter reaction involved hydrolysis, decarboxylation, and ring closure to the desired product (III). Myosmine was prepared by a similar procedure in the present investigation, and the picrate derivative was found to be identical with the picrate of the pyrolysis material.

A study of the pyrolytic reactions of nicotine and resulting products, such as nicotyrine, directs attention to the pyrogenic behavior of N-substituted pyrroles and pyrrolidines. The pyrolysis of N-substituted pyrroles yields two types of reaction products. One reaction course, exemplified by the isomerization of N-acetylpyrrole to 2-acetylpyrrole, involves a migration of the substituting group from the 1 to 2 position.[9] The pyrogenic conversion of N-methylpyrrole to pyridine illustrates a second reaction type resulting in ring enlargement.[10] In this reaction the formation of a six-membered ring is apparently preceded by isomerization to 2-methylpyrrole. Similar reactions have not been reported in the pyrrolidine series.

Insofar as the authors are aware, the pyrolytic conversion of nicotine to myosmine is a new type of reaction. Since the formation of methane was not established, it is not known whether myosmine is produced by the direct elimination of methane from nicotine or by a more involved reaction. The fact that Meisenheimer and Schütze[11] obtained fair yields of methane and 2-propylquinoline by continued refluxing of N-methyl-2-propyldihydroquinoline at 270° may be indicative of the simpler reaction mechanism.

Experimental

Apparatus.—The iron reactor employed in most of the pyrolysis experiments consisted of a 4-foot length of 1-inch iron pipe maintained in a vertical, tubular, electrically heated furnace. An iron "Y" tube was connected to the upper opening of the reactor. The top of the vertical side of this fitting was provided with a cap, which served as a support for a sealed-in iron thermocouple well. The

other opening of the "Y" tube was employed for addition of the nicotine. The thermocouple well was centered in the iron reactor and extended down through a bed of quartz chips. This well was supplied with a movable thermocouple in order that the temperature could be determined at any point within the heated zone. About 350 cc. of 4- to 6-mesh quartz chips was maintained in a 34-inch length of the heated reactor. At a maximum temperature of 570° within the quartz bed, a 15° temperature differential (555–570°) was observed over a 12-inch length of the reactor. The volume of quartz within this temperature range was 124 cc., and this value was employed in the corresponding space-velocity calculations below. The bottom of the reactor was connected to a receiving train, which consisted in turn of a 1-liter 2-neck flask immersed in an ice-bath, a water-cooled condenser, a dry-ice trap, and an exhaust tube leading to a well-ventilated hood. In experiments at 550° or lower, the iron reactor was replaced by a Pyrex-glass tube of equal size.

Procedure.—The following data, unless otherwise indicated, were taken from Experiment 6 (Table I) to illustrate the experimental procedure. Nitrogen was passed through the apparatus for a period of fifteen minutes before the pyrolysis. Two hundred and fourteen grams of nicotine was then added, at a uniform rate over a period of one hundred and ninety minutes, to the iron reactor, which was maintained at a temperature of 570°. Although a total of 350 cc. of 4- to 6-mesh quartz was employed as a contact material in the heated reactor, only 124 cc. of this volume was within the temperature range of 555–570°. After all the nicotine had been added, the apparatus was again flushed with nitrogen to remove volatile products from the reactor.

The 201 g. of liquid condensate collected in the ice-cooled receiver was fractionally distilled through a helix-packed column (2.2 × 50 cm.) equipped with a reflux head. Several of the fractions were obtained in too small a quantity to be reliably identified by redistillation. In view of these small amounts and the possibility of an azeotropic distillation, each fraction was characterized by means of its picric acid derivative.

Identification of Pyrolysis Products

The identity of the derivatives of all pyrolysis products reported below was confirmed by the fact that the melting points remained unchanged when the derivatives were mixed with authentic specimens.

Myosmine and Nicotyrine.—Since this investigation resolved itself into a determination of the optimum pyrolytic conditions for the production of myosmine, the data relating particularly to myosmine are summarized in Table I. In view of the fact that other identified pyrolysis products were obtained in low yields in all experiments, these values have not been included in the table. Thirty grams of myosmine distilled at 119.0 to 130.0° (4.3 mm.). After recrystallization from water, the picric acid derivative of this fraction melted at 183.0 to 184.0°. An additional 5 g. of myosmine was obtained from higher boiling fractions. On cooling to 5°, all these fractions crystallized. The 35 g. represents an 18.1% conversion on the basis of the weight of the original nicotine and 33.3% of the theoretical yield on the basis of nicotine consumed in the pyrolysis experiment. A 90% recovery of pure product could be obtained by twice recrystallizing the combined myosmine fractions from petroleum ether cooled in an acetone–dry-ice mixture.

TABLE I

[a] Cc. of nicotine at reaction temperature per hour divided by cc. of contact material. [b] Glass reactor used. [c] Iron reactor used.

To remove steam-volatile bases, the crude myosmine was subjected to steam distillation through a six-ball Snyder column. Although Wenusch and Schoeller[6] reported myosmine to be steam volatile, it was observed that the alkaloid did not distill azeotropically with water. With an efficient fractionating column, the base was still retained in the distillation flask when test portions of the aqueous distillate were no longer alkaline. This is in agreement with Smith's observations[12] that nicotine distilled azeotropically with water while nornicotine and anabasine did not. The latter two alkaloids contain a cyclic secondary amino group, as does myosmine.

Portions of the steam distillate were taken at varying intervals and treated with picric acid. The melting points of the picrates showed that nicotine was the principal contaminant in the early stages of the distillation, while traces of 3,2′-nicotyrine were obtained in subsequent portions. The suspected nicotyrine picrate melted at 169.0 to 170.0°.

The steam-distillation residue was made strongly alkaline and extracted many times with ether. The ether extract was dried over anhydrous sodium carbonate and filtered, and the filtrate was then saturated with dry hydrogen chloride until precipitation was complete. The filtered myosmine dihydrochloride was dissolved in sodium hydroxide. Pure myosmine was obtained by extracting the alkaline solution with ether, drying the extract over anhydrous sodium carbonate, removing the drying agent by filtration, and then evaporating the solvent. After being pressed on a porous plate, the residual myosmine melted at 44.0 to 45.0°, which is in agreement with the melting point reported by Späth and Mamoli.[8] *Anal.* Calcd. for $C_9H_{10}N_2$: C, 73.97; H, 6.85; N, 19.18. Found: C, 73.74; H, 6.87; N, 19.38. The picric acid derivative melted at 183.0 to 184°, which agrees with the melting point observed by Späth, Wenusch and Zajic.[7]

The identity of this material was conclusively established by comparison with the picrate of synthetic myosmine. Three and four-tenths grams of N-benzoylpyrrolidone-2 was condensed with 2.7 g. ethyl nicotinate, according to the method of Späth and Mamoli.[8] The reaction mixture was then refluxed for forty-two hours with 60 cc. of 48% hydrobromic acid. After the acid reaction mixture was made strongly alkaline, the solution was thrice extracted with ether, and the ether extract was then dried over anhydrous calcium sulfate. The drying agent was then removed by filtration, and the filtrate was concentrated on a steam-bath. The 0.7 g. of residual oil was treated with an aqueous solution of picric acid. After two recrystallizations from water, the precipitated picrate melted at 183.0 to 184.5° and was identical with the picrate from the purified pyrolysis product because the mixture had the same melting point.

Hydrogen Cyanide, Ammonia and Methylamine.—The presence of hydrogen cyanide in the pyrolysis products was detected in the exit gases. Distillation of the liquid condensate in the receiver resulted in the sublimation of ammonium cyanide, which crystallized on the cold finger of the reflux head. The formation of ammonia in pyrolysis Experiment 4 was confirmed by allowing the products collected in the dry-ice trap to distill into water. Phenyl thiourea melting at 156 to 157.5° was produced when the solution was treated with phenyl isothiocyanate. A similar procedure in Experiment 7 resulted in the formation of methyl phenyl thiourea, which melted at 112 to

(12) Smith, *Ind. Eng. Chem.*, **34**, 251 (1942).

Digitized by Arya Samaj Foundation Chennai and eGangotri

113°, and thereby established the presence of methylamine.

Pyridine.—Pyridine was not isolated from the pyrolysis products of nicotine over quartz at temperatures of 600° or lower. Pyridine was obtained, however, when nicotine was pyrolyzed at 700° in the presence of quartz or at 500° over activated alumina. The picric acid derivative melted at 168.5 to 170°.

β-Picoline.—Only 1.4 g. of the product distilled at 100 to 135°. Although this fraction appeared to have no definite boiling point, it was shown to be principally β-picoline by its picric acid derivative, which melted at 148.0 to 149.0°. The 4.1 g. distilling at 135.0 to 155.0° was shown to be β-picoline by the same procedure.

β-Ethylpyridine.—The 7.0-g. fraction distilling at 155 to 180° was probably a mixture of β-ethylpyridine and β-vinylpyridine. Repeated recrystallization of the picric acid derivative of this fraction did not yield a pure picrate. Redistillation of the fraction gave a distillate which again yielded an inseparable mixture of picrates, while the residue in the distillation flask yielded a picrate melting at 141 to 143°. The latter compound was identical with β-vinylpyridine picrate.

In Experiment 8, however, the fraction distilling at 155 to 180° yielded a picrate which melted at 128.0 to 129.5°. Since this is the reported melting point of β-ethylpyridine picrate, a synthetic sample of β-ethylpyridine was prepared by the following procedure:

A solution of 7.6 g. of β-acetylpyridine hydrochloride[13] dissolved in 30 ml. of water was added to a solution of 5.6 g. of semicarbazide hydrochloride and 8.0 g. of sodium acetate in 30 ml. of water. After being warmed on the steam-bath for twenty minutes and then cooled in an ice-bath, the semicarbazone acetate salt precipitated. The yield of product after drying *in vacuo* was 13.1 g.

The semicarbazone acetate salt was reduced to β-ethylpyridine by the general method of Wolff and Kishner. Thirteen grams of the semicarbazone acetate salt was mixed with 15.6 g. of sodium ethylate in a distillation flask, which was then heated in an oil-bath. As the oil-bath temperature was gradually increased to 180°, a few grams of liquid distilled which had the smell of alcohol and formed no picrate. The 2.8 g. of liquid distillate obtained at a bath temperature of 180 to 220° formed a picrate melting at 128.5 to 130.0° (cor.) after two crystallizations from water. Stoehr[14] reported 128.0 to 130.0° as the melting point of β-ethylpyridine picrate. The melting point was not depressed when this picrate was mixed with the suspected β-ethylpyridine picrate from the nicotine pyrolysis.

β-Vinylpyridine.—About 0.7 g. of the pyrolysis product distilled at 57.0 to 66.0° (2.7 mm.). The picric acid derivative melted at 142.0 to 144.0°, which is in agreement with the reported melting point of β-vinylpyridine picrate. An authentic sample of β-vinylpyridine was prepared by the dehydration of 3-(α-hydroxyethyl)-pyridine with phosphorus pentoxide.[15] The picrate of the synthetic material melted at 142.0 to 144.0°, and was identical with the picric acid derivative of the pyrolysis product.

Nicotine.—A total of 97.4 g. of unchanged nicotine was recovered from the reaction mixture. The major portion distilled at 104 to 109° (4.9 mm.). The limited number of experiments herein reported indicated that the highest yields of myosmine were obtained under experimental conditions which did not completely destroy the nicotine.

Unidentified Fraction and Residue.—The 4.1-g. fraction distilling at 152.0 to 165.0° (2.8 mm.) was not soluble in water or distillable with steam. No crystalline derivatives were obtained with methyl iodide or picric acid.

The 46.0 g. of distillation residue solidified to an amorphous mass on cooling. No nicotinic acid was isolated from the oxidation products when this residual, resinous material was oxidized with alkaline permanganate. This negative result may indicate that the pyridine nucleus of the nicotine molecule was partially destroyed in the pyrolysis but no conclusive evidence was obtained to confirm this assumption.

Summary

1. Ammonia, methylamine, hydrogen cyanide, pyridine, β-picoline, β-ethylpyridine, β-vinylpyridine, and 3,2′-nicotyrine have been obtained in small quantities from the pyrolysis products of nicotine.

2. Myosmine, a comparatively rare alkaloid, has been obtained in fair yields by the pyrolysis of nicotine over quartz at 570°.

3. A new synthesis of β-ethylpyridine is described.

The Dissociation of Hexaarylethanes. XVI.[1] Alkyl and Halogen Derivatives

BY C. S. MARVEL, H. W. JOHNSTON, J. W. MEIER, T. W. MASTIN, JOHN WHITSON AND CHESTER M. HIMEL

Earlier papers in this series[2] have shown that in general unsymmetrically substituted hexaarylethanes are less dissociated than are closely related symmetrically substituted ethanes. Thus, di-*p*-*t*-butylphenyltetraphenylethane is dissociated to the extent of 7.5 ± 1% and tetra-*p*-*t*-butylphenyldiphenylethane to the extent of 8.5 ± 1% under the same conditions where hexa-*p*-*t*-butylphenylethane is dissociated to the extent of 20–25%.[2] Likewise di-*p*-tolyl-tetra-*p*-*t*-butylphenylethane and di-*p*-*t*-butylphenyl-tetra-*p*-tolylethane show equal degrees of dissociation of 5 ± 1%. We were accordingly very much surprised to find in the present work that a variety of alkyl substituted hexaarylethanes with mixed *m*- and *p*-substitution showed in general a higher degree of dissociation than many related hexa-*p*-alkylphenylethanes. We have no theory to account for the unexpected values which are reported here, for the work was stopped before a sufficiently large variety of compounds could be studied to make generalization significant.

The *p*-*t*-butyl group seems to have a very marked effect in promoting dissociation in the

Tetraphenyldi-*m*-fluorophenyl	5.9	.1	.6885	5.8	5.8
	4.4	.073	.6952	5	4
Diphenyltetra-*m*-fluorophenyl	6.4	.1	.6856	5.5	5.5
	6.3	.1	.6902	3.9	3.9
Tetra-*p*-tolyldi-*m*-tolyl	6.5	.1	.7011	2.1	2.1

hexaarylethanes of this type. For example, di-*o*-tolyl-tetraphenylethane shows a dissociation of 25 ± 1%[2] whereas introduction of four *p*-*t*-butyl groups in its four unsubstituted benzene rings raises the dissociation of the ethane to 65–68%. Likewise di-*o*-bromophenyltetraphenylethane shows a dissociation of 17 ± 1%[3] whereas di-*o*-bromophenyltetra-*p*-*t*-butylphenylethane shows a value of 94%.

The hexaarylethanes substituted with cyclohexyl groups in the *m*- and *p*-position were prepared in the hope that one would be identical with the hexacyclohexylphenylethane described earlier[4] as the pure *para* isomer but later shown[5] to be a mixture of mixed *m*- and *p*-derivatives. This hope was not realized. It should be noted, however, that the magnetic susceptibility measurements reported on tetra-*p*-cyclohexylphenyl-di-*m*-cyclohexylphenylethane may be low, as this ethane has a tendency to crystallize from a 0.05 *M* solution. However, a more dilute solution gave unsatisfactory readings. All of the ethanes having *p*-cyclohexylphenyl groups were very unstable and in a few hours decomposed in solution as shown by magnetic susceptibility measurements. The *p*-*t*-butylphenyl substituted ethanes were stable in benzene solution over a period of twenty-four hours.

Since it is doubtful when work on this general problem can again be taken up in this Laboratory, we are recording in this paper some fluorine substituted hexaphenylethanes whose dissociations have been checked by the magnetic susceptibility methods. We are also recording a variety of intermediates which have been prepared in anticipation of further study of related ethanes.

(5) Marvel and Himel, *ibid.*, **62**, 1550 (1940).

The fluoro substituted ethanes showed marked decomposition when their solutions stood for twenty-four hours.

The values for the dissociation of the ethanes (α) recorded in Table I were obtained by the magnetic susceptibility method.[6]

Experimental

***p*-*t*-Butylbenzoic Acid.**—This compound was prepared by the general method illustrated in "Organic Syntheses"[7] for the conversion of *t*-butyl chloride to *t*-butylacetic acid. Thirty-four and seven-tenths grams of magnesium turnings, covered with 100 cc. of dry ether, and 304 g. of *p*-*t*-butylbromobenzene in 300 cc. of dry ether were used for making the Grignard reagent. The crude *p*-*t*-butylbenzoic acid was twice recrystallized from ethanol and water to yield 198 g. (78%) of a product which melted at 164°. Kelbe and Pfeiffer[8] have reported a melting point of 164°.

Ethyl *p*-*t*-Butylbenzoate.—A procedure similar to that used in the preparation of ethyl *m*-methoxybenzoate[9] was followed with the exception that calcium carbide was used to fill the extraction shell. One hundred and twenty-four grams of *p*-*t*-butylbenzoic acid, 1000 cc. of absolute ethanol, 200 cc. of dry benzene and 4 cc. of concentrated sulfuric acid were used as reactants. The reaction mixture was refluxed for seventy-two hours and was then worked up as described in the previous preparation. The yield was 108 g. (75%) of product; b. p. 120–120.5° (4 mm.).

Anal. Calcd. for $C_{13}H_{18}O_2$: C, 75.72; H, 8.74. Found: C, 75.62; H, 8.63.

Cyclohexylbenzene.—Cyclohexylbenzene was prepared according to the procedure given in "Organic Syntheses."[10] The product boiled at 237–238° (740 mm.).

***p*-Bromocyclohexylbenzene.**—The bromination of cyclohexylbenzene was carried out according to directions given

by Marvel and Himel.[5] The yield of bromo compound was 85% of the theoretical amount; b. p. 135–137° (6 mm.).

p-Aminocyclohexylbenzene.—This compound was prepared by reduction of *p*-nitrocyclohexylbenzene over Raney nickel in 85% yield; m. p. 53–54°.

p-Cyclohexylacetanilide.—Four hundred and seventy-eight grams of *p*-aminocyclohexylbenzene was dissolved in 400 cc. of glacial acetic acid. One gram of zinc dust was added and the solution refluxed for seven hours. Connected to the reaction flask was an air condenser made of an 18-mm. Pyrex tube 120 cm. long. The flame was adjusted so that the condensing vapors of acetic acid remained about 15 cm. from the top of the condenser. By this means, most of the water formed in the acylation was lost through the air condenser thus forcing the reaction forward. This technique is described by Fieser[11] for the preparation of acetanilide.

The hot acetic acid solution was poured into 7 liters of cold water. The precipitated product was filtered off, washed with water and recrystallized from 50% ethyl alcohol. The yield of *p*-cyclohexylacetanilide was 507 g. (86%); m. p. 129–130°. Ipatieff and Schmerling reported a melting point of 130–131°.[12]

2-Bromo-4-cyclohexylacetanilide.—Six hundred and thirty-two grams of *p*-cyclohexylacetanilide was dissolved in 1800 cc. of glacial acetic acid and 3 g. of powdered iron was added to the solution. The reaction vessel was a 3-liter, three-necked flask equipped with a gas trap, dropping funnel and stirrer. The stirrer was started and 480 g. of bromine was added dropwise to the reaction mixture. The temperature was kept between 30 and 40° by means of a cold bath. When about one-third of the bromine had been added, a solid began to precipitate. Stirring was continued for five hours after all the bromine had been added; then the reaction mixture was poured into 12 l. of vigorously stirred cold water. The precipitate was filtered off, washed with water and partially dried. The crude material was recrystallized twice from 70% ethanol. The yield was 580 g. (71.5%) of a product melting at 122–123°.

Hydrolysis of 2-Bromo-4-cyclohexylacetanilide.—Five hundred and eighty grams of 2-bromo-4-cyclohexylacetanilide was dissolved in a mixture of 1600 cc. of 95% ethanol and 1000 cc. of concentrated hydrochloric acid. The solution was boiled for two or three minutes before the hydrochloride started crystallizing out. At this point a cold water-bath was used to prevent the alcohol from going out the top of the condenser. After this initial vigorous reaction had subsided, the solution was refluxed for two hours. The mixture was cooled and the product separated on a Büchner funnel, washed once with cold 95% ethanol and allowed to dry. The yield of 2-bromo-4-cyclohexylaniline hydrochloride was 564 g. (98%); m. p. 207° with decomposition.

m-Bromocyclohexylbenzene.—In a 5-liter flask equipped with a dropping funnel, stirrer and thermometer were placed 363 g. of 2-bromo-4-cyclohexylaniline hydrochloride, 1800 cc. of glacial acetic acid, 1200 cc. of water, and 400 cc. of concentrated hydrochloric acid. The stirrer was started and the mixture cooled to 0–5° in an ice-bath. From the dropping funnel was added slowly 92 g. of sodium nitrite dissolved in 500 cc. water. The temperature was kept between 0 and 5° throughout the addition of sodium nitrite solution. The clear diazonium solution (0°) was poured into 2200 cc. of cold (0°) 30% hypophosphorous acid and the total solution allowed to stand in an icebox at 5° for three days. The flask was removed and allowed to stand at room temperature for an additional day. The red-colored oil which separated was removed by use of a separatory funnel, dissolved in ether, washed with water, 5% sodium hydroxide solution and again with water. The ether solution was dried over calcium chloride, the ether removed and the product distilled. The yield of *m*-bromocyclohexylbenzene was 236 g. (79%); b. p. 122–123° (4 mm.); $n^{20}D$ 1.5602.

Anal. Calcd. for $C_{12}H_{15}Br$: C, 60.25; H, 6.29. Found: C, 60.58; H, 6.43.

p-Bromo-*t*-butylbenzenes.—In a 3-liter, three-necked flask equipped with a mechanical stirrer, dropping funnel and reflux condenser leading to a trap for absorption of hydrogen bromide, were placed 375 g. of *t*-butylbenzene[13] and 5 g. of iron powder. The mixture was stirred and cooled by an ice-bath to 0–5°. From the dropping funnel was added, over a period of one to two hours, 500 g. of bromine. Stirring was continued for two hours after all the bromine had been added. The reaction mixture was allowed to stand overnight and then washed with 5% sodium sulfite solution, twice with 5% sodium carbonate solution, twice with water and dried over calcium chloride. The product was distilled from a modified Claisen flask and collected at 80–81° (2 mm.). The yield of *p*-bromo-*t*-butylbenzene was 444 g. (75%). This method of preparation is faster than that described in a previous paper of this series.[14]

p-Amino-*t*-butylbenzene.—This compound was prepared by reduction of *p*-nitro-*t*-butylbenzene over Raney nickel catalyst in a manner similar to that used for the preparation of *p*-aminocyclohexylbenzene. The yield was 298 g. (73%) of product from 488 g. of *p*-nitro-*t*-butylbenzene. The boiling point was 90–93° (3 mm.).

m-Bromo-*t*-butylbenzene.—This compound was synthesized in a manner similar to that used for *m*-bromocyclohexylbenzene. The product boiled at 222–223° (740 mm.); $n^{20}D$ 1.5279.

Anal. Calcd. for $C_{10}H_{13}Br$: Br, 37.56. Found: Br, 38.51.

Ethyl *p*-Cyclohexylbenzoate.—A procedure similar to that used in the preparation of ethyl *m*-methoxybenzoate[9] was followed. From 204 g. of *p*-cyclohexylbenzoic acid, 800 cc. of absolute ethanol, and 5 cc. of concentrated sulfuric acid there was obtained 214 g. (92%) of product; m. p. 58–60°.

m-Cyclohexylbenzoic Acid.—This compound was prepared in a manner similar to that for the preparation of *p*-*t*-butylbenzoic acid. From 24.3 g. of magnesium, and 240 g. of *m*-bromocyclohexylbenzene there was obtained 159 g. (68%) of product; m. p. 120–121°.

Anal. Calcd. for $C_{13}H_{16}O_2$: C, 76.50; H, 7.85. Found: C, 77.05; H, 8.18.

Esterification of *m*-Cyclohexylbenzoic Acid.—The esterification was carried out exactly as the esterification of the *para* isomer.[9] The yield of ester from a one mole run was 204 g. (88%); b. p. 137–139° (3 mm.); $n^{20}D$ 1.5239.

Anal. Calcd. for $C_{15}H_{20}O_2$: C, 77.59; H, 8.62. Found: C, 77.65; H, 8.77.

Ethyl *m*-Toluate.—Seventy-five grams of *m*-toluic acid (m. p. 107–109°) was esterified with 600 cc. of absolute ethanol, 150 cc. of dry benzene and 3 cc. of concentrated sulfuric acid.[9] Five grams of *m*-toluic acid was recovered, and on this basis the yield was 55 g. (64%) of product which boiled at 117° (15 mm.).

Another preparation was made using 200 g. of *m*-toluic acid. The extractor was in this case filled with calcium carbide. The yield was 218 g. (90%) of a product which boiled at 95–97° (15 mm.).

Ethyl *o*-Toluate.—A procedure similar to that for the preparation of ethyl *m*-toluate was used. From 175 g. of *o*-toluic acid, 1200 cc. of absolute ethanol and 4 cc. of concentrated sulfuric acid there was obtained 155 g. (75.5%) of ester; b. p. 88–92° (5 mm.).

Ethyl *o*-Bromobenzoate.—From 165 g. of *o*-bromobenzoic acid, 110 cc. of absolute ethanol, and 6 cc. of concentrated sulfuric acid there was obtained 150 g. (82%) of ester which distilled at 117° (17 mm.).

Ethyl *m*-Bromobenzoate.—In a manner similar to that used for the above esters, 100 g. of *m*-bromobenzoic acid was esterified, using 1000 cc. of absolute ethanol and 3 cc.

TABLE II

TRIARYLCHLOROMETHANES

Chloromethane	Solvent	M. p., °C.	Active chlorine analyses, % Calcd.	Found
Phenyldi-*p*-chlorophenyl-	Low-boiling petroleum ether	50–51	10.22	10.11
Di-*m*-cyclohexylphenyl-*p*-cyclohexylphenyl	Ethyl acetate and low boiling petroleum ether	151–152	6.77	7.07
Di-*p*-cyclohexylphenyl-*m*-cyclohexylphenyl		172–173	6.77	6.65
Di-*m*-cyclohexylphenyl-*p*-*t*-butylphenyl	Ethyl acetate and low boiling petroleum ether	133–134	7.11	6.78
Di-*m*-*t*-butylphenyl-*p*-cyclohexylphenyl		127–129	7.53	7.26
o-Tolyldi-*p*-*t*-butylphenyl	Mixed petroleum ether	171–172	8.77	8.79
m-Tolyldi-*p*-*t*-butylphenyl	Ethyl acetate	132–133	8.77	8.52
o-Bromophenyldi-*p*-*t*-butylphenyl	Petroleum ether	135–136	7.56	7.77
m-Bromophenyldi-*p*-*t*-butylphenyl	Mixed petroleum ether	144–145	7.56	7.27
Diphenyl-*m*-fluorophenyl	Low boiling petroleum ether	84–84.5	11.94	12.12
Phenyldi-*m*-fluorophenyl	Low boiling petroleum ether	72.5–73	11.28	11.57
Tri-*m*-fluorophenyl	Ethyl acetate[a]	92–93	10.66	10.92
Phenyldi-*m*-chlorophenyl	Mixed petroleum ether	57–59	10.21	10.10
Tri-*m*-chlorophenyl	High boiling petroleum ether	90–92	9.32	9.57
m-Tolyldi-*p*-tolyl	Ethyl acetate[b]	67–69	11.05	10.92

[a] The chloromethane was best prepared by refluxing the carbinol in dry ethyl acetate for two hours with a large excess acetyl chloride. [b] It was found that the usual refluxing with acetyl chloride and benzene resulted in low yields of chloromethane. A less vigorous treatment consisted of treating the carbinol with a large excess of acetyl chloride for forty-five minutes at room temperature. The excess acetyl chloride was removed under vacuum and the resultant oil recrystallized from dry ethyl acetate containing a trace of acetyl chloride.

of sulfuric acid. The yield was 98 g. (88%); b. p. 115° (7 mm.).

Ethyl *m*-Chlorobenzoate.—From 20 g. of *m*-chlorobenzoic acid, 140 cc. of absolute ethanol and 1 cc. of concentrated sulfuric acid there was obtained in the usual manner 19 g. (81%) of product; b. p. 85–86° (5 mm.).

Phenyl-di-*p*-chlorophenylcarbinol.—The carbinol was prepared in good yield from 17 g. of magnesium, 128 g. of *p*-bromochlorobenzene and 50 g. of ethyl benzoate. The carbinol melted at 87–88° after recrystallization from high petroleum ether. Gomberg and Cone[15] reported a melting point of 87°.

***p*-*t*-Butylphenyl-di-*m*-tolylcarbinol.**—The crude carbinol was prepared from 35 g. of magnesium, 246.3 g. of *m*-bromotoluene and 108 g. of ethyl *p*-*t*-butylbenzoate. It could not be caused to crystallize even though distilled (b. p. 175° (1 mm.)). It was converted into the ethyl ether by treatment of the oily residue with an excess of hot absolute ethanol and a few cc. of concentrated sulfuric acid for two hours. When the solution was cooled, crystallization occurred. After recrystallization from absolute ethanol the yield was 180 g. (67%); m. p. 79–80°.

Anal. Calcd. for $C_{27}H_{32}O$: C, 87.05; H, 8.66. Found: C, 87.06; H, 8.76.

Di-*m*-cyclohexylphenyl-*p*-cyclohexylphenylcarbinol.—From 135 g. of ethyl-*p*-cyclohexylbenzoate, 239 g. of *m*-bromocyclohexylbenzene and 24 g. of magnesium turnings 128 g. (49%) of product was recovered; m. p. 139°, recrystallized from a mixture of dry ethyl acetate and low boiling petroleum ether.

Anal. Calcd. for $C_{37}H_{48}O$: C, 87.87; H, 8.97. Found: C, 87.64; H, 9.01.

Di-*p*-cyclohexylphenyl-*m*-cyclohexylphenylcarbinol.—The same procedure that was used in the preparation of di-*m*-cyclohexylphenyl-*p*-cyclohexylphenylcarbinol was followed. From 24 g. of magnesium, 135 g. of ethyl *m*-cyclohexylbenzoate and 239 g. of *p*-bromocyclohexylbenzene there was obtained an oil which could not be caused to crystallize. A crystalline chloromethane was obtained from this product as described later.

Di-*m*-cyclohexylphenyl-*p*-*t*-butylphenylcarbinol.—From 239 g. of *m*-bromocyclohexylbenzene, 24 g. of magnesium and 103 g. of ethyl *p*-*t*-butylbenzoate an oil was obtained which was converted into a crystalline chloromethane as described later.

Di-*m*-*t*-butylphenyl-*p*-cyclohexylphenylcarbinol.—From 213 g. of *m*-bromo-*t*-butylbenzene, 24 g. of magnesium and 135 g. of ethyl *p*-cyclohexylbenzoate there was obtained an oil which was converted into a crystalline chloromethane as described later.

***o*-Tolyl-di-*p*-*t*-butylphenylcarbinol.**—From 82 g. of ethyl-*o*-toluate, 213 g. of *p*-bromo-*t*-butylbenzene, and 24 g. of magnesium there was recovered 70 g. (32%) of crude crystals. Recrystallization from petroleum ether yielded a product which melted at 129.5–130°.

Anal. Calcd. for $C_{28}H_{34}O$: C, 87.07; H, 8.80. Found: C, 87.23; H, 8.99.

***m*-Tolyl-di-*p*-*t*-butylphenylcarbinol.**—From 213 g. of *p*-bromo-*t*-butylbenzene, 24 g. of magnesium and 74 g. of ethyl *m*-toluate an oil was obtained which was converted into a crystalline chloromethane as described later.

***o*-Bromophenyl-di-*p*-*t*-butylphenylcarbinol.**—From 70 g. of ethyl-*o*-bromobenzoate, 130 g. of *p*-bromo-*t*-butylbenzene, and 14.6 g. of magnesium there was recovered 60 g. (43%) of crude carbinol; m. p. 136.5–137° after recrystallization from high boiling petroleum ether.

Anal. Calcd. for $C_{27}H_{31}OBr$: C, 71.84; H, 6.87. Found: C, 72.01; H, 6.95.

***m*-Bromophenyl-di-*p*-*t*-butylphenylcarbinol.**—From 90 g. of *p*-bromo-*t*-butylbenzene, 9.9 g. of magnesium and 47 g. of ethyl *m*-bromobenzoate there was obtained an oil which could not be caused to crystallize. A crystalline chloromethane was obtained from this product as described later.

Phenyl-di-*p*-fluorophenylcarbinol.—The crude carbinol has been prepared by Bacon and Gardner.[16] A white crystalline product melting at 100° was obtained after several recrystallizations from petroleum ether.

Anal. Calcd. for $C_{19}H_{14}OF_2$: C, 77.03; H, 4.73. Found: C, 77.03; H, 4.76.

Tri-*p*-fluorophenylcarbinol.—Bacon and Gardner[16] obtained the crystalline carbinol but did not report the melting point or analysis. We have recrystallized the carbinol from low petroleum ether; m. p. 94°.

Anal. Calcd. for $C_{19}H_{13}OF_3$: C, 72.61; H, 4.14. Found: C, 72.63; H, 4.25.

Diphenyl-*m*-fluorophenylcarbinol.—From 82 g. of benzophenone, 80 g. of *m*-fluorobromobenzene, and 10.9 g. of magnesium there was obtained 100 g. (80%) of the crude

carbinol, which, after recrystallization from high boiling petroleum ether, melted at 117°.

Anal. Calcd. for $C_{19}H_{15}OF$: C, 82.01; H, 5.40. Found: C, 81.96; H, 5.48.

Phenyl-di-*m*-fluorophenylcarbinol.—From 25.7 g. of ethyl benzoate, 60 g. of *m*-fluorobromobenzene, and 8.25 g. of magnesium, 35 g. (70%) of crude carbinol was obtained; m. p. 114–114.5°, recrystallized from high boiling petroleum ether.

Anal. Calcd. for $C_{19}H_{14}OF_2$: C, 77.03; H, 4.73. Found: C, 77.19; H, 4.85.

Tri-*m*-fluorophenylcarbinol.—From 20.8 g. of ethyl carbonate, 100 g. of *m*-fluorobromobenzene, and 13.7 g. of magnesium 40 g. (80%) of crude carbinol was isolated; m. p. 118.5–119° after recrystallization from high boiling petroleum ether.

Anal. Calcd. for $C_{19}H_{13}OF_3$: C, 72.61; H, 4.14. Found: C, 72.76; H, 4.13.

Phenyl-di-*m*-chlorophenylcarbinol.—From 125 g. of *m*-chlorobromobenzene, 15.6 g. of magnesium and 47 g. of ethyl benzoate a concentrated oil was obtained which failed to crystallize. A crystalline chloromethane was obtained from this product as described later.

Tri-*m*-chlorophenylcarbinol.—From 39.5 g. of *m*-bromochlorobenzene, 5 g. of magnesium, and 19 g. of ethyl *m*-chlorobenzoate a concentrated oil was obtained which was converted into a crystalline chloromethane as described later.

***m*-Tolyldi-*p*-tolylcarbinol.**—From 67 g. of ethyl *m*-toluate, 150 g. of *p*-bromotoluene, and 21 g. of magnesium, 78 g. (62%) of crude carbinol was obtained; m. p. 95–96° after recrystallization from petroleum ether.

Anal. Calcd. for $C_{22}H_{22}O$: C, 87.44; H, 7.28. Found: C, 87.44; H, 7.42.

Triarylchloromethanes.—The chloromethanes were prepared by treating the carbinols in dry benzene with excess acetyl chloride.[17] They are described in Table II.

Preparation of Peroxides.—After the magnetic susceptibility measurements had been completed the benzene solutions of the ethanes were exposed to air and then worked up for peroxides. The yields of pure crystalline peroxide usually ran about 40–60% of the theoretical. The peroxides were crystallized from benzene by the addition of five to six volumes of absolute alcohol and slow evaporation of the resultant solution at room temperature. Recrystallization was accomplished by redissolving the crystals in hot dry benzene and addition of absolute alcohol in large excess to the hot solution after which the solvent was permitted to evaporate at room temperature.

The new peroxides are listed in Table III.

Summary

Twelve new substituted hexaarylethanes containing different alkyl groups and various halogen atoms have been prepared and their dissociations measured by the magnetic susceptibility method. Some related derivatives have been characterized and the methods of preparation are reported.

Surface of Solids. X. Extension of the Attractive Energy of a Solid into an Adjacent Liquid or Film, the Decrease of Energy with Distance, and the Thickness of Films

BY WILLIAM D. HARKINS AND GEORGE JURA

1. Introduction: Heats of Adsorption.—A fundamentally important, entirely unsolved problem of physics and chemistry, is that of the distance to which the attractive field from a solid has an effect upon the energy of molecular interaction with an adjacent liquid or film. The solution of this problem involves a determination of the variation of the intermolecular energy with the distance. This paper presents an experimental, though difficult, method by means of which the problem may be solved, together with experimental data for a single case, that of water on titanium dioxide in the form of pure anatase. From earlier results obtained in this Laboratory, many other solids should exhibit the same general relationship between energy and distance.

Although calculations have been made of the heats of adsorption of gases on ionic crystals,[1] on metals,[2] and on graphite,[3] no calculation, which is even approximately correct, has been made of the variation of the attractive energy with the distance.

2. Theories of Adsorption.—For many years there have been two contradictory theories of the ultimate thickness of adsorbed films on a solid subphase: (1) the *monomolecular* theory, the principal exponent of which is Langmuir, and (2) the *polymolecular* theory.[3a] The latter theory does not assume that all adsorbed films are polymolecular, since it is evident that films of water on paraffin, graphite, talc and other hydrophobic solids may be monomolecular even at values of p/p_0 nearly as high as unity. Indeed it seems possible in such cases that even at saturation, the film is either monomolecular, or, if a second layer is formed, it is far from completely filled. However, *evidence* which indicates the existence of adsorbed monolayers on *non-porous solids at high values of* p/p_0 *is almost non-existent*, since there seems to be not *more than a single known isotherm for a non-porous solid*, that of propyl alcohol on barium sulfate, which indicates a film that remains almost monomolecular up to pressures as high as $p/p_0 = 0.95$. Presumably this is due to some extent to the neglect by investigators of systems of this type. This isotherm is discussed later (Section 6). Langmuir's recent statement[4] of the monomolecular nature of films is, that for films of argon, nitrogen, hydrogen, and methane, at liquid air temperatures "the amount adsorbed increases about in proportion to the pressure, but at higher pressures reaches a limiting value which in every case studied corresponds to less than a monolayer. Evidently, therefore, even with these cases of adsorption which involve merely van der Waals forces, the effective range of action of the forces responsible for the adsorption is less than the molecular diameter, so that we are still clearly dealing with forces which act between atoms or molecules in contact."

Many other investigators have adopted this general point of view, as expressed by Langmuir's adsorption isotherm.[5]

A theory which gives an isotherm which indicates polymolecular adsorption, has been developed by Brunauer, Emmett and Teller[6] (BET) on the basis of the earlier work of Emmett and Brunauer.[7] This isotherm has proved to be remarkably successful and will be discussed in a later paper of this series.

3. Variation of the Attractive Energy with Distance: Thermodynamic Theory and Experimental Method.—We will first consider a sample of a crystalline powder which exhibits an area of 1 sq. cm. The surface of the solid (quartz, TiO_2, $BaSO_4$, $ZrSiO_4$, etc.) is made clean by outgassing at as elevated a temperature as can be employed without affecting the nature of the surface. During this operation the powder is in the tube H of Fig. 1. The apparatus is now placed in a thermostat and after thermal equilibrium is attained, the tip of the small glass tube T is broken. This tube contains a small amount of water whose weight is determined on a microbalance. In different experiments the amounts of liquid are so chosen that the final vapor pressures of the adsorbed films at equilibrium cover well the range from $p = 0$ (no liquid) to $p/p_0 = 1$.

A calorimeter (Fig. 2) which contains n' moles of liquid is used for the measurements of energy. A 36-junction copper–constantan thermel with a sensitivity of 2×10^{-5}° was employed. For the sake of simplicity the equations are developed for an amount of powder which has an area of 1 sq. cm. The processes (Fig. 3) are as follows:

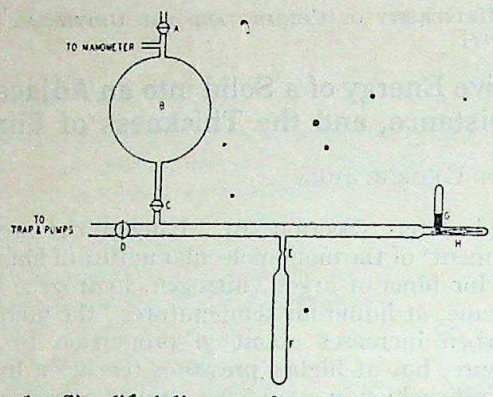

Fig. 1.—Simplified diagram of apparatus for the adsorption of water vapor on a finely divided crystalline solid in *six* bulbs (F). The water is weighed in the tube H before adsorption and adsorbed on the solid in the bulbs. G is a piece of soft iron used for breaking off the point of the tube H, and B is a gas filled bulb used for the determination of the free volume of the remainder of the apparatus up to the stopcocks C and D.

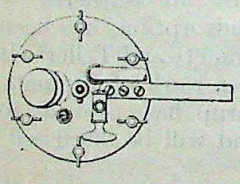
first step, the powder, with an area of 1 sq. cm., on which area n moles of liquid has been adsorbed at a value of $p/p_0 \leqq 1$, is immersed in the liquid. The change (ΔH) in the value of the Gibbs heat function (enthalpy) which accompanies this proccess is:



$$\Delta H_1 = -h_{E(S_fL)} \quad (1)$$

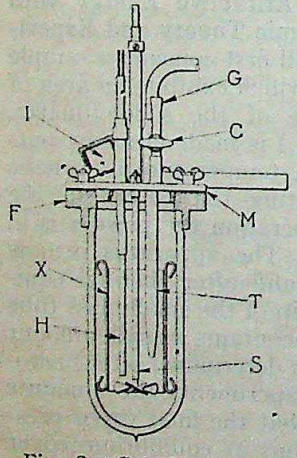


Fig. 2.—Calorimeter. T, 36-junction thermel; H, heating element; G, inlet for liquid; C, stopcock; X, chimney to give better circulation of powder; I, opening for introduction of powder. For non-aqueous liquids the calorimeter used is shown by Boyd and Harkins, THIS JOURNAL, 64, 1791 (1942).

where E indicates the process of emersion, which is the opposite of immersion, h indicates the increase in the value of enthalpy per unit area, and $E_{(S_fL)}$ indicates the emersion of the solid, covered by its film, from the liquid. Second step: since by the actual process (immersion) n moles of liquid have been added to the n' moles initially present, this amount of n moles is now evaporated from the liquid. Now for this step

$$\Delta H_2 = n\lambda \quad (2)$$

where λ is the molar latent heat of vaporization of the liquid. Third step: the sample of powder is now emersed from the liquid into a vacuum, carrying no film with it, so

$$\Delta H_3 = h_{E(SL)} \quad (3)$$

It is obvious that this process must be carried out in the reverse direction, *i. e.*, by immersion instead of emersion, so $q_{I(SL)} = h_{E(SL)}$, where $q_{I(SL)}$ is the heat evolved in the process of immersion.

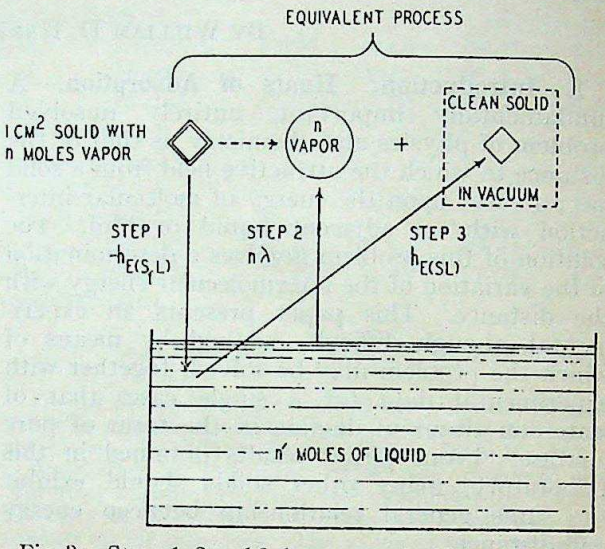

Fig. 3.—Steps 1, 2 and 3, by means of which a solid with an area of 1 sq. cm., with n moles adsorbed on the surface, is transformed into n moles of vapor and the solid in a vacuum. The equivalent process involves merely the desorption of the n moles from the surface.

As the effect of the summation of these three processes the solid of area 1 sq. cm., covered by a film of n moles in equilibrium with vapor at a pressure p, is converted into the solid with a clean surface and n moles of vapor. Thus the complete process corresponds to the desorption of n moles of vapor from 1 sq. cm. of surface of the solid, so the increase of enthalpy on desorption [$h_{D(VS_f)}$] is given by the summation of the three terms or

$$h_{D(VS_f)} = h_{E(SL)} - h_{E(S_fL)} + n\lambda \quad (4)$$

Now

$$h_{E(SL)} = h_S - h_{SL} \quad (5)$$

and

$$h_{E(S_fL)} = h_{S_f} - h_{SL} \quad (6)$$

Substitute (5) and (6) in (4), which gives

$$h_{D(VS_f)} = h_S - h_{S_f} + n\lambda \quad (7)$$

Now, since in general if γ represents the free surface energy

$$h = \gamma - T(\partial\gamma/\partial T)_{p,\Sigma} \quad (8)$$

$$h_{D(VS_f)} = \gamma_S - \gamma_{S_f} - T\left(\frac{\partial\gamma_S}{\partial T} - \frac{\partial\gamma_{S_f}}{\partial T}\right)_{p,\Sigma} + n\lambda \quad (9)$$

In cal. g.$^{-1}$ Eq. 7 may be written

$$H_{D(VS_f)} = H_{E(SL)} - H_{E(S_fL)} + n'\lambda \quad (10)$$

where n' is now the number of moles adsorbed per gram. $H_{E(SL)}$ is the heat of emersion of the clean powder from the liquid in cal. g.$^{-1}$, and $H_{E(S_fL)}$ is that for 1 g. of solid on whose surface n' moles of vapor has been adsorbed. In cal. mole^{-1}

$$H_{D(VS_f)} = \frac{1}{n'}\left[H_{E(SL)} - H_{E(S_fL)}\right] + \lambda \quad (11)$$

These equations are applicable to porous as well as non-porous solids.

The relationship used *universally* in the literature *is incorrect*, even though it is believed to be applicable only at saturation

$$H_{D(vs_f)} = H_{E(sL)} + n'\lambda \qquad (A)$$

For example, the correct equation applied to the data of Razouk[8] gives a heat of adsorption (q_a) of 9.9 cal. g.$^{-1}$ for methyl alcohol on charcoal at 13.5% of saturation, while the *incorrect* equation (A) gives $q_a = 22.4$ cal. g.$^{-1}$.

γ free surface energy
γ_s the free surface energy of the clean solid (ergs cm.$^{-2}$)
γ_{s_f} the free surface energy of the solid with adsorbed film
λ heat of vaporization (cal. mole^{-1})

4. Variation of Energy of Interaction with Distance from the Surface of the Solid.—For the experimental work a sample of pure non-porous titanium dioxide in the form of anatase was used. This is oil free, not surface treated, and its cell constants have been determined as $a = 3.77$ Å. and $c = 9.49$ Å. while Wyckoff gives $a = 3.78$ Å. and $c = 9.50$ Å. A part of this same sample was photographed by the use of an electron microscope (Fig. 4).

The area of this sample is 13.8 m.^{2}g.$^{-1}$ as determined by our absolute method. This consists in adsorbing a duplex film of water on the surface in saturated water vapor, and then immersing in water in the calorimeter. The heat developed, expressed in ergs, when divided by 118.5 erg cm.$^{-2}$, the surface energy of water at the temperature employed, gives the area of the powder. A very small correction is made for the known thickness of the duplex film. The area of this same sample when calculated by the use of the isotherm of Brunauer, Emmett and Teller,[8] and of Emmett's value of 16.2 sq. Å. for the mean area of the nitrogen molecule, is 13.9 m.^{2}g.$^{-1}$, or a difference of less than 1% between the results of the two methods.

The isotherms of water on this anatase at 25° and of nitrogen at −195.6° are exhibited in Fig. 5, while Fig. 6 and Table I give the relationship between the energy of emersion of the solid from water at 25°, and the amount of water left on the surface of the solid. For the emersion of the dry solid the energy is 512 erg cm.$^{-2}$.

The relationship between the energy of desorption of water to give a dry surface, with the number of moles per sq. cm., is exhibited in Fig. 7, as calculated by Equation 4, while Figure 8 gives values for the molal heat of desorption of the vapor as a function of the weight of water adsorbed.

These figures give in addition the thickness (T) of the films in Å. These are calculated on the basis of the assumption that the *mean density* of the film is the same as that of the three dimen-

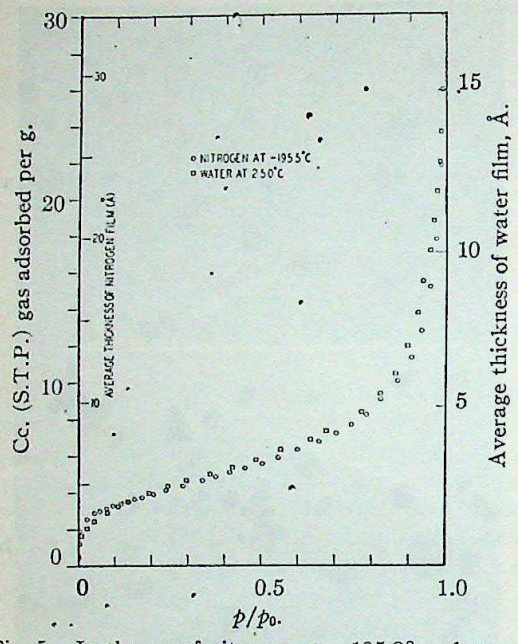

Fig. 5.—Isotherms of nitrogen at −195.8° and water at 25°. The number of molecules adsorbed at any (not too high) given value of p/p_0 is practically the same. However the nitrogen molecules are larger than those of water, so the nitrogen films are thicker (see graph) than those of water. At saturation the nitrogen film is much thicker.

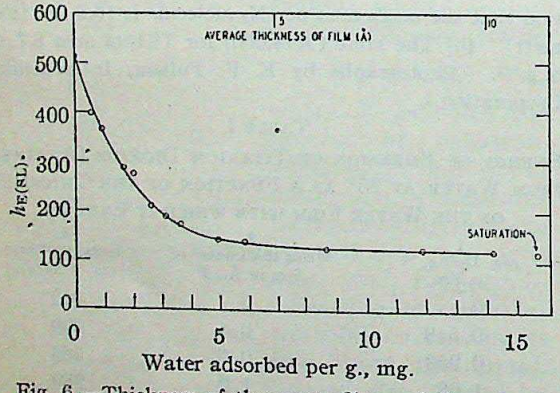

Fig. 6.—Thickness of the water film and the energy of emersion per sq. cm. of the surface of TiO_2 (anatase). The weight of water adsorbed per gram of anatase is also given.

sional liquid at the same temperature. Obviously this cannot be quite correct, but it should become more nearly correct as the film thickens. There is also involved the assumption that the thickness is uniform over the whole surface. The mass of the film was determined by *weighing* in all cases in which the energy was determined. The total amount of water adsorbed is sufficient to allow this to be done.

Figure 5 indicates that at saturation at 25°, the thickness of the adsorbed water film is somewhat greater than 15 Å., (or 5 molecules of water) since it has this thickness at the last point which represents a pressure below saturation. The amounts of water adsorbed for this isotherm were calculated from the volume of vapor.

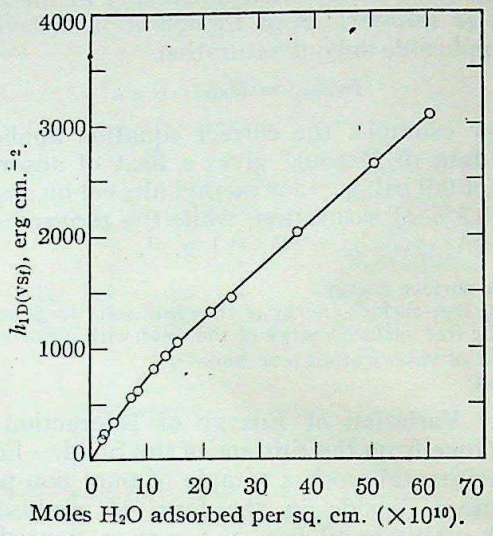

Fig. 7.—Variation of the energy of emersion per sq. cm. of area of TiO_2 (anatase) with the weight of water vapor adsorbed.

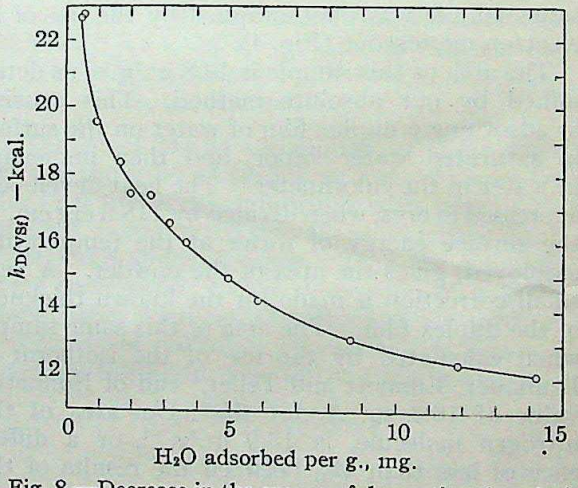

Fig. 8.—Decrease in the energy of desorption, in calories per mole of water, from the surface of TiO_2 (anatase) as a function of the weight of water adsorbed.

5. Variation of the Energy of Desorption with the Number of Molecular Layers.—It is of interest to estimate the variation of the molar energy of desorption with increase in the number of molecular layers (Table II).

The increase in the energy of vaporization of water by the presence of the adjacent solid is given in column 4. Thus the vaporization of the first molecular layer requires 6550, the second 1380, and the third 450 cal. mole^{-1} more energy to vaporize than if water alone were present. Thus these values give the increase in molecular interaction due to the presence of the solid.

The theory of Brunauer, Emmett and Teller was used to calculate the number (N) of molecules in the monolayer (1) next to the surface of the solid. It was assumed as the basis of the cal-

Sum of all above 5			30 (?)	

Column 2 gives the energy of desorption for a whole layer, when all of the lower layers are complete.

Column 3 gives the internal energy of vaporization which does not include the work done.

[a] The BET theory gives a value for E_1-E_L of 2100 cal. mole^{-1}.

culation that the number of molecules in each higher layer is also equal to N. The values obtained by the application of this theory indicate that the water molecules in the first layer (1) are somewhat loosely packed, at 25°, while at −195.8° nitrogen molecules (which are larger) are more nearly in contact.

The values of column 4 suggest an exponential decay in the energy of desorption. In column 5 it is assumed that the value of 6550 cal. mole^{-1}, as given in column 4 is correct, and that the energy for any other layer is one-fourth of that of the layer just beneath it. In *general* this gives the same rate of decay as that exhibited by the experimental values but it may be noted that these latter are lower for even layers and higher for odd layers, than corresponds to the exponential decay. This is just what would be expected if the more polar part of the water molecules is turned toward the solid in the first layer, away from it in the second, toward it in the third, etc. This is exactly the type of orientation exhibited in built-up multilayers of polar–non-polar molecules. Unfortunately, the values of column 4 do not have sufficient accuracy to prove that this alternation in orientation actually occurs.

6. Discussion: Polymolecular Films.—The important relation brought out in Section 4 is that for water on a non-porous crystalline "polar" solid (anatase) the attractive energy exhibits an essentially exponential decay. The term "polar" solid is used because a better term has not, as yet, been introduced. The term is used to designate solids, such as quartz, etc., whose molecular interactions may be considered to exhibit not too small *relative* intensities of both dispersion forces and those due to segregated electrical charges, in addition to repulsive forces. On such solids the curve which represents the decrement ($-\Delta\gamma = \Delta\pi$) of free surface energy due to a film of nitrogen at −195.8° has the same form (with smaller magnitudes) as that for water at 0°. The film of nitrogen attains, very slightly *below* saturation, a thickness of 36 Å., while for water, as cited earlier, the value is 15 Å. On the whole it does not seem improbable that nitrogen, a non-polar adsorbate, also may exhibit an essentially exponential decay of the attractive energy.

The saturated film of butane at 0° on this same solid, is 64 Å. thick, so it is not essential to use a polar adsorbate in order to have a highly polymolecular film. However, it is true that the butane molecule has a high polarizability. While the water film attains a thickness of about 5, and that of nitrogen about 10 molecular layers, the number for butane cannot be specified, since in its first monolayer *the molecules lie flat*, while near the outer surface of the film they must have much more nearly the type of orientation exhibited by the surface of liquid butane. If the thickness of this film is to be specified in molecules as units all that can be said is that its thickness is of the same general order as that of nitrogen (10 molecules).

It is of interest to note in connection with the discussion of the two preceding paragraphs, that with the particular sample of titanium dioxide used for this work the adsorption isotherms for nitrogen at −195.6° and water at 25° are practically identical except possibly very close to saturation, both in form and the volume of gas adsorbed (Fig. 5).

Thus the writers have obtained entirely definite evidence that adsorbed films of water, nitrogen, and butane on titanium dioxide in the form of anatase are highly polymolecular, with *thicknesses* of 15, 36 and 64 Å., respectively, at pressures just below saturation. We believe that these are correct thicknesses for pressures *very* slightly below saturation, except that the thickness of the water film may be greater than 15 Å. As has been specified these values express the volume of the liquid at the given temperature divided by the area, as determined by the area of the surface of the solid. If the film has a density higher than the three dimensional liquid, then these values in actual ångström units are that much too high, but in terms of molecular diameters the values are not affected.

No uncertainty is introduced by the value of the area which is employed for the calculation, since the determination of area was made by our absolute method. This method is based upon the premise that water on anatase forms a film sufficiently thick to be *duplex*, *i. e.*, the surface of the film is sufficiently thick to give inappreciable (experimentally) interaction between the outermost layer of the film and the solid. Thus the surface energy of the outer part of the film is supposed to be the same as that of water at the same temperature. That this is true within the limits of experimental error is shown by the fact that as the thicker films thicken there is no de-

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

tectable decrease in the energy of immersion. Thus, for the first time, certain evidence has been obtained for the highly polymolecular character of certain adsorbed films. As mentioned earlier, no attempt is made here to prove the *non-existence* of monomolecular adsorbed films at high values of p/p_0 that are less than unity.

Monomolecular films of stearic acid are formed by adsorption of the acid at the interface between *dry* benzene and TiO_2 (anatase) such as that used in this investigation. In fact, even the monolayer is loosely packed, since only about 70% as much stearic acid is adsorbed as the amount required for close packing.

The writers have considered it important to obtain *definite* evidence, already presented in this paper, which shows that by the adsorption process alone films taken up from vapors on the surfaces of solids become highly polymolecular at the higher values of p/p_0, provided the contact angle between the solid and the liquid is zero. That this point of view is not universal among specialists in the field of adsorption, is shown by a recent statement by Brunauer,[9] who is, himself, an enthusiastic supporter of the theory of polymolecular (multimolecular) adsorption:

"Many advocates of the capillary condensation theory maintain that adsorption in porous bodies is largely due to capillary condensation, although they do not deny the existence of unimolecular adsorption. The two schools (unimolecular and capillary condensation) of thought meet on a common ground, namely, that adsorption on a plane surface where capillaries do not exist must be unimolecular."

Since Langmuir is the principal advocate of the uni- or mono-molecular theory, it is important to consider his point of view, as presented in the following quotations[10]:

"The theory requires that in typical cases of true adsorption the adsorbed film should not exceed one molecule in thickness. This is contrary to the usual viewpoint. The discrepancy is accounted for by the fact that nearly all investigators have worked with porous bodies in which the adsorbing surface is indeterminate, or have used nearly saturated vapors so that condensation of liquid occurred in capillary spaces. Others have mistaken solution or *ab*sorption for adsorption.

"With gases or vapors at pressures much below saturation the surface of a solid tends to become covered with a single layer of molecules. The reason for this is that the forces holding gas molecules (or atoms) on to the surface of solids are generally much stronger than those acting between one layer of gas molecules and the next. When the vapor becomes nearly saturated, however, the rate of evaporation from the second layer of molecules is comparable with the rate of condensation so that the thickness of the film may exceed that of one molecule."

Since the experiments of the authors and of others show that most of the known films on *non-porous* solids are polymolecular at values of p/p_0 greater than 0.3 or less, the above conception of Langmuir cannot be used as the basis of *any* general theory of adsorption.

Capillary Condensation Theory.—The monomolecular theory of adsorption on solids receives support at the present time only because the apparent discrepancies which it introduces are explained away by the theory of capillary *condensation*. Undoubtedly this phenomenon is prominent in highly porous solids, but it does not contribute as much to the "sorption" as is assumed by the adherents of this theory.

Indeed, at high relative pressures, the total amount adsorbed is commonly *greater per unit area on a plane surface*, where the high value cannot be explained by the assumption of capillary condensation, *than the total amount of "sorption" for the same area exhibited by a porous solid*. The explanation of this fact is simple: the adsorption in pores is limited by the growth of the film from all sides of the pore. In the simple case of a pore with parallel plane walls the "film" cannot be thicker than half the distance between the walls. When the values for the thicknesses of films of water, nitrogen, and butane given in this paper are considered, it is evident that many of the smaller pores in a silica gel or a catalyst of high area, would become completely filled by adsorption even if capillary condensation were absent.

That capillary condensation, as suggested by Zsigmondy,[11] plays an important part in the sorption, is undoubtedly true. However, the assumption by others than Zsigmondy that this phenomenon is responsible for all of the material taken up from a vapor by a porous body, with the exception of a single monolayer, is certainly false. If this assumption had not been made, the monomolecular theory of adsorption could not have survived up to the present time.

7. Monomolecular and Slightly Thicker Films on Solids.—It is shown earlier in this paper that almost all of the films on non-porous solids thus far investigated begin to lose their monomolecular character at a relatively small value of p/p_0 which is of the order of 0.08 to 0.12 for nitrogen at $-195.6°$ and of 0.15 to 0.25 for *n*-butane at 0° and for water at 25°.

If it is desired to find a film which remains in the monomolecular state up to high values of p/p_0 when adsorbed on a polar solid, it would seem that the choice of a substance whose molecules are polar–non-polar, would be a good one. Thus molecules of an alcohol should, in the first

monolayer, be oriented with their long axis perpendicular to the surface of a polar solid and with the polar group toward the solid. This leaves the hydrocarbon chains, which resemble paraffin, and which exhibit little attractive energy, on the outside. It would seem that this would give a good chance of obtaining a film which remains monomolecular up to high values of p/p_0. However, the presence of the polar group makes the position of the molecule highly dependent on the surface lattice of the crystal used for adsorption, which should on this account give variations in the thickness of the adsorbed film.

As mentioned earlier (Section 2) the only system which the writers know, that exhibits monomolecular adsorption on a non-porous solid, is propyl alcohol on barium sulfate. The area available per molecule of the alcohol, and the mean thickness of the films are given in Table III as a function of the relative vapor pressure (p/p_0).

TABLE III

PROPYL ALCOHOL FILMS; MONOMOLECULAR ON BARIUM SULFATE UP TO $p/p_0 = 0.9$; DO NOT COMPLETE THEIR SECOND LAYER ON TiO_2 AT $p/p_0 = 0.8$, AND COMPLETE THEIR SECOND LAYER ON QUARTZ AT $p/p_0 = 0.7$.

The lattice constants of these three types of crystalline solids indicate that the first monolayer of propyl alcohol should exhibit at a given vapor pressure, the most loose packing on barium sulfate, the tightest on quartz, with that for anatase intermediate.

The end of the monolayer on the surface of the solid occurs at a relative pressure (p/p_0) of about 0.9 (which is very high) with barium sulfate, at about 0.2 with anatase, and about 0.15 with quartz. With quartz the second layer is completed at a relative pressure of about 0.7. Since there is no known method of determining at just what pressure the second layer is actually completed, it is assumed that when the first monolayer is completed the propyl alcohol molecules are closely packed, and the same assumption is made for the second layer. Thus where the area per molecule adsorbed is equal to that which a propyl alcohol molecule should exhibit in perpendicular orientation, it is considered that the film is a monolayer, and if the mean molecular area is half as large, the film is assumed to be two molecules thick.

While the literature contains a very great number of isotherms which represent the adsorption of vapors upon the surfaces of solids, it is unfortunate that most of these isotherms were obtained with porous solids, where adsorption and capillary condensation are inextricably mixed. It is also unfortunate that a large percentage of the work on non-porous solids has not been carried to saturation of the vapor. Thus the literature gives almost no data which help in the development of a theory of adsorption uncontaminated by the effects of capillary condensation.

8. Theory of Adsorption.—This paper has considered the decrease in the surface enthalpy which occurs when a film of any thickness is adsorbed upon the surface of a solid. This decrease of enthalpy is equal, within the limits of experimental accuracy, to the decrease ($-\Delta E$) in surface energy. In the case investigated the angle of contact between the solid and liquid is zero. In such a case the amount of vapor adsorbed increases very rapidly with pressure at the lower values of p/p_0.

The relations are very different with a system such as that of water on graphite or on paraffin, which exhibit contact angles of 85.5° and 105 to 111°, respectively. There seem to be no carefully determined adsorption isotherms for a case of this type. A sample of graphite used with water in this Laboratory was found later to contain about 10% of ash, which may have greatly distorted the adsorption isotherm. With pure graphite the adsorption isotherm should be of Type III (convex to the pressure axis).

With films of this type the amount adsorbed increases with extreme slowness with pressure at low relative vapor pressures. The simplest explanation of non-spreading of the liquid in such a case would be to assume that even close to saturation the surface of the graphite (or paraffin) is sparsely populated by water molecules, and that there are many holes of molecular dimensions in the water layer. This gives so few points of attachment for the liquid water that the latter does not spread.

The theory of adsorption may be stated very simply as follows: Adsorption in any closed system which contains a solid and a vapor continues as long as the process can occur with a decrease of the Helmholtz free energy (A), while at constant pressure the condition is the same with respect to the Gibbs free energy (F). Since for unit area of the solid the decreases of free energy on adsorption is represented by

$$-\Delta F = -\Delta\gamma = \pi$$

the value of the film pressure (π) gives the decrease in free energy per unit area. It is not at all difficult to calculate π at any vapor pressure (p) if data are available for the adsorption isotherm at all pressures below p down to sufficiently low

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

pressures. This is done by the method of Bangham.[12]

By a consideration of this free energy decrease on adsorption, and a simple assumption, a method has been developed for the determination of the area of a solid from an adsorption isotherm.

The free energy changes involved in adsorption will be treated in a later paper of this series. The free surface energy of *decrease* (π) of the surface of a solid increases with increase of thickness of a film upon it. Since $\pi = -\Delta\gamma$, the free surface energy decreases with thickness of the film.

From our calorimetric measurements the decrease of internal or "total" surface energy $(E_S - E_{S_f}) = (h_S - h_{S_f})$ may be calculated. The values of this quantity, together with the related values of the *decrease* of free surface energy, and of the latent heat $[T(s_S - s_{S_f})]$, where s is the entropy, are represented in Fig. 9.

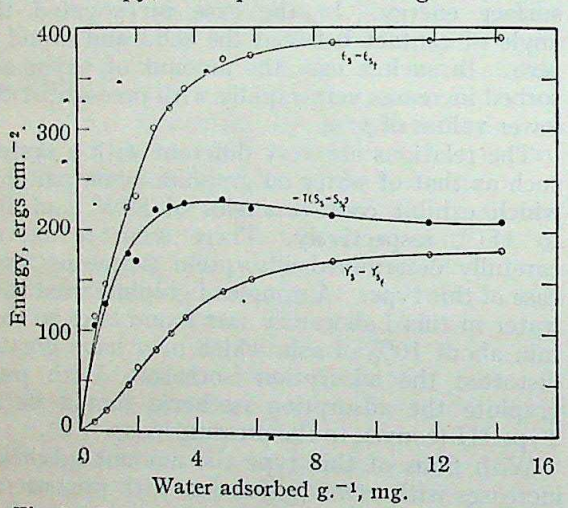

Fig. 9.—Lowering of the surface energy of TiO_2 (anatase) by an adsorbed water film. The *lowering* of the total surface energy is $\epsilon_S - \epsilon_{S_f}$, of the free energy $\pi = \gamma_S - \gamma_{S_f}$, and of the latent heat $l = T(s_S - s_{S_f})$, where s is the entropy per unit area.

All of these quantities increase very rapidly at first with the amount adsorbed, but the free energy changes much less rapidly than either the total surface energy (E) or the latent heat ($l = TS$). It should be kept in mind that increases in the values of these quantities, which give the effects of the film on the surface of the solid, represent *decreases* in the surface energy of the solid. Thus the maximum in the curve for latent heat in Fig. 9 represents a *minimum* latent heat for the film covered surface of the solid. This minimum begins at approximately the end of the adsorption of the first monolayer, and the beginning of the deposition of the second layer.

9. Absence of an Effect of Closer Packing upon the Amount of Butane Sorbed at High Relative Vapor Pressures (Note: Added December 15, 1943).—In our work on the adsorption of butane and other vapors there had been no attempt to pack the powder tightly, so it was deemed advisable to determine whether a tighter packing would increase the amount of vapor taken up. If capillary condensation is an important factor in the process of sorption, then a significant increase should accompany the tighter packing.

An electron microscope photograph of the anatase used in this work was obtained at a magnification of 45,000 and this shows that it consists largely of aggregates. These give a very loose packing of the powder in the glass bulb where the sorption takes place. Thus with the ordinary type of packing in the bulb of 27 cu. cm. capacity, it was found in one experiment that only 3.78 cu. cm. of anatase was present, and this is approximately the average amount found. It is simpler to consider the volume of anatase per cu. cm. of capacity of the bulb. This amounts to 0.14 cu. cm. or 14%, so that the free space is 0.86 cu. cm. or 86%. Of this free space between 0.0429 and 0.0527 cu. cm. is filled up by "liquid" butane. Here 0.068 cu. cm. is the highest value attained at a pressure below that of saturation, and 0.078 cu. cm. is a value obtained at saturation. As usual the volumes given for the adsorbed film of butane do not represent its actual volume, but that of the same mass of liquid butane at −0.3° and 760 mm. pressure.

Later, additional anatase powder was packed in the bulb by tapping the bottom of the bulb on the wooden top of a desk until no tighter packing could be obtained by this means, when 4.61 cu. cm. of anatase was found to be present. The

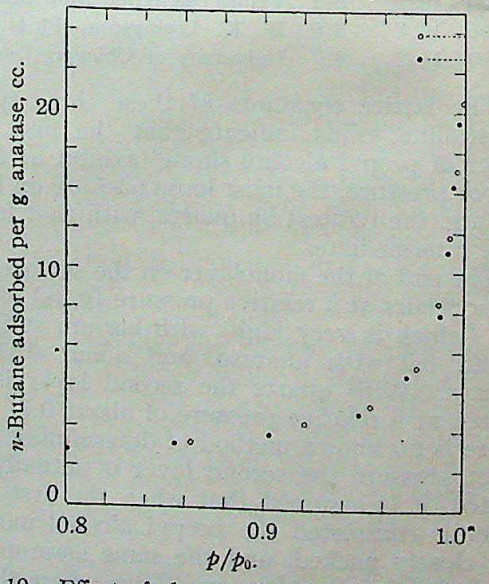

Fig. 10.—Effect of change of spacing between crystals and crystalline aggregates upon the amount of butane adsorbed at high relative pressures. Black circles indicate tighter packing, and open circles looser packing. Within the limits of experimental error the two curves are identical and no effect of packing is indicated. The dotted lines indicate the amount adsorbed at $p/p_0 = 1.0$.

Digitized by Arya Samaj Foundation Chennai and eGangotri

new volume relations were per cm.^{3}: 0.171 cu. cm. of anatase in the vacuum, 0.829 cu. cm. of free space. The volumes of butane, calculated as liquid taken up just below and at saturation, were 0.0580 and 0.0673 cu. cm., respectively. These values are higher than for loose packing on account of the greater mass and area of the powder in the bulb.

The two adsorption isotherms for the looser and tighter packing, as given in Fig. 10, are the same within the limits of experimental error and give no evidence that the tighter packing increases the amount of butane sorbed. This might not be the case if the butane vapor in the bulb were kept extremely close to saturation for a very great length of time. In the determination of adsorption at lower pressures the time is extended until equilibrium is attained. For the highest pressures indicated there was no change of pressure (0.1 mm. can be detected with certainty) in four hours at $p/p_0 = 0.9990$ for the more tightly packed sample, and no change in fourteen hours at $p/p_0 = 0.9976$ for the more loosely packed sample. From this evidence it seems that capillary condensation cannot play any significant role.

While this paper deals principally with adsorption on a single solid, the writers have determined similar adsorption isotherms for more than one hundred solids, and have obtained equations for the isotherms which represent the behavior of condensed, intermediate, expanded, and gaseous films on solids. Two condensed phases have been discovered, so that we have now found five phases in films on solids. Some of these equations give remarkably accurate values of the area of the solids.

Summary

1. Almost all of the films adsorbed on the surfaces of non-porous solids, which have been investigated thus far, are highly polymolecular at vapor pressures very slightly below saturation.

2. For the first time, a determination has been made of the effect of distance on the intermolecular attraction (in energy units) between a solid and an adjacent liquid or adsorbed film. This energy of interaction is found to suffer a decay which is essentially an exponential function of the distance.

3. At 25°, the energy of vaporization of water is 10540 cal. mole^{-1}. If, however, the water is in the form of a monolayer on the otherwise clean surface of crystalline titanium dioxide (as anatase) the heat of vaporization is increased by 62%, or by 6550 cal. mole^{-1}. For the second layer this is reduced to a 13% increase, or 1380 cal. mole^{-1}, for the third to 4%, or 450 cal. mole^{-1}, while for the fourth and fifth layers, the values are of the order of 80 and 40 cal. mole^{-1}. These energy values indicate that the film of water adsorbed on titanium dioxide (anatase) should attain a minimum thickness of 5 molecular layers before saturation of the vapor is attained. Measurements of the thickness of the film just below saturation show that this is justified, since the thickness attained is over 15 Å. (five molecular layers). The measured thickness attained is 36 Å. or 10 molecular layers for nitrogen at −195.6°. Non-polar adsorbates attain considerable thicknesses. Thus *n*-butane at 0° attains a thickness of 64 Å., while the thickness of the first molecular layer is only about 4 Å., since the molecules *lie flat on the surface*. However, in the sixth or seventh layer, the degree of orientation should be small, and in the surface of the film should exhibit practically the same orientation as that in the surface of liquid butane at the same temperature. The thickness of this film is about 11 or 12 molecules.

4. The results obtained are contrary to Langmuir's theory of the general occurrence of monomolecular adsorption at vapor pressures moderately close to saturation. They also show that the combined monolayer plus capillary condensation theory, upheld by a large number of the workers in this field, is incorrect. They do not show that monomolecular adsorption cannot occur, nor are they in opposition to the idea that capillary condensation may occur in porous solids. They do show that *ad*sorbed films on plane surfaces commonly attain greater thicknesses than in porous solids. However, this should not be the case for water on hydrophobic solids, nor is it true for propyl alcohol on barium sulfate.

5. The theory of adsorption favored by these results is in agreement with the general picture indicated by the multimolecular theory of Brunauer, Emmett and Teller (BET). However, we show the incorrectness of one of the primary assumptions in their more simple theory: that the energy of vaporization of the second adsorbed layer is no greater than the energy of vaporization of the liquid, or $E_2 = E_L$. This is not offered as an adverse criticism of their theory, since this assumption was introduced by them in order to obtain a simple, two-constant adsorption isotherm. The areas given by their simple theory are surprisingly good, but the energy values ($E_1 - E_L$) are much too low. (The BET theory gives a value for $E_1 - E_L$ of 2100 cal. mole^{-1} while our experimental result corresponds to 6550 cal. mole^{-1}.) The great usefulness of their isotherm lies in the fact that it is the first and only method for the calculation of the number of molecules in a complete monolayer when the isotherm is of the sigmoid (S) or common type. The Langmuir equation also gives the number of molecules, but with non-porous solids there seems to be, unfortunately, only one known case to which it can be applied.

6. Evidence is presented which indicates that capillary condensation does not play any significant role in the sorption with a crystalline powder of the type used in this work.

High-temperature Heat Contents of Magnesium Nitrate, Calcium Nitrate and Barium Nitrate[1]

BY C. HOWARD SHOMATE[2]

Thermal properties of several nitrates are of interest in connection with the hydrometallurgy of manganese, and the Pacific Experiment Station of the Bureau of Mines has undertaken studies of their low- and high-temperature specific heats and their heats of formation. The present paper reports high-temperature heat-content data of magnesium nitrate, calcium nitrate, and barium nitrate, in the anhydrous crystalline state. No previous reliable data for these substances exist.

Materials and Method

Magnesium nitrate was prepared from reagent-quality magnesium nitrate hexahydrate. The latter was heated *in vacuo*, the temperature gradually being raised from 65 to 150° over a period of forty hours. Analysis gave 16.43% Mg (calcd. 16.40%) and 0.17% MgO.

Reagent-grade calcium nitrate tetrahydrate was used for the preparation of anhydrous calcium nitrate. The tetrahydrate was melted and most of the water removed under reduced pressure. The material then was broken up and heated in a furnace at 300° for twenty-four hours. Analysis gave 24.43% Ca (calcd. 24.42%) and 0.04% CaO.

The sample of barium nitrate used was a reagent-grade material dried at 115°. Analysis gave 52.50% Ba (calcd. 52.55%).

All formula weights are in accord with the 1941 International Atomic Weights. Sample weights were corrected to vacuum, using the following densities: magnesium nitrate, 2.2; calcium nitrate, 2.36; and barium nitrate, 3.24, g./cc.

The heat content determinations of magnesium nitrate and calcium nitrate were corrected for the oxide impurities indicated above. These corrections averaged 0.15 and 0.03%, respectively.

The high temperature heat contents were determined in an apparatus previously described.[3] The calorimeter was calibrated electrically, using the defined calorie (1 cal. = 4.1833 int. joules). Each sample was enclosed in a gold-sealed platinum–rhodium alloy capsule during the measurements. The heat content of the capsule was determined in a separate series of experiments.

Results

The experimentally determined heat contents above 298.16°K. of magnesium nitrate, calcium nitrate, and barium nitrate are given in Tables I, II, and III. Determinations were made starting at about 100°, and extending up to the point where dissociation was detected. No discontinuities were found in the temperature ranges studied.

Heat content equations, given below, of the form $H_T - H_{298.16} = aT + bT^2 + c/T + d$ were derived for each of the three substances. The coefficients a, b, c and d were determined by plotting the function

$$\frac{T[(H_T - H_{298.16}) - C_{p_{298.16}}(T - 298.16)]}{(T - 298.16)^2}$$

of the experimental values against T, and drawing the best straight line through the points. The slope of this straight line is the coefficient b in the above general equation. The value of the y-intercept is $c/(298.16)^2$. The coefficient $a = c/(298.16)^2 - 596.32\ b + C_{p_{298.16}}$ and $d = (298.16)^2\ b - 2c/298.16 - 298.16 C_{p_{298.16}}$.

$$Mg(NO_3)_2: H_T - H_{298.16} = 10.68T + 0.03560T^2 - 179{,}000/T - 5{,}749 \quad (1)$$

$$Ca(NO_3)_2: H_T - H_{298.16} = 29.37T + 0.01840T^2 + 413{,}000/T - 11{,}778 \quad (2)$$

$$Ba(NO_3)_2: H_T - H_{298.16} = 30.05T + 0.01785T^2 + 401{,}000/T - 11{,}891 \quad (3)$$

Differentiating the above equations gives the following specific heat relationships

$$Mg(NO_3)_2: C_p = 10.68 + 0.07120T + 179{,}000/T^2 \quad (4)$$

$$Ca(NO_3)_2: C_p = 29.37 + 0.03680T - 413{,}000/T^2 \quad (5)$$

$$Ba(NO_3)_2: C_p = 30.05 + 0.03570T - 401{,}000/T^2 \quad (6)$$

The coefficients in these equations were chosen so that the equations would give the specific heats at 298.16°K. recently determined by Shomate and Kelley.[4] These values for $C_{p_{298.16}}$ are as follows: magnesium nitrate, 33.92; calcium nitrate, 35.69; and barium nitrate, 36.18 calories per mole, respectively. The agreement of the above heat content equations with the experimental data is shown in Tables I, II and III.

Table IV is a compilation, at 50° intervals, of the heat content and entropy above 298.16°K. of magnesium nitrate, calcium nitrate, and barium nitrate. These values have been derived from smoothed curves drawn through points representing the experimental data.

Summary

High-temperature heat content measurements of magnesium nitrate, calcium nitrate, and barium nitrate were made from about 100° up to as high a temperature as was permitted by the thermal stability of each substance.

Heat content and specific heat equations, adequately representing the experimental data, have been derived for each nitrate.

The entropy increments above 298.16°K., at 50° intervals, have been tabulated along with smoothed values of the heat contents.

Crystallized Basic Zinc Chromates

BY O. F. TARR, MARC DARRIN AND L. G. TUBBS

The yellow pigment which is ordinarily produced by the reaction of acidified zinc oxide and potassium bichromate is known as zinc yellow. For almost a century there has been controversy as to whether it is a definite chemical compound, an adsorption complex or a mixture. The great variation in analyses and impurities, the selective solution of CrO_3 and K_2O, and a lack of crystalline form, led Mellor[1] to consider the various suggested formulas as representing adsorption products rather than a pure chemical compound. Although recent investigators[2,3] have reported some analyses corresponding fairly closely to molecular proportions of the combined oxides, and the major evidence[2,4] indicates the probable existence of the compound, $K_2O{\cdot}4ZnO{\cdot}4CrO_3{\cdot}3H_2O$, no prior investigator has reported the preparation of a pure crystallized compound. The authors obtained well-defined crystals having analyses corresponding to simple molecular proportions by the following procedure.

Basic Potassium Zinc Chromate

Preparation.—Zinc yellow having an analysis corresponding to the formula $K_2O{\cdot}4ZnO{\cdot}4CrO_3{\cdot}3H_2O$ was prepared by the direct reaction between an aqueous suspension of zinc oxide and a solution of potassium tetrachromate,[5] thus

$$4ZnO + K_2Cr_4O_{13} + 3H_2O \longrightarrow K_2O{\cdot}4ZnO{\cdot}4CrO_3{\cdot}3H_2O$$

On separation and drying the zinc yellow appeared to be a non-crystalline powder. When suspended in water it slowly underwent partial decomposition, releasing into solution a mixture of K_2CrO_4 and $K_2Cr_2O_7$. Equilibrium was reached when the concentration of dissolved chromate and bichromate was equivalent to about 15 g. of $K_2Cr_2O_7$ per liter.

Ten grams of the above zinc yellow was suspended in a solution containing 22.5 g. of $K_2Cr_2O_7$ in 1500 ml. of water, and brought into solution at room temperature by the addition of a minimum amount of nitric acid. This solution was slowly neutralized at 80° without mechanical agitation, with a solution containing 5 g. of potassium hydroxide and 20 g. of potassium chromate per liter. Heat was applied at the edge of the beaker and the caustic solution was added dropwise to the rising convection current. After the addition of about 300 ml., which required from six to twenty-four hours, small crystals could be seen

in the convection stream, with larger, well-defined, transparent yellow crystals (Fig. 1) settling out loosely on the bottom of the beaker. The *p*H of the reaction solution at this time was 6.4. When the reaction was continued to a higher *p*H (about 6.7) an additional yield was obtained of smaller crystals of the same system and class. The analysis was the same for all crystals and the zinc yellow from which they were obtained. Reaction periods extending over several weeks, also long standing at various temperatures, did not increase the size of single crystals—although some agglomerates were formed. Increasing the speed of neutralization resulted in a decrease in the size of the crystals, down to the precipitation of a powder similar to the original zinc yellow.

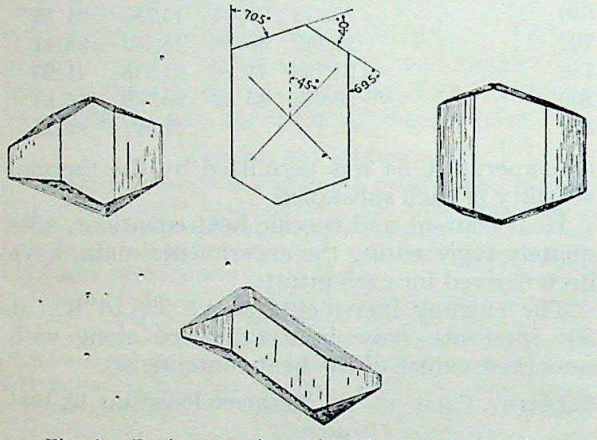

Fig. 1.—Basic potassium zinc chromate crystals.

Description.—The crystals (Fig. 1) were small, elongated, doubly-terminated, transparent yellow plates, belonging to the triclinic system, pinacoidal class. These crystals were hard but very friable. Maximum size observed for a single crystal was $10 \times 50 \times 90\ \mu$; plane angles of crystal outline measured 70.5°, 40°, 69.5°; crystals were strongly birefringent but not pleochroic. Indices of refraction were very high, being in the neighborhood of 2.0; extinction angle was about 45°, and oblique to the length of the crystal. One of the optic axes was oblique to the plate making an angle of about 21° with the normal to the plate. Dispersion was extreme, and greater at the red end of the spectrum than at the violet. Specific gravity, d^{25}_4 3.47. The crystals were soluble in alcohol, slightly soluble in water with partial decomposition to a less soluble product, and readily soluble in acids or ammonium hydroxide. They were stable in air at room temperature but lost water slowly above 100°.

Anal. Calcd. for $K_2O{\cdot}4ZnO{\cdot}4CrO_3{\cdot}3H_2O$: K_2O, 10.8; ZnO, 37.2; CrO_3, 45.8; H_2O, 6.2. Found: K_2O, 10.7; ZnO, 37.3; CrO_3, 45.4; H_2O, 6.5.

Basic Sodium Zinc Chromate

Riskin and Pugacheva[3] prepared a large variety of zinc yellows containing sodium oxide as replacement for potassium oxide, but no evidence has been presented of the existence of the pure sodium compound. By a method similar to that employed in making the potassium compound, the authors obtained quantitative yields of a new crystallized compound directly from the reaction

$$4ZnO + Na_2Cr_4O_{13} + 3H_2O \longrightarrow Na_2O{\cdot}4ZnO{\cdot}4CrO_3{\cdot}3H_2O$$

Under the microscope at 350 diameters the product appeared as small, highly refractive, transparent yellow, diamond-shaped plates, or short prisms; specific gravity, d^{25}_4 3.24. General properties were similar to those of the potassium compound. Analysis corresponded quite closely to the formula, $Na_2O{\cdot}4ZnO{\cdot}4CrO_3{\cdot}3H_2O$, as regards ratio of sodium oxide to zinc oxide to chromic anhydride; but the crystals were a little higher in water than $3H_2O$, probably due to difficulty of complete drying without decomposition.

Anal. Calcd. for $Na_2O{\cdot}4ZnO{\cdot}4CrO_3{\cdot}3H_2O$: Na_2O, 7.4; ZnO, 38.7; CrO_3, 47.5; H_2O, 6.4. Found: Na_2O, 7.4; ZnO, 38.3; CrO_3, 46.9; H_2O, 7.3.

Basic Ammonium Zinc Chromate

The ammonium compound was prepared in the same general manner as the potassium compound, but it was more difficult to obtain well-defined crystals. In preparing crystals of the ammonium compound it was found best to use a higher concentration and a little lower *p*H (5.3 to 5.7). Under the microscope at 350 diameters the crystals appeared as small, highly refractive, transparent yellow prisms, having a low order of symmetry. The product, however, did not consist entirely of crystals of this type. Mixed with these prismatic crystals were a few thin, transparent, yellow, hexagonal plates. All crystals were too small or too friable to separate by mechanical means. There was some variation in the analyses of crystals from different batches of the ammonium compound. The analysis of a typical batch of these crystals corresponded fairly closely to the formula, $(NH_4)_2O{\cdot}4ZnO{\cdot}4CrO_3{\cdot}3H_2O$, as regards percentages of zinc oxide and chromic anhydride; but the crystals were higher in ammonia with a corresponding decrease in water.

Anal. Calcd. for $(NH_4)_2O{\cdot}4ZnO{\cdot}4CrO_3{\cdot}3H_2O$: ZnO, 39.2; CrO_3, 48.1; $(NH_4)_2O$, 6.2; H_2O, 6.5. Found: ZnO, 39.8; CrO_3, 47.5; $(NH_4)_2O$, 8.0; H_2O, 4.6.

Alkali-Earth Compounds

The corresponding alkali-earth compounds were not obtained by the described method. When a solution of calcium tetrachromate, or magnesium tetrachromate, was substituted for potassium tetrachromate, the product was a basic zinc chromate containing only a trace of alkali earth.

Acknowledgment.—The authors wish to express their appreciation to J. D. N. Donnay, Institute de Geologie et de Mineralogie, Quebec, Canada, for his most helpful assistance in the crystallographic measurements of the potassium salt.

Summary

By the preparation of new, well-defined, crystals of a series of basic zinc chromates in which the oxides are combined in simple molecular proportions, it is shown that some of these products are definite chemical compounds, verifying the belief of the majority of prior investigators.

Redistribution Reactions in the Halides of Carbon, Silicon, Germanium and Tin

BY GEORGE S. FORBES AND HERBERT H. ANDERSON

The fundamental papers of Urey and co-workers on isotopic exchange equilibria[1,2,3] emphasize the fact that not even units so closely similar as isotopic atoms attain a truly random distribution among similar molecules. These investigators have set up general equations for calculation of equilibrium constants based on the distribution functions of diatomic and polyatomic molecules, and have quantitatively predicted those important deviations from random distribution which have served them so well in their separations of isotopes. One might expect *a priori* that any exchange reactions involving different organic groups, or even different halogen atoms, would exhibit substantial deviations from simple probability laws.

An important series of papers by Calingaert and co-workers[4,5,6,7,8,9] reports, however, that random exhange of organic radicals occurs within experimental error among certain alkyls, chloroalkyls and esters, likewise different halogen atoms among ethylene halides. From the laws of probability alone they work out a general equation for quantitative prediction of equilibria in such reactions, and stress the absence of chemical or energy factors affecting random distribution. They emphasize that "the redistribution reaction is adaptable as a new method of organic synthesis".[10]

It would seem that inorganic chemists have long possessed at least an instinctive realization of the possibilities of the redistribution reaction, especially in the synthesis of mixed halides containing a single atom of a quadrivalent element. For instance, Besson[11] obtained all the chloroiodides of silicon by passing iodine monochloride over silicon heated to redness. He found that if a silicon chloroiodide (plus iodine) was passed over heated silicon, silicon tetrachloride was one of the products, and he astutely remarks ". . . this is not surprising if one takes account of the partial dissociation of chloroiodides under the action of heat." Subsequently[12] he obtained mixed halides from the action of hydrogen bromide on phosphoryl chloride. He points out that the boiling point of $POClBr_2$, when distilled at normal pressure, is not fixed, since at this temperature (about 165°) it undergoes a progressive decomposition according to the equations

$$2POClBr_2 = POCl_2Br + POBr_3$$
$$\text{and } 3POClBr_2 = POCl_3 + 2POBr_3$$

Lecompte, Volkringer and Tchakirian,[13] improving a procedure of Besson,[14] heated chloroform with bromine in a sealed tube at successively higher temperatures up to 250°, allowing hydrogen bromide to escape after each heating. By fractional freezing, in addition to distillation, all the mixed halides were obtained.

Raeder[15] measured molar elevations of boiling points and molar depressions of freezing points in a great number of solutions made by dissolving a given halide of a given element from a middle group of the periodic system in excess of a second halide in the same category. By plotting $\pm\Delta T$/mole against mole per cent. of the first halide, he arrived at the following conclusions. The halides of phosphorus, arsenic, antimony, titanium, tin (and by prediction germanium as well) easily exchange their halogen atoms so as to enter into readily mobile equilibria and form mixed halides incapable of isolation in the solid or in the gaseous phase. On the other hand, the tetrahalides of carbon and silicon, which are characterized by great chemical inertness, form mixed halides only with difficulty and only under special conditions. Once formed, however, they can be isolated as pure compounds. Raeder cites Trümpy's analyses of Raman spectra of such systems[16] as confirmation of the above interpretations.

Papers of references 1 to 14 do not contain quantitative data on yields, so that closeness of approach to random distribution cannot be figured. Our interest in the stabilities of halides, cyanates and thiocyanates prompted a survey of the redistribution problem over Group IVA of the periodic system, in which at least the mixed chlorides of four elements enjoy some measure of stability. A subsequent paper by Anderson[17] describes the preparation and properties of three new compounds, $SiCl_3NCO$, $SiCl_2(NCO)_2$ and $SiCl(NCO)_3$ and shows that these, as well as mixtures of the end members of the series, attain at elevated temperatures distributions random within experimental error. In the present paper it is shown that their behavior fits into a larger scheme of relative stabilities.

Carbon Chlorobromides.—No reaction between carbon tetrachloride and tetrabromide was detected after seven hours in a sealed tube at 170°, or in a second experiment in which dry aluminum chloride was added. In the three

experiments listed in Table I, slightly moistened aluminum chloride was used as a catalyst, and the pressure of hydrogen chloride in the sealed tube was apparent. Random distribution was now attained within experimental error. The calculated mole percentages in Table I are figured from Calingaert's equations.[4] We have found no previous record of a direct reaction between carbon tetrachloride and carbon tetrabromide.

Experimental.—Carbon tetrabromide was precipitated from a water solution containing 25 g. of sodium hydroxide, 1 cc. of acetone and 5 cc. of bromine per liter as recommended by Wallach.[18] About 120 g. of crude product was recovered, washed, dried by suction and fused. A mixture with carbon tetrachloride in a known mole ratio was heated in a sealed tube at 170° for seven hours. Decomposition of carbon tetrabromide would have been excessive at higher temperatures or over longer periods. The reaction, if any, was less than 10% of the whole. A second experiment, with introduction of dry aluminum chloride, generated no pressure in the tube and appeared to yield no chlorobromides. In the succeeding experiments the aluminum chloride was spread out on paper, and breathed upon to activate it, presumably through formation of hydrogen chloride. Redistribution now occurred readily. After washing with caustic solution and drying with calcium chloride, the liquid mixture, 5–7 ml. in volume, was distilled using a column 30 cm. high and 7 mm. in diameter with a spiral of No. 22 copper wire having 80 turns, and was surrounded with a vapor jacket. Simultaneous readings were made of temperature, and of the depth of liquid collected in small flat-bottomed tubes backed by a millimeter scale. Satisfactory "flats" were observed at the boiling points of the first four members of the series, namely, 77°, 104°, 134°, and 160°. The cuts were made half-way between these temperatures. Small corrections were applied to the fractions for the estimated molar volumes of the respective chlorobromides. We encountered difficulties in separating the last of the chlorotribromide from tetrabromide in the last, very small, fraction. Our system was further complicated by presence of the compounds C_2Br_4 and C_2Br_6. In Experiment 3, presence of carbon tetrabromide was established qualitatively, but the figures in the last column indicate nothing beyond orders of magnitude. The other volumes, read within 0.05 ml., yielded mole percentages significant, we believe, within 2%.

Silicon Chlorobromides.—Silicon tetrachloride and tetrabromide were heated for seventy hours in a sealed tube at 140° without a catalyst. The physical properties of the fractionated products were measured, or remeasured to improve previously existing data. The figures are being submitted for separate publication in THIS JOURNAL. For redistribution studies, however, the different reactants in known mole ratios were passed through a tube at 600° approximately. Equilibrium was established quite rapidly, but the first experiment was evidently too hurried, so that mixtures 2 and 3 were passed at a half and a quarter of this rate, respectively. Table II summarizes the results. Corrections for the respective molar volumes have been applied.

Experimental.—In Experiment 1, 12 ml. of mixed liquids passed through a tube of 17-ml. volume at about 600° in forty-five minutes, but about 20% of the reactants escaped reaction. Table II shows that the second and third rates were not too rapid at the temperatures prevailing. During distillation in the apparatus described above, the temperature moved very slowly, over considerable volume intervals, in the vicinity of the boiling points of the five pure compounds, 57°, 80°, 104.5°, 128° and 153°, respectively. The last half of fraction 4 in Experiment 3 boiled at an average temperature of 132° instead of 128°, indicating the presence of some 16% of silicon tetrabromide. The volumes of tetrabromide in Experiments 2 and 3 indicate orders of magnitude only.

Since the members of the series carbon tetrachloride through carbon tetrabromide require a catalyst for rearrangement at 170°, while the members of the corresponding silicon series rearrange without a catalyst, it appears that carbon tetrahalides are much more stable with respect to rearrangement than those of silicon.

Silicon Chloroiodides.—Treatment of silicon tetrachloride with fused potassium iodide yielded a relatively small amount of $SiCl_3I$. Upon passage through a hot tube, a mixture of all five members of the series was obtained. At 58°, 114° and 172°, the boiling points of the first three members, the "flats" were especially sharp. The fractions in Table III approximate random distribution.

TABLE III

	$SiCl_4$	$SiCl_3I$	$SiCl_2I_2$	$SiClI_3$	SiI_4

Digitized by Siddhanta eGangotri Gyaan and eGangotri

the products are separated without appreciable rearrangement.

Germanium Chlorobromides.—Booth and Morris[19] prepared the closely related germanium fluorochlorides. Held at −78°, these rearranged to the extent of 60% within two weeks. We passed an equimolar mixture of tetrachloride and tetrabromide, prepared separately from the elements, through a hot tube at 600°. Five milliliters of the liquid product was distilled through the column described above, but more rapidly than the carbon and silicon chlorides. The initial rise in the actual distillation curve (Fig. 1) is consistent with a small percentage of tetrachloride and a low reflux ratio. Next, $GeCl_4$ and $GeCl_3Br$ are formed at the expense of higher chlorobromides and bled off. The first intermediate, $GeCl_3Br$, evidently distills off at 112°, between 25 and 36 atom per cent. of bromine allowing for products already distilled. Its calculated boiling point, 109°, is one-quarter of the way between 83° and 186.5°, the boiling points of the end members. On the whole the separate existence of germanium trichlorobromide, boiling point 111 ± 3°, is supported by the data. Redistillation of 12 ml. of distillate collected between 96° and 122° yielded relatively little at 109°, and large fractions approximating the end members. Evidently rearrangement is quite rapid between these temperatures. In another distillation, still more rapid, inconclusive retardations of the temperature rise seemed to occur near 135° and 161°, but we are reluctant to offer these in evidence. The upper half of the actual distillation curve shown in Fig. 1 resembles a curve for a mixture of stable end members.

Mixed Stannic Halides.—Besson[20] found it impossible to separate stannic chlorobromides from each other by repeated fractionation even under greatly diminished pressure. He states that this would result in total decomposition of the desired products into stannic chloride and stannic bromide. By fractional freezing he then obtained three products which he held to be the three chlorobromides of tin—quite nearly pure.

Raeder's freezing point curves for the systems $SnBr_4 + SnI_4$[21] and $SnCl_4 + SnBr_4$[22] indicated continuous series of mixed crystals without compound formation. He showed[22] why Besson's procedure led to fractions having the properties observed by him. In the system $SnCl_4 + SnI_4$, however, he found evidence of the compound $SnCl_2I_2$[22] having an incongruent melting point, and stable only below −47°.

As we were disinclined to undertake a further study of this problem, we merely passed equal volumes of stannic chloride and bromide through the hot tube, and redistilled the condensate in the same apparatus as used with the other chlorobromides, over a half-hour period. The distillation curve (Fig. 1) shows no retardations of temperature increase at any of the calculated boiling points of the chlorobromides. Its initial slope suggests rapid replacement of tetrachloride at the expense of chlorobromides. It lacks the steep middle portion to be expected, in this apparatus, of two non-reacting liquids boiling at 114° and 202°, respectively. Extrapolating the findings for carbon, silicon and germanium, one would predict a random mixture of all members of the tin series, very rapidly rearranging at all the distillation temperatures, in harmony with Raeder's conclusions. It would be of interest to determine whether mixed tin halides containing one or more fluorine atoms could be isolated.

Summary

Mixtures of carbon tetrachloride and tetrabromide, as well as the carbon chlorobromides, rearrange in seven hours at 170° with slightly moistened aluminum chloride as a catalyst, until halogen atoms are distributed among the five members of the series according to the laws of probability

The corresponding rearrangements in the silicon series (chlorobromides and chloroiodides) in seven hours at 140° without catalyst are partial, but complete after passage through a tube at 600°. These random mixtures can be fully separated by fractional distillation at normal pressure without appreciable rearrangement.

Distillation curves of the hot tube product from germanium tetrachloride and tetrabromide show definite indications of the new compound $GeCl_3Br$ at 112° approximately. Upon redistillation of such a fraction, rapid redistribution takes place.

The slope of a distillation curve of the stannic chlorobromides showed no irregularities near the boiling points calculated for the mixed compounds. Some indication of redistribution was obtained, although the individual compounds could not be isolated, presumably because of redistribution during distillation.

None of the phenomena observed were inconsistent with the hypothesis that all possible members of the germanium and tin chlorobromide series coexisted in random distribution.

The stability, against rearrangement, of the chlorobromides of Group IVA decreases steadily from carbon to tin.

Chloro(iso)cyanates of Silicon, Including Rearrangements at High Temperatures

BY HERBERT H. ANDERSON

Numerous series of volatile mixed halides have been discovered in the past, such as fluorochlorides, fluorobromides, fluorochlorobromides, chlorobromides, chloroiodides and bromoiodides. Their physical properties have been investigated moderately well, but comparatively little is known of their stabilities under various conditions. Recent work in this Laboratory has established the existence of volatile (iso)cyanates, and of one volatile cyanate: $Si(NCO)_4$,[1] $Ge(NCO)_4$,[2] $P(NCO)_3$,[1] $PO(NCO)_3$,[3] $PS(NCO)_3$,[2] and $As(NCO)_3$[3]; also $Si(OCN)_4$.[1] Thiocyanates are known also: $Si(SCN)_4$,[4] $P(SCN)_3$,[5] and $PO(SCN)_3$.[3] *This report* includes the isolation of all three chloro(iso)cyanates of silicon, and a study of their thermal rearrangements. *Further work*, now nearing completion, concerns chloro(iso)cyanates of phosphorus and phosphorus, chlorothiocyanates of silicon and phosphorus, and chlorobromides of carbon, silicon and germanium.

Preparation of Silicon Chloro(iso)cyanates.—Methods are listed in the order of importance.

(a) **Interaction of Silicon Tetrachloride and Silicon (iso)cyanate at 600°.**—A mixture of 66 ml. of $SiCl_4$ and 70 ml. of $Si(NCO)_4$[1] was passed slowly through a hot tube. A separatory funnel with constricted outlet served in regulating the drip of the liquid over a two-hour period. The first distillation yielded crude fractions of 10 ml. of $SiCl_4$, 32 ml. of $SiCl_3(NCO)$, 45 ml. of $SiCl_2(NCO)_2$, 35 ml. of $SiCl(NCO)_3$, and 11 ml. of $Si(NCO)_4$. Boiling points were 86.8° for $SiCl_3(NCO)$, 117.8° for $SiCl_2(NCO)_2$, and 152° for $SiCl(NCO)_3$. The redistillation of each of the above fractions was limited to a two-hour period to minimize decomposition; the boiling point ranges of fractions collected for measurements did not exceed 0.5°.

(b) **Sealed Tube Method; $SiCl_4$ and $Si(NCO)_4$.**—Fifteen ml. of $Si(NCO)_4$ and 11.3 ml. of $SiCl_4$ were heated in a Carius tube for seventy hours at 135°. Products were 4.8 ml. of $SiCl_4$, 2.8 ml. of $SiCl_3(NCO)$, 3.3 ml. of $SiCl_2(NCO)_2$, 6.5 ml. of $SiCl(NCO)_3$, and 6.0 ml. of $Si(NCO)_4$. On the basis of equilibria shown later in Table II, a period of a week at 135° would be required for random rearrangement of the products.

(c) **Gradual Addition of AgNCO to a Large Excess of $SiCl_4$ in Solution.**—The possibility of making chloro(iso)cyanates by very gradual addition of silver (iso)cyanate was considered. A mixture of 90 ml. of $SiCl_4$, 35 ml. of CS_2, and 70 ml. of C_2H_5Br was used; 80 g. of silver (iso)cyanate was added in small portions, over a period of an hour, with constant and vigorous shaking. The liquid boiled slowly because of the heat of reaction. Distillation yielded 6.8 ml. of $SiCl_3(NCO)$, 5.5 ml. of $SiCl_2(NCO)_2$, and 5.7 ml. of $Si(NCO)_4$; $SiCl(NCO)_3$ was absent, or less than 0.3 ml. This method is important, although not so valuable as the high temperature method, which gives all three compounds.

Chloro(iso)cyanates as By-products in the preparation of $Si(NCO)_4$, as previously described[1]: 517 g. of AgNCO and 108 ml. (9 ml. excess) of $SiCl_4$ were used. Redistillation of the fraction boiling between 95 and 183° yielded 0.8 g. of $SiCl_2(NCO)_2$, 3.3 g. of $SiCl(NCO)_3$, 147 g. of $Si(NCO)_4$ and an estimated 5 g. of $Si(OCN)_4$. On a basis of (iso)cyanate, the yield exceeded 90%. It has been found advisable to use about this excess of silicon tetrachloride, in order to convert the silver (iso)cyanate completely into silver chloride.

Analysis.—A weighed sample was frozen and dropped beneath a 6-cm. column of absolute alcohol in a test-tube; ethyl silicate, ethyl cyanate (or isocyanate), and hydrogen chloride were the products. Water was added immediately. This method is superior to decomposition by water with the consequent formation of silica gel. Chloride was determined with standard silver nitrate solution, using potassium chromate as indicator. For $SiCl_3(NCO)$: calcd. 60.28% Cl; found 60.1, 60.5. For $SiCl_2(NCO)_2$ calcd. 38.75% Cl; found 38.6, 38.9. For $SiCl(NCO)_3$ calcd. 18.70% Cl; found 18.8, 18.9. Molecular weights were found by the Dumas method. For $SiCl_3(NCO)$ calcd. 176.45; found 176, 180. For $SiCl_2(NCO)_2$ calcd. 183.01; found 180, 188. For $SiCl(NCO)_3$ calcd. 189.57; found 193, 196.

Physical Properties.—All three chloro(iso)cyanates are colorless liquids characterized by a peculiar "isocyanate odor." Boiling points were measured to 0.5°, immediately followed by measurement of the boiling point of pure benzene or water or bromobenzene under identical conditions. Densities were measured at 25°, using a 1.7 ml. bulb with a long capillary inlet bearing a reference mark. The height of the meniscus was measured in each case.

The system was calibrated with water and probably gave densities good to two parts per thousand. The index of refraction was measured with an Abbe refractometer (calibrated with water and carbon tetrachloride) in white light at 20°.

Melting points were determined using about 3 ml. of pure sample and a toluene thermometer, with its bulb wholly immersed in the liquid. This thermometer was calibrated at 0 and −78°; melting point ranges were much less than a degree. Table I shows the trends in properties from $SiCl_4$ through to $Si(NCO)_4$.[1] The calculation of boiling points of $SiCl_3(NCO)$, $SiCl_2(NCO)_2$, and $SiCl(NCO)_3$ by linear interpolation between those of $SiCl_4$ and $Si(NCO)_4$ gave 89.6°, 121.6°, and 153.6°. The average observed value falls 2.6° lower than the calculated figure—a reasonable agreement.

TABLE I

Compound	B. p., °C.	M. p., °C.	Density, 25°	n	Molecular vol., ml.
$SiCl_4$	57.57	−70	1.469[a]	1.4126	115.7
$SiCl_3(NCO)$	86.8	−69 ± 1.5	1.445	1.4262	122.4
$SiCl_2(NCO)_2$	117.8	−80 ± 1.5	1.437	1.4380	127.3
$SiCl(NCO)_3$	152.0	−35 ± 1.5	1.437	1.4507	131.9
$Si(NCO)_4$[1]	185.6	26.0	1.434[a]	1.4610	136.8

[a] Pycnometric value recently obtained.

Boiling points and indices of refraction are the best means of physical identification of members of the series. Melting points and densities are less distinctive.

Chemical Properties.—All three chloro(iso)cyanates of silicon, like other (iso)cyanates, are vigorously decomposed by water, with the formation of gas bubbles; they react vigorously with alcohol, but no bubbles appear. The (NCO) group in this series is quite stable at 600°. Oxidation is negligible in air at 200°.

Rearrangements of Chloro(iso)cyanates of Silicon.—As shown in the section on preparation, $SiCl_4$ and $Si(NCO)_4$

				calcd.	0.4	4.7	21.1	42.2	31.6

[a] Too small for satisfactory measurement, although $SiCl_3(NCO)$ started to distill at 80°, instead of 87°.

react together; all five possible compounds are produced in amounts predictable by assuming random distribution of groups. Previous work on redistribution in the lead alkyl series[7] indicated random distribution of groups, and included a method of calculating the percentage occurrence of each compound. Thermal rearrangement of individual compounds ($SiCl_3(NCO)$, $SiCl_3(NCO)$, and $SiCl(NCO)_3$) was studied carefully; vapor was passed through a hot tube at 600°, at a slow rate, with later determination of products by fractional distillation. Table II summarizes the results.

Experimental Work on Rearrangements.—The redistribution between $SiCl_4$ and $Si(NCO)_4$ was done on a large scale and produced large amounts of the compounds desired, as explained at the beginning of the section on preparation. By adjusting the amounts found according to molecular volumes (Table I), the correct molecular ratios were obtained. Rearrangements of $SiCl_3(NCO)$, $SiCl_2(NCO)_2$, and $SiCl(NCO)_3$ were obtained by the passage of 5 ml. of each pure compound through a small Pyrex tube at 600°, over a period of thirty minutes. Values in Table II have been rounded off to the nearest per cent. More precise and therefore slower distillation would have led to secondary rearrangements of considerable magnitude. Amounts of less than 2% are difficult to determine, notably if the least volatile compound is involved. Volumes were measured to 0.05 ml. in calibrated receivers of the same bore and with nearly flat bottoms.

The percentages indicate random distribution within a few per cent. Secondary rearrangements are too close for attainment of theoretical ratios. Values of the chief component are a little low in all cases, but this is within experimental error, and without significance.

(7) Calingaert, Beatty and Soroos, THIS JOURNAL, 62, 1100 (1940).

A sample of $SiCl_2(NCO)_2$ rearranged to the extent of several per cent. after standing four months at room temperature. Mixtures of $Si(NCO)_4$ and $SiCl_4$, as well as the three chloro(iso)cyanates, are being set aside at room temperature with the intention of determining the distribution of products after considerable time intervals.

The author is much indebted to Professor George S. Forbes of this Laboratory for many helpful suggestions. Other work on rearrangement of mixed halides and on cyanates and thiocyanates is in progress and will be reported soon.

Summary

1. $SiCl_3(NCO)$, $SiCl_2(NCO)_2$, and $SiCl(NCO)_3$ have been prepared. The progression of several physical properties in the series $SiCl_4$ through $Si(NCO)_4$ has been tabulated. $SiCl_4$ and $Si(NCO)_4$ react rapidly at 600° to give all three chloro(iso)cyanates. Interaction is moderate in rate at 135°, and extremely slow at room temperature. Gradual addition of AgNCO to a large excess of $SiCl_4$ in solution yields $SiCl_3(NCO)$ and $SiCl_2(NCO)_2$, but no $SiCl(NCO)_3$.

2. Random distribution, such as previously found by Calingaert, Beatty and Soroos in the lead alkyl series, also applies to the rearrangement of any mixture or pure compound in the series $SiCl_4$ through $Si(NCO)_4$. No catalyst is needed.

A Study of Organic Parachors. VI. A Supplementary Series of Tertiary Alcohols[1]

BY OSBORNE R. QUAYLE AND KATHERINE O. SMART

The parachor values for a series of tertiary alcohols[2] have been previously reported from this Laboratory and values for the CH_2 group in various positions have been determined and suggested as a means of calculating the parachors of other tertiary alcohols. Nine additional supplementary tertiary alcohols have been prepared and their refractive indices, densities, surface tensions and parachors have been determined. The alcohols were prepared by standard methods and were purified by successive vacuum distillations.[3] To minimize decomposition the temperatures of distillation were kept below 75°. Refractive indices were determined at 20, 25 and 35°. Densities and surface tensions were measured at 25, 45 and 55°, and the parachors were calculated for the same temperatures, using the standard formula $P = M\gamma^{1/4}/(D - d)$. The data obtained are shown in Table I. The varia-

tions of refractive indices, densities, surface tensions, and parachors with temperature are shown in Figs. 1, 2, 3, 4, respectively.

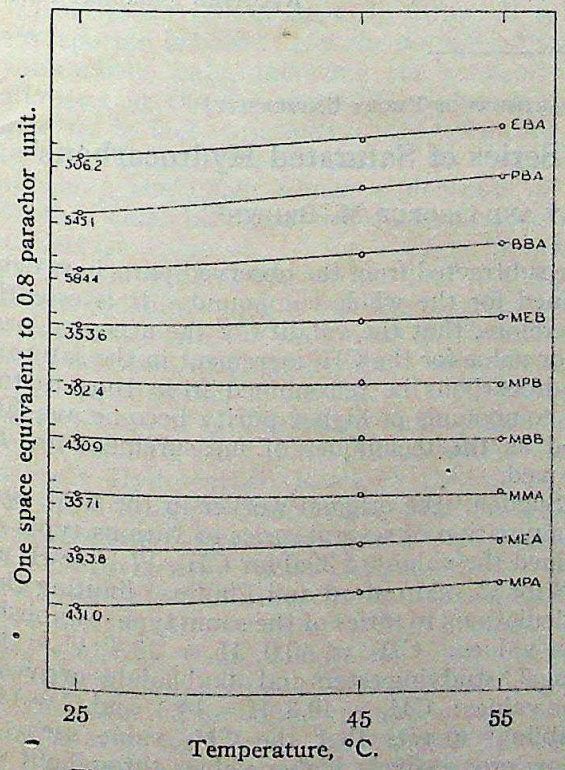

Fig. 4.—Parachors of tertiary carbinols.

Surface tensions were determined by the maximum bubble pressure method. Certain modifications were made in the design of the bubbler to ensure greater accuracy and reproducibility of readings, as well as to decrease the time necessary for measurement. It has long been recognized that it is essential that the bubbler tubes be vertical. In order to check this the tubes were attached to a cap, with an externally ground glass joint, so that they might be conveniently rotated. After a reading was completed the tubes were rotated 180° and a second reading made. If the same value, within experimental error, was obtained the tubes were considered vertical and the readings were accepted as a measurement. Each measurement was independently checked by a second observer. To avoid loss of time in readjusting the tubes to the vertical position after a change in sample, the bubbler was equipped with a heavy ground-glass flange fitting into a heavy ground collar. If the collar is securely clamped, the bubbler after being removed and replaced will seat itself in the same vertical position. In order to permit the use of samples as small as three cubic centimeters the bubbler may be slightly smaller in diameter below the flange. The design of the bubbler is shown in Fig. 5. While the modifications described may appear to be minor, the changes greatly facilitate more accurate and more rapid measurement.

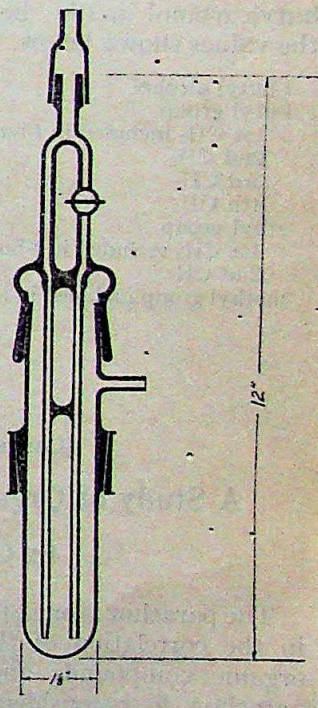

Fig. 5.—Bubbler for surface tension.

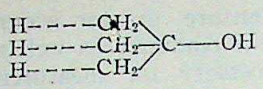
The results obtained offer an opportunity to test the values on the parachor in tertiary alcohols previously reported.[2] Using the previously reported position values for the CH_2 increments in obtaining calculated parachors, the maximum deviation between an experimental value and the corresponding calculated value was found to be 0.3% in the case of methylpropylamylcarbinol. In no other case did the deviation exceed 0.1%. The experimental error has been considered to be 0.1%. These values are given in Table I.

From the newly-determined tertiary alcohols several additional CH_2 values for various positions in tertiary alcohols may be calculated. Combining these values with those previously reported a table may be constructed for the estimation of the parachor of any tertiary alcohol having unbranched alkyl groups. Assuming the parachor value for

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

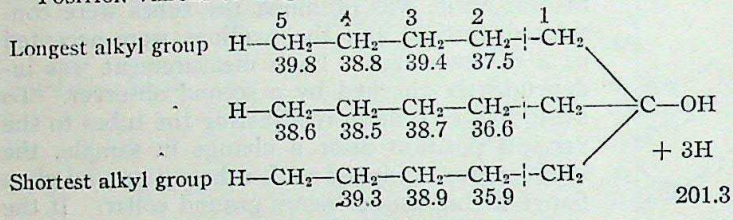
Digitized by Arya Samaj Foundation Chennai and eGangotri



to be the determined value 201.3 of *t*-butyl alcohol, the parachor of any tertiary alcohol may be estimated by adding the CH_2 values for the various positions as given in Table II.

TABLE II

POSITION VALUES OF CH_2 IN PARACHORS OF TERTIARY ALCOHOLS



For example, the parachor for methylethyl butylcarbinol would be calculated by adding the values shown below.

t-butyl alcohol	201.3
butyl group	
1st CH_2 included in *t*-butyl linkage	———
2nd CH_2	37.5
3rd CH_2	39.4
4th CH_2	38.8
ethyl group	
1st CH_2 included in *t*-butyl linkage	———
2nd CH	36.6
methyl group included in *t*-butyl linkage	———
	———
	353.6

Values for CH_2 units further removed from the —OH group than the amyl position may be considered constant at 40.0. It should be remembered in the use of this table that the actual value of the CH_2 is, in all cases, considered to be essentially a constant, 40.0. The values in the table to be added in calculation represent the sum of two factors; the increase of the added CH_2 minus the effect of increasing the carbon chain upon the $>C—OH$ group. Also, each position value is only an average of values which (by the fundamental assumption of variation with different attached groups) would not be expected to be identical.

Summary

1. The refractive indices, densities, surface tensions, and parachors of nine additional tertiary alcohols have been reported for three temperatures.

2. The experimental values for the parachor have been shown to be in close agreement with the calculated values.

3. A table for the estimation of parachors for tertiary alcohols has been given.

4. Modifications in the bubbler for determining surface tension more accurately and rapidly have been described.

A Study of Organic Parachors. VII. A Series of Saturated Hydrocarbons[1]

BY OSBORNE R. QUAYLE, R. A. DAY AND GEORGE M. BROWN[2]

The parachor is one of the more useful constants in the correlation of the physical properties of organic compounds and their structures. The parachor, first considered an additive property, has been found to be susceptible to minor as well as to gross variations in structure. It is particularly so to any variations in the degree of unsaturation of the molecule. The parachor values in normal saturated hydrocarbons have been found to be almost unique in being additive in nature.[3] In calculating the values of other groups the alkyl residues are, therefore, considered to be of known value and are subtracted from the observed parachors determined for the whole compound. It is essential, therefore, that the validity of the accepted parachor value for the CH_2 increment in the saturated hydrocarbons be reëxamined from time to time as compounds of higher purity become available and as the techniques of measurement are improved.

Sugden,[4] the original worker in the field, upon examination of several series of various types obtained the values of 39.0 for CH_2, 17.1 for H, and 4.8 for C. Mumford and Phillips,[5] limiting their calculations to series of the same type, established the values: $CH_2 = 40.0$, H = 15.4, C = 9.2. Vogel,[6] studying esters and alkyl halides arrived at the values: $CH_2 = 40.3$, H = 14.4, and C = 11.5. Gibling[7] asserts that the CH_2 value seems to show progressively higher values throughout any homologous series due to decreasing "interference"

(1) The authors wish to express their gratitude to Prof. E. Emmet Reid, research consultant to the department, for his continued interest and suggestions in connection with the problem; to the American Petroleum Institute for samples of hydrocarbons; and to the University Center in Georgia for a grant for the purchase of a constant temperature bath.

(2) New York Community Trust Fellow, Emory University 1942–43; present address Princeton University, Princeton, N. J.

(3) Even the values for the saturated chains are not considered to be strictly additive by some observers. However, they are at least essentially so. If variations exist they appear to be of a distinctly lower order of magnitude for chains of short or moderate length.

effects. His formula gives somewhat better agreement between observed and calculated values for high molecular weight compounds.

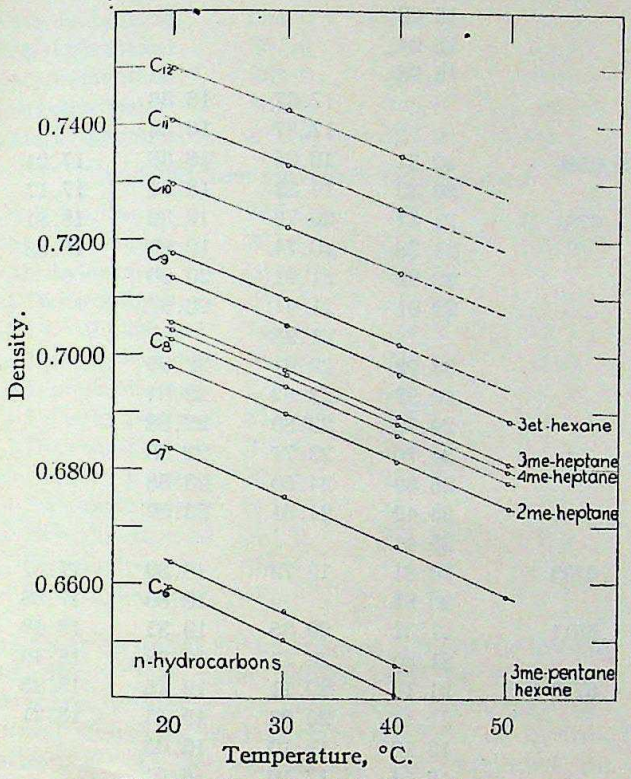

Fig. 1.—Densities of hydrocarbons.

The re-evaluation of the CH_2, C, and H values here reported is based upon the normal saturated hydrocarbons only, following the concept that variations in the apparent CH_2 value of other series are in fact variations in the values for the other non-hydrocarbon parts of the molecules. Branching the chain causes a decrease in the parachor which has been termed a strain constant. An average value of -3 for a single branching has been in general use. This does not appear to be a constant value. The hydrocarbons used in this work, with the exceptions of nonane, decane, undecane and duodecane, were prepared under the direction of Professor C. E. Boord of the Department of Chemistry of The Ohio State University as a part of the American Petroleum Institute Hydrocarbon Research Project in the Industrial Research Foundation of the University. The *n*-hexane, 2-methylpentane, 3-methylpentane and 3-ethylhexane were designated as "best liter" purity. The other A. P. I. hydrocarbons were designated as "pure." The nonane, decane, undecane, and duodecane were obtained from the Eastman Kodak Company and were refractionated. The boiling ranges of the latter samples were as follows: nonane, 148.6–148.7° at 738.0 mm.; decane, 97.8–98.4° at 69.0 mm.; undecane 108.7–109.0° at 50.5 mm.; duodecane, 66.0–66.1° at 2.3 mm.

The maximum bubble pressure method was used in the measurement of surface tension, the apparatus used being a modification[8] of that of Sugden. Surface tensions were checked by two observers. Each value reported represents a value calculated from a minimum of four observations. Where two or more values are recorded (Table I), these are entirely independent determinations made after intervening measurements, temperature changes, etc., in an endeavor to minimize any constant errors. All temperatures were maintained to within $\pm 0.05°$. The precision in the determination of surface tension was somewhat greater than one part in five hundred. The over-all precision in the determination of the parachor was in the order of one part in two thousand.

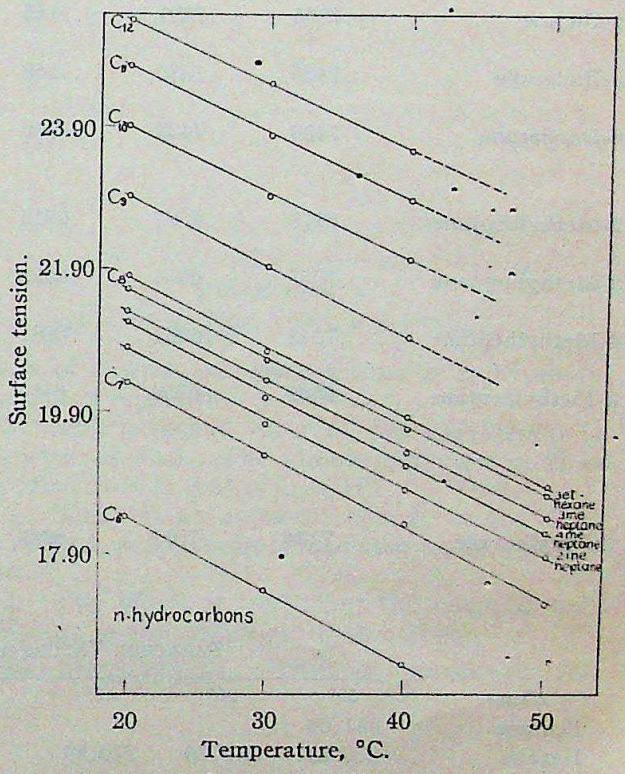

Fig. 2.—Surface tensions of hydrocarbons.

The densities and surface tensions determined are given in Table I. The parachor values were calculated by the equation $P = M\gamma^{1/4}/(D - d)$ where γ is the surface tension, M the molecular weight, D the density of the liquid, and d the density of the vapor at the same temperature. The calculated density of the vapor is relatively small and is included in the calculations only where its value is appreciable. The parachors of the normal saturated hydrocarbons and of the CH_2 increment are given in Table II. The parachors of the branched chain hydrocarbons and the values for the "strain constant" for branching are given in Table III.

The average CH_2 increment in the series of normal hydrocarbons is 40.0. There is no apparent change in this value as the chain increases within the limits here investigated. The change

Av. CH_2, 39.9 at 20°, 40.0 at 30°, 40.0 at 40°, over-all average 40.0

of parachor over the range of temperature studied is in no case over 0.15%. The maximum deviation from the average obtained for any calculated CH_2 increment is 1.7%; for any single compound 1.3%. It should be noted that while the value for CH_2 of 40.0 is identical with that reported by Mumford and Phillips,[5] (based on determinations of Hunten and Maass[9] primarily upon fatty acids) the value reported in the earlier work was obtained by averaging values which differed from each other by as much as 22%. Calculation from each determination of the present study gives an average atomic parachor value for H of 15.5; for C the value is 9.0.

The effect of branching the chain in the compounds studied is not uniform. The effect is increased as the branch is moved toward the center of the chain, and as the length of the branch chain is increased. Among the compounds here measured the effect is greatest in 3-ethylhexane, which has, obviously, the most symmetrical compact molecular structure. Since the parachor is a volume factor it might be expected that

2,3-Dimethylheptane	391.0	373.1	−9.0
2,7-Dimethyloctane	431.0	426.4	−2.3
2,4-Dimethyloctane	431.0	422.9	−4.1

the most compact structure would have the lowest parachor. The same effect may be noted in parachor values calculated from previously recorded densities and surface tensions of hydrocarbons.[10] These values are also included in Table III. While certain regularities appear, sufficient data are not available to properly evaluate the variations in the effect of branching the chain.

Summary

1. The densities, surface tensions, and parachors of a series of hydrocarbons of high purity have been reported.

2. The parachor value of the CH_2 group is reported as 40.0. The atomic parachor of H is reported as 15.5, that of C as 9.0.

3. There is no apparent change in the CH_2 increment as the chain is increased up to duodecane.

4. The effect of branching the chain is not constant in the saturated hydrocarbons

A Spectrographic and Kinetic Study of the Alkaline Fading of Tetraiodophenolsulfonphthalein

BY EDWARD S. AMIS AND RALPH THEODORE OVERMAN

The alkaline form of iodo phenol blue (tetraiodophenolsulfonphthalein) has a characteristic absorption curve the intensity of which is a function of the amount of the dye present in the blue form. If an excess of the alkaline hydroxide is added to a solution of the iodo phenol blue, the dye fades to a colorless condition. The rate of fading depends upon the concentration of hydroxide present. When the colorless solution is acidified, the characteristic yellow acid form of iodo phenol blue develops progressively with time. This regeneration reaction has been studied quantitatively in the case of the brom phenol blue.[1] It is possible to study the structure of the faded and unfaded form of the dyes both spectrographically and kinetically.

In this investigation a spectrographic study was made of both the unfaded and regenerated tetraiodophenolsulfonphthalein to determine whether the two were identical. A kinetic study of the fading process in the presence of iodide salt also was made. By these methods it was hoped that definite conclusions could be reached as to the validity of proposed mechanisms for the fading and regeneration processes.

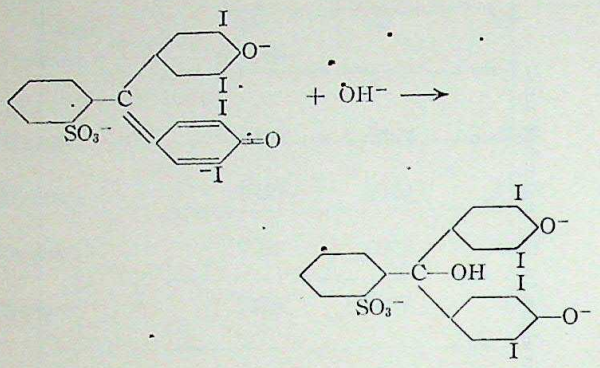
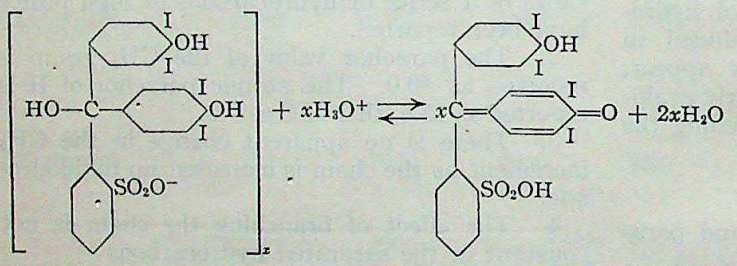
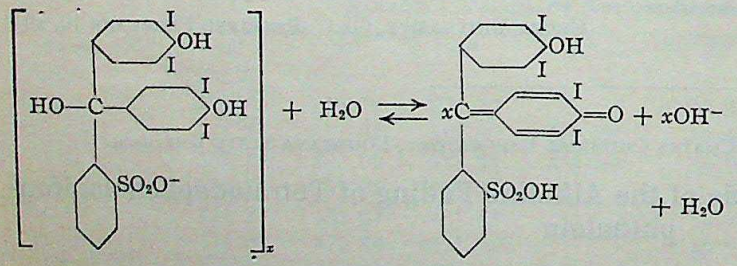
I. The Spectrographic Study.—The fading is assumed to take place according to the reaction[2,3]



and hence the regeneration is simply the reforming of the colored quinoid form of the dye from the colorless carbinol. According to Brode[4] the quinoid structure has a characteristic absorption band at a more or less definite region of the spectrum depending on the other groups present. The product formed in reaction (1) would show absorption due to the carbinol, phenol and sulfonic acid groups which have no absorption in the range of the normal photographic plate.[4] The regeneration reaction it is presumed (1) takes place according to the following mechanisms





Thus the quinoid structure of the dye is regenerated and since this material is identical with the unfaded acid form of the dye, the absorption spectrum of the regenerated material should of necessity coincide with that of the acid form of the unfaded iodo phenol blue when the two are at like *p*H.

Apparatus and Procedure.—The spectrographic data were obtained using a large Littrow spectrograph with spectrometric attachments. For these experiments dye solutions were made up to 10^{-5} molar using the same quality of dye and the same procedure employed by Amis and LaMer[3] in studying the kinetics of the fading of bromo phenol blue. The alkali for the fading was made up according to the specifications of the above authors. All measurements were made from cells with a column of absorbing medium which was 2 cm. in length. The light source for the visible region was a Mazda filament lamp and for the ultraviolet region was a hydrogen discharge tube. The setting for the visible spectra was position 3 of the glass system covering a frequency of 450–700 fresnel units. For the ultraviolet absorption of the faded dye, positions 5 and 9 of the quartz system covering a region of 450–1500 fresnel units (2000–6000 Å.) were used.

The procedure consisted of printing a millimeter scale on the plate, exposing the plate as a blank with no absorption cells in the light beam, and then interposing the cells, one being filled with distilled water and the other containing the sample being studied and measuring the absorption. The respective cells for the water and for the sample were always the same. The blank was made necessary by the fact that it was found to be impossible to equate the light intensities of the two parts of the beam visually so that they gave identical readings on the densitometer. The blank made it possible to correct for the initial difference in intensity of the two beams. The times of exposure were three, four and five seconds. The final curve was plotted from the average of the three densitometer readings corresponding to a given frequency.

The absorption as a function of the degree of fading was determined by setting the dye (10^{-5} *m*) to fade at room temperature in a known strength of alkali and at stated intervals of time measuring the absorption of the fading material. The fading was carried out in such concentrations of alkali that the short time used in taking absorption represented little change in the condition of the dye since the rate of fading was very slow.

The densitometer used was an Applied Research Laboratories Instrument which measures the density of the plate by use of a photoelectric cell. In this instrument the dark current is set to zero on the galvanometer scale and the reading of 100 as the transmission of a clear portion of the plate. The densitometer readings (D's) then ranged from zero to one hundred.

The logarithm of the ratio of the galvanometer deflection (D) for the beam which had passed through the dye to that (D_0) which had passed through the water can be related to the absorption of the incident light by the dye solution when proper corrections are made for the corresponding deflections (D' and D_0') obtained from the blank,

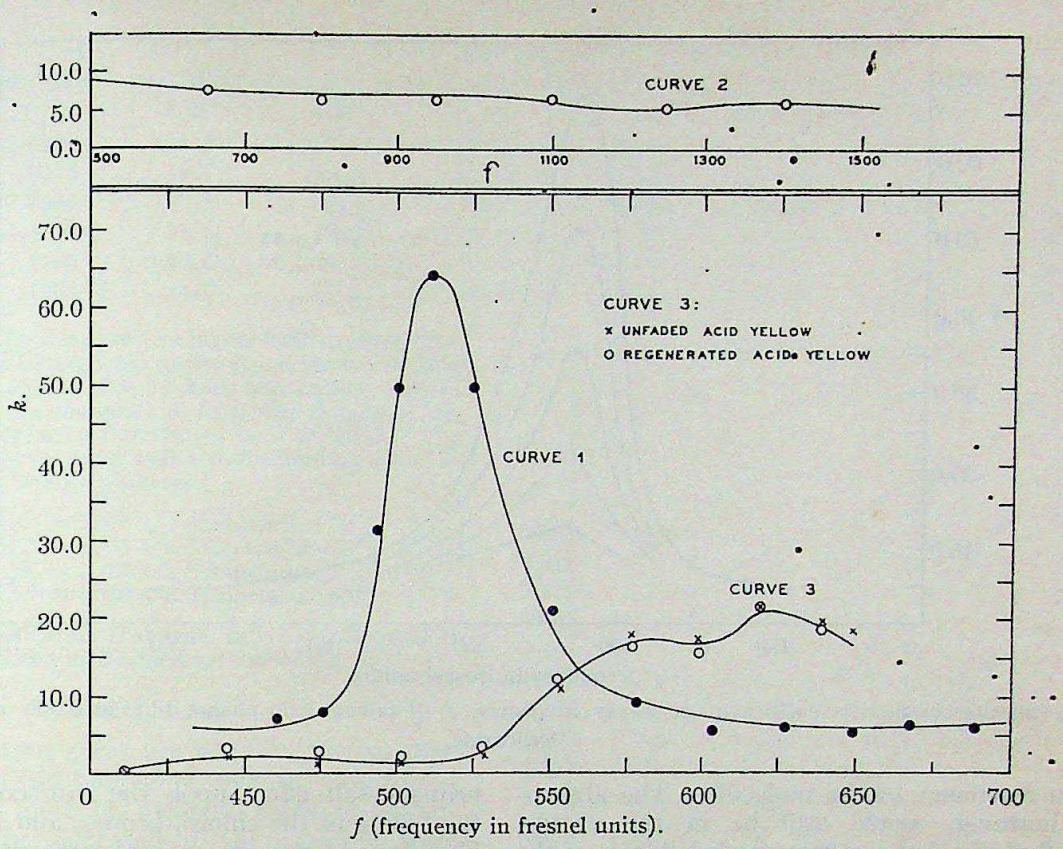

Fig. 1.—Specific extinction coefficient, k, *versus* frequency, f: Curve 1, monosodium salt of iodo phenol blue; Curve 2, iodo phenol blue faded in 0.009 molar sodium hydroxide; Curve 3, unfaded and regenerated iodo phenol blue in like strength of dilute hydrochloric acid.

and from this relationship we calculate the specific extinction coefficient, k, which according to Beer's law is given by

$$\log \frac{I}{I_0} = -kcd = \log \frac{D_0}{D} - \log \frac{D_0'}{D}$$

or

$$k = \frac{1}{cd} \log \frac{DD_0'}{D_0D'}$$

This is plotted against frequency according to the suggestion of Brode.[4]

Data and Discussion.—The specific extinction coefficients and the corresponding wave lengths of the unfaded monosodium salt of iodo phenol blue (10^{-5} molar) in solution containing no excess alkali are plotted in Curve 1 of Fig. 1 using frequency in fresnel units as abscissas and specific extinction coefficients as ordinates. This method of plotting corresponds to decreasing wave lengths of light from left to right. The dye is seen to have a sharp absorption maximum at a frequency of 510 fresnel units or 5808 Å. The specific extinction coefficient as a function of frequency for the alkaline faded iodo phenol blue in 0.009 molar sodium hydroxide is plotted in Curve 2 of Fig. 1. This absorption spectrum is typical of non-chromophoric molecules, *i. e.*, molecules containing linkages similar to those found in alcohols, acids, etc.

The specific extinction coefficient as a function of frequency of both the unfaded and of acid regenerated iodo phenol blue is likewise plotted in Curve 3 of Fig. 1, the measurements being taken in dilute hydrochloric acid solution of like concentration (pH 3) in both cases. The two spectra are identical and hence the regenerated dye corresponds exactly to the unfaded material. Thus the regeneration process is merely a change from the colorless carbinol to the yellow acid quinoid structure of the iodo phenol blue.

These spectrographic data would support the mechanism of the fading to be the formation of the colorless carbinol from the quinoid form of the dye as accepted by Thiel,[2] Biddle and Porter,[5] Kober and Marshall,[6] Kolthoff,[7] and Amis and LaMer[3] rather than the mechanism proposed by Kilpatrick and co-workers.[8,9,10] These investigators thought that the fading was due to the substitution of one of the four iodine atoms in the dye molecule by the hydroxide ion yielding iodide ion.

Now if the fading mechanism were one of substitution of a heavier iodide atom by a lighter hydroxyl radical there should be only a shifting of the absorption band to correspond to the differ-

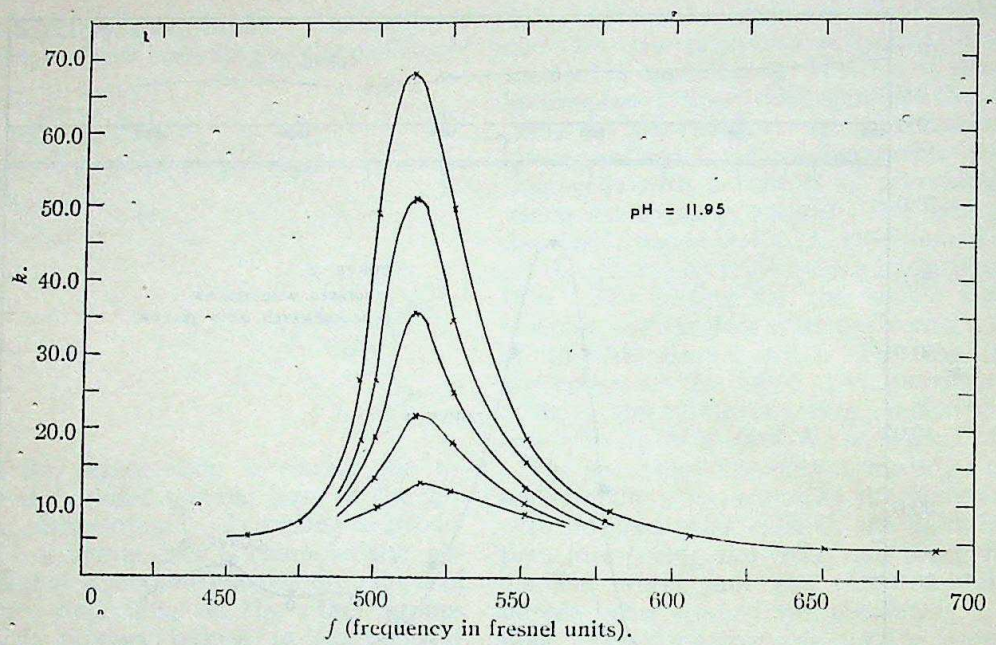

Fig. 2.—Specific extinction coefficient, k, *versus* frequency, f, of fading iodo phenol blue in 0.009 molar sodium hydroxide.

ence in resonance of the molecule. The absorption, however, would still be in the visible. Curve 2 of Fig. 1 shows that the faded form of the dye is non-chromophoric and has, therefore, lost its quinoid structure. Further, the regenerated acid form of the dye is identical in absorption with the acid form of the unfaded dye as shown by Curve 3 of Fig. 1. It appears that the acid regeneration is the removal of the hydroxyl radical from the carbinol and the reforming of the quinoid structure of the dye, rather than the re-entering by acidification of the iodine atom into the benzene nucleus.

Figure 2 represents the absorption of the iodo phenol blue as a function of the degree of fading in 0.009 molar sodium hydroxide. These curves strongly resemble the absorption of the phthalein dyes as a function of the pH of the solution.[11] And as in the case of change of pH, the absorption band does not shift greatly in wave length but simply changes in intensity, with the increased fading of the dye.

II. The Kinetic Study.—The fading of brom phenol blue as a function of hydroxide ion concentration has been carefully studied.[3] In helping to prove the mechanism of the reaction it would be pertinent to study the salt effect upon the reaction velocity. Especially would it help if the rate were run in the presence of an iodide salt, since if the mechanism proposed by Kilpatrick, *et al.*, is correct the iodide ion should exert a mass effect whereas if the fading is due to the formation of carbinol the iodide salt should exert a primary salt effect and increase the reaction rate since the reactants are both negatively charged. Panepinto and Kilpatrick[10] found a primary salt effect upon the rate constants for the fading of the chloro, bromo, and iodo phenol blue dyes in the presence of potassium chloride and bromide but found the values for the internal energy were not of sufficient accuracy to test the primary salt effect upon this function.

Materials and Procedure.—The materials and methods in these studies were essentially those used by Amis and LaMer.[3] The stock solution of iodo phenol blue was 1×10^{-4} molar. The sodium iodide (J. T. Baker analyzed) was made up before each run by weighing on an analytical balance and diluted to a suitable volume. The temperature was held constant to $\pm 0.01°$.

Ten milliliters of the 1×10^{-4} molar dye solution was placed in a volumetric flask and sufficient sodium iodide solution, sodium hydroxide solution and water were added to make a total volume of 100 milliliters of solution which was 1×10^{-5} molar with respect to the dye, 0.006 molar with respect to the sodium hydroxide and with such concentrations of sodium iodide as to give the various ionic strengths used in the studies. The time of addition of sodium hydroxide was noted and used as the initial time in the runs. A standard neutral solution of the dye (1×10^{-5} molar) was also made up and placed in the thermostat. To make a reading five milliliters of the fading dye solution was pipetted into one colorimeter cup and five milliliters of the standard unfading dye into the other colorimeter cup. Using a Klett top-reading colorimeter the amount of fading was determined as a function of time. The illumination used was a Mazda lamp with a blue filter.

The rate constants were calculated using the pseudo-unimolecular rate equation. The bimolecular rate constant was obtained by dividing the pseudounimolecular rate constant by the molarity of the sodium hydroxide which remained sensibly constant throughout a given run. The concentration was expressed in moles per liter and the time in days.

In Table I are tabulated the bimolecular rate constants at various ionic strengths and for the temperatures 25, 35 and 45°; also the energies of activation and the Arrhenius frequency factors are recorded in this table. The quantitative agreement of the data on the rate constants with the requirements of Brönsted's theory of primary salt effect can be illustrated by plotting log k *vs.* $\sqrt{\mu}$ (see Fig. 3).

TABLE I

DATA FOR WATER WITH ALKALI HYDROXIDE AND ALKALI SALT ADDED: DYE 10^{-5} M, NaOH 0.006 N WITH ADDED NaI

		k, 25°	k, 35°	k, 45°	ΔE^*, 25–35°	ΔE^*, 35–45°	B, 25–35°	B, 35–45°
0.000	0.0000	(14.3)	(27.7)	(50.2)	12,070	11,520	10.00	9.61
.006	.0775	19.7	38.5	69.9	12,180	11,640	10.24	9.84
.008	.0895	20.8	40.6	73.9	12,190	11,660	10.28	9.87
.010	.1000	21.6	42.2	76.9	12,210	11,680	10.32	9.91
.012	.1096	22.6	44.2	80.6	12,230	11,700	10.34	9.96
.016	.1265	24.0	47.0	86.0	12,250	11,730	10.37	10.01

Log k obeys the limiting law to a higher ionic strength than would ordinarily be expected as was found for the alkaline fading of brom phenol blue by Amis and LaMer.[3] Plots can be made of the energies and Arrhenius frequency factors, respectively, as a function of ionic strength. The slopes of these curves agree well with the limiting values of the slopes given by the equations[12]

$$\Delta E^* = 1569\sqrt{\mu}\ \text{(temperature 30°)}$$
$$\Delta E^* = 1605\sqrt{\mu}\ \text{(temperature 40°)}$$
$$\Delta S^*/2.3R = 3.19\sqrt{\mu}\ \text{(temperature 30°)}$$
$$\Delta S^*/2.3R = 3.25\sqrt{\mu}\ \text{(temperature 40°)}$$

There is no indication that mass action is influential in the observed kinetics with added sodium iodide.

Conclusions

1. Absorption spectrum data on the alkaline faded iodo phenol blue show that the absorption approximates that of alcohol, acids or water. This would be expected if the carbinol were formed during the fading process.

2. Absorption spectra of the unfaded and regenerated acid solution of the dye are identical and it would appear that the fading process is reversed in acid solution.

3. The absorption of the fading dye as a function of the degree of fading, shows no marked shift in the absorption band during the fading process, but only a decrease in the intensity of absorption.

4. The influence of added sodium iodide upon the kinetics of the fading of iodo phenol blue is that of the Brönsted primary salt effect rather than a mass action effect.

5. These observations lead to the conclusion that the fading process is one of carbinol formation with the corresponding disappearance of the quinoid structure and that the regeneration process is the reconstruction of the quinoid form of the dye.

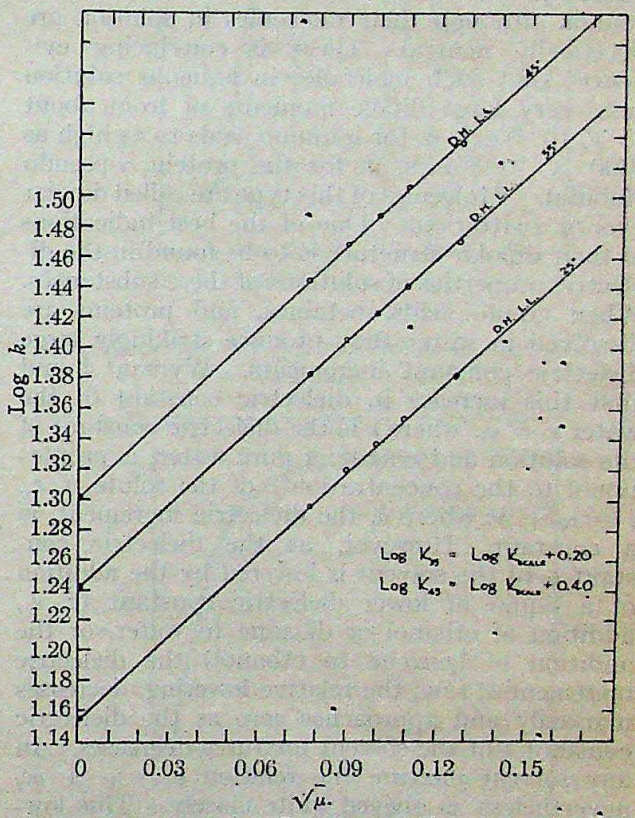

Fig. 3.—Log k *versus* $\sqrt{\mu}$ for the alkaline fading of iodo phenol blue in 0.006 molar sodium hydroxide and various concentrations of sodium iodide.

The Dielectric Constants of Solutions of Glycine and Pyridine Betaine in Water–Dioxane Mixtures

BY GERALD OSTER,[1] DONNA PRICE,[2] LESLIE G. JOYNER[3] AND JOHN G. KIRKWOOD

Introduction

The amino acids, betaines, and proteins exhibit certain properties similar to those of ionic compounds although their molecules in solution are electrically neutral. There is convincing evidence[4] that such molecules in aqueous solution have very large dipole moments of from about 15×10^{-18} e. s. u. for α-amino acids to as high as 1300×10^{-18} e. s. u. for the protein γ-pseudo globulin. Molecules of this type are called dipolar ions or zwitterions. One of the best indications of their dipolar structure is to be found in the dielectric properties of solutions of these substances. When amino acids, betaines, and proteins are dissolved in water they produce strikingly large dielectric constant increments. Wyman[5] found that this increase in dielectric constant of the water $\epsilon - \epsilon_0$, where ϵ is the dielectric constant of the solution and ϵ_0 that of pure water, is proportional to the concentration c of the solute, *i. e.*, $\epsilon = \epsilon_0 + \delta c$ where δ, the dielectric increment, is a constant. However, as the dielectric constant ϵ_0 of the solvent is lowered by the addition of a liquid of lower dielectric constant (*e. g.*, addition of ethanol or dioxane to water, or the addition of benzene to ethanol) the dielectric increment δ, *i. e.*, the relative lowering, decreases markedly and approaches zero as the dielectric constant ϵ of the solvent mixtures decreases. In any solvent mixture the relation $\epsilon = \epsilon_0 + \delta c$, nevertheless, is obeyed quite closely. This lowering of δ which corresponds to an apparent decrease in the dipole moment of the dipolar ions was thought to be due to an actual movement of the charged groups toward each other since lowering the dielectric constant of the solvent medium increases the coulombic attraction between the charges. It was thought that either there was an equilibrium between dipolar ions and completely uncharged molecules due to the movement of charged groups, or else a gradual decrease in dipole moment due to the distortion of chemical bond angles, so that the charges could come close together.

In order to examine these hypotheses two types of dipolar substances were examined, glycine and pyridine betaine. Glycine $^+NH_3CH_2COO^-$ offers the possibility of a shift of a hydrogen atom to the COO^- group thereby forming a nondipolar molecule, while pyridine betaine  contains no groups which can shift to form the un-ionized molecule.

Experimental

Apparatus.—The apparatus used to measure the dielectric constant was similar to that of Geddes and Kraus[6] with some modifications. The method is a resonance method due to Wyman.[7] The technique consists essentially in completely immersing in the medium a resonator of fixed inductance and capacity. The resonator is coupled inductively to an oscillator, the frequency of which is adjusted by a variable capacity until it corresponds to the natural period of the resonator. From the frequency of the resonator in vacuum (air) or in a standard of known dielectric constant and its frequency in the unknown medium the dielectric constant of the latter may be determined.

Certain features of the apparatus will be described briefly.

The resonator was of the shielded type used by Wyman for measurements in benzene. Due to the corrosive action of glycine solutions on many metals the resonator was constructed of platinum–10% iridium alloy.

The resonator was suspended in a cell containing 400 cc. of fluid. This cell was set in a double walled flask through which oil from a constant temperature bath was circulated. The double-walled flask was in turn surrounded by a Dewar flask. Thus the temperature of the solution was maintained at 25.0 ± 0.01°.

Since the dielectric constant of a water-dioxane mixture is very sensitive to the composition, it was necessary to take elaborate precautions to avoid evaporation of the dioxane during a run. A system of pipets, completely closed except for a small capillary hole, was used for filling and making dilutions. Ground glass joints were used throughout. Nitrogen was used to force the solutions into the pipets which were calibrated to ±0.01 ml.

Materials.—Practical dioxane was purified by the modified method of Vingee and Kraus.[8] Ammonia-free glycine was purified by three recrystallizations from water–alcohol solutions. The pyridine betaine was prepared by the general method of von Gerichten[9] and was purified by recrystallizations from absolute alcohol; decomposition point, 204°. Conductivity water whose specific conductivity was less than 10^{-6} ohm^{-1} was used in the solutions. The concentrations of the glycine solutions were determined to an accuracy of 0.1% by a micro-Kjeldahl analysis. Pyridine betaine exhibited greater solubility than glycine in the lower dielectric constant solvent mixtures so that its solutions were made by dissolving a known weight of the substance.

Experimental Results

In these experiments the dielectric constants of solutions of glycine and of pyridine betaine in water–dioxane (ϵ_0 from 5.7 to 78.5) were measured. The results are presented in Table I and illustrated in Figs. 1 and 2.

In the case of glycine there was some decrease in the dielectric increment δ with concentration

at very low concentrations (below 0.005 mole/liter) of glycine. The values of δ presented in Table I, therefore, represent the extrapolated values at infinite dilution. The δ values for pyridine betaine remained constant with concentration over the concentrations range measured.

Discussion

The decrease in δ with ϵ_0 for glycine and pyridine betaine are both of the general form of the decrease of that for glycine betaine and the benzbetaines in ethanol–water and ethanol–benzene mixtures as observed by Edsall and Wyman.[11] However, before seeking a common mechanism for this decrease in dielectric increment with decreasing dielectric constant of the medium it would be well to examine in the case of pyridine betaine the possibility of reversion to the un-ionized form in low dielectric constant media, thus accounting for the decrease in increment.

The positive charge in pyridine betaine is probably located near the nitrogen in the pyridine ring. Due to resonance the pyridine ring is a very stable structure and its stability is further enhanced by the resonance in the carbon–oxygen bonds of the $-CH_2-C\begin{matrix}O\\O^-\end{matrix}$ side group. Therefore it does not seem possible (except at considerably elevated temperatures) that a bond rupture between the nitrogen and a carbon atom could take place with a consequent movement of the positive charge toward the negative charge.

(11) J. T. Edsall and Jeffries Wyman, Jr., *ibid.*, **57**, 1964 (1935).

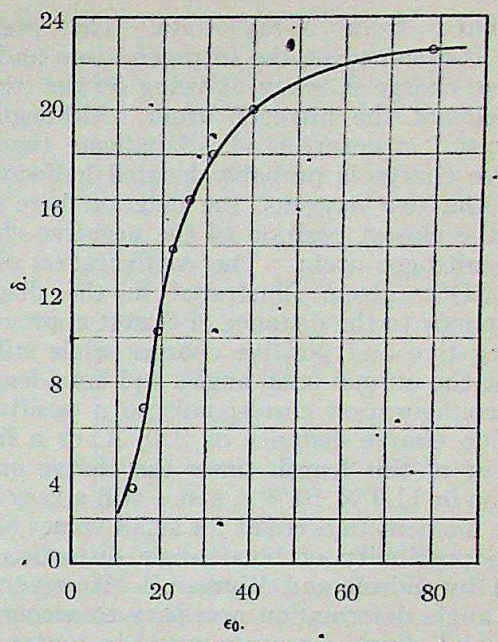

Fig. 1.—Dielectric increment of glycine in water–dioxane mixtures.

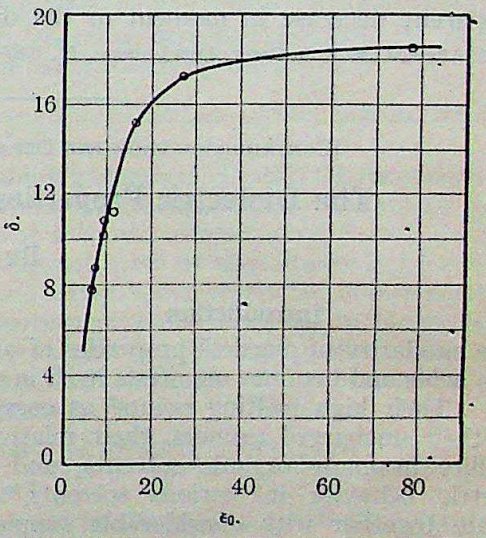

Fig. 2.—Dielectric increment of pyridine betaine in water–dioxane mixtures.

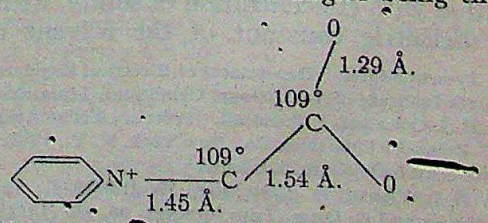
Another possibility is that since the carbon–carbon bond is $-CH_2-COO^-$ has nearly free rotation possibly by rotating the atoms about, some favorable position might be achieved in which the positive and negative charges would be very close to each other. However, from structural considerations this proves not to be the case. Below is a diagram of the pyridine betaine molecule, the atomic distances and angles being those



$$d = 1.45 \cos (180-109) + 1.54 + 1.29 \cos (180-109)$$

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

determined from X-ray data. The positive charge is assumed at the nitrogen atom and the negative charge is taken as being on the oxygen atom closest the nitrogen atom. Although X-ray crystal structure studies[12] indicate that the negative charge is probably located halfway between the two oxygens, the diagram here indicates the closest position of the negative charge to the nitrogen atom. The configuration of the —C—COO⁻ group illustrated in the diagram corresponds to the distance of closest approach of the negative and positive charges while still retaining the normal bond angles and bond lengths. This configuration corresponds to a positive to negative charge distance of 2.48 Å. or a dipole moment of this length times the charge on the electron or 11.9×10^{-18} e. s. u.—still a very large dipole moment to account for small values of δ.

The possibility of bond angle distortion was raised by Edsall and Wyman.[11] However, the bond angle deformation necessary to account for such small dipole moments would be tantamount to breaking the chemical bonds.

Of course, dipole association could account for an apparent decrease in moment of the dipole. However, this would be expected to be dependent on the concentration of the dipoles giving a decrease in δ with increasing concentration. In these experiments no such effects were observed.

An explanation for the "anomalous" lowering of δ with lowering of ϵ_0 lies in the electrostatic behavior of dipoles in mixed solvents, a general theory of which is presented in the following paper.

(12) G. Albrecht and R. B. Corey, THIS JOURNAL, 61, 1087 (1939).

Summary

1. The dielectric constants of solutions of glycine and of pyridine betaine in mixtures of water and dioxane were determined.

2. The dielectric increments both of glycine and of pyridine betaine showed a regular decrease with decreasing dielectric constant of the solvent mixture. This decrease is similar to that exhibited by glycine betaine and the benzbetaines.

3. The possibility of reversion of pyridine betaine to the un-ionized was examined. Calculations show that the charged groups could approach each other (and thus account for the experimental results) only if the valence bonds were tremendously distorted.

The Dielectric Properties of Dipolar Ions in Mixed Solvents

BY GERALD OSTER[1]

Introduction

The similarity of physical properties of all the amino acids and betaines manifests itself in many ways. Their high melting points[2] as compared with their uncharged isomers, their relative insolubility in many organic solvents, and their dielectric behavior in various solvents,[3a,b] all indicate together with considerable supplementary evidence,[4] the presence of a common property, namely, the existence of these substances in the form of dipolar ions.

In this paper the dielectric properties of these dipolar ions (or zwitterions, as they are sometimes called) in solution will be considered since it is these properties which are so closely similar among the various amino acids and betaines. Glycine and different betaines when in mixed solvents exhibit similar behavior of the dielectric increment, the change in dielectric constant of the solution with concentration of solute, with changing dielectric constant of the solvent mixture. With all the amino acids and betaines studied (ortho, meta and para benzbetaines,[3a] glycine, pyridine betaine)[3b] a regular decrease in the dielectric constant of the solvent mixture (alcohol–water, dioxane–water, or benzene–alcohol mixtures) was observed. A decrease in the dielectric increment corresponds to an effective decrease in dipole moment, the quantitative relation being shown below. A detailed study of the structure of one of these substances[3b] indicates that rearrangement of the charged groups within the molecule to form an uncharged molecule is probably not possible. The argument presented in reference (3b) may be carried over to other betaines and amino acids. In fact, there is further evidence[5] that the benzbetaines and glycine betaine do not exist in the uncharged form in solvent mixtures of low dielectric constant in that the known uncharged isomers (esters of these dipolar ions, prepared by heating the dipolar solid to very high temperatures) have solubility properties vastly different from the dipolar substances.

A theory of the behavior of dipolar ions in mixed solvents will now be presented in which the existence (in any appreciable quantities) of the uncharged dipolar ion need not be assumed. The

theory should be equally valid for all amino acids and betaines (aminophenol being a rare exception because of its unusual molecular structure). There is abundant evidence[2] that amino acids and betaines do exist almost completely in the dipolar form in water and mixtures of water and ethanol. However, there is no direct evidence that the uncharged form is present also. It will be shown that the presence of the uncharged form, a notion incompatible with many of the properties of these substances, need not be assumed in order to explain the dielectric behavior of betaines and amino acids.

It is known from electrostatic considerations[6] that ions in mixed solvents will cause a sorting of the components of the solvent mixture so that the component of the solvent having the higher dielectric constant will gather about the ions, this being an arrangement corresponding to minimum free energy. For the same reason we would expect sorting by dipolar ions in mixed solvents. The actual evaluation of the minimized free energy will not be attempted here since the problem is quite difficult even for ordinary ions; furthermore, the exact distribution of the solvent components around the dipolar ions need not be known except that we would expect the layer of solvent immediately surrounding the dipolar ions to be made up predominantly of that solvent mixture constituent having the greater dielectric constant. Thus, we would expect water in water–dioxane or water–alcohol mixtures to gather about the dipolar ions. Alcohol in alcohol–benzene mixtures would be expected to do likewise.

From electrostatic theory it will be shown that the net effect of surrounding the dipole with a shell of material of dielectric constant greater than that of the bulk of the liquid is to reduce the effective moment of the dipolar ion. This shielding effect becomes more prominent as the difference in dielectric constant of the shell surrounding the dipolar ion and the dielectric constant of the liquid in the bulk of the solution becomes greater. This, then, accounts for the decrease in dielectric increment of the dipolar ions as the dielectric constant of the solvent mixture is decreased.

Relation of Dielectric Increment to Dipole Moment.—The dielectric increment, δ, is defined by the relation that the dielectric constant of the solution of dipolar ions of concentration c is $\epsilon = \epsilon_0 + \delta c$ where ϵ_0 is the dielectric constant of the solvent. Wyman[2] found that δ is practically independent of concentration, c.

A relation between the dielectric increment and the dipole moment of the solute may be derived from the general theory of dielectrics due to Kirkwood[7] which has been applied with some success to polar liquids by Oster and Kirkwood.[8] In the ternary system of solvents of mole fractions

(6) P. Debye and J. McAuley, *Physik. Z.*, **26**, 22 (1925); G. Scatchard, *J. Chem. Phys.*, **9**, 34 (1941).

(8) G. Oster and J. G. Kirkwood, *ibid.*, **11**, 175 (1943).

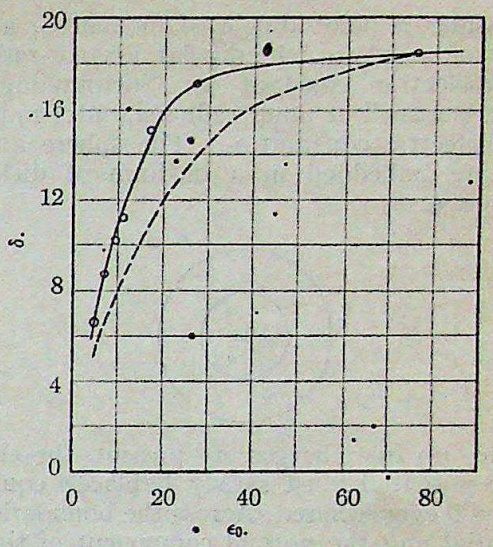

Fig. 1.—Experimental and theoretical dielectric increments of pyridine betaine in water–dioxane mixtures: ———, experimental; – – – –, theoretical.

x_2 and x_3 with solute (the dipole ions) of concentration x_1 the dielectric constant of the solution, ϵ, is related to the mean molar volume, v, the mole fractions, and polarizations P_1, P_2 and P_3 of the constituents by the formula

$$\frac{(\epsilon - 1)(2\epsilon + 1)}{9} = \frac{x_1P_1 + x_2P_2 + x_3P_3}{v} \quad (1)$$

Combining equation (1) with the formula $\epsilon = \epsilon_0 + \delta c$, where ϵ_0 is the dielectric constant of the mixture of solvents, constituents 2 and 3, and c is the concentration of the dipolar ion (constituent 1) and after some algebraic manipulation and conversion of mole fractions to moles per liter one obtains the limiting polarization of the dipolar ions due to their permanent dipole moments

$$P_1 = \frac{4\pi N}{3}\frac{\mu\bar{\mu}}{3kT} = \frac{2000}{9}\delta + \frac{(\epsilon_0 - 1)(2\epsilon_0 - 1)}{9\epsilon_0}v - R \quad (2)$$

where $\mu\bar{\mu}$ is the scalar product of the dipole moment μ of the dipolar ion and dipole moment $\bar{\mu}$ of the dipolar ion and its shell of neighbors, beyond which the dielectric constant equals the macroscopically observed dielectric constant. v is the molal volume of the dipolar ion and R is its molar refractivity.

Equation (2) is valid for most substances when the dielectric constant of the solvent, ϵ_0 is above ten. Between ten and five the first term on right side of equation (3) must be replaced by the approximation $\frac{2000}{9}\delta\left(1 + \frac{1}{2\epsilon_0^2}\right)$.

Inserting numerical values for the constants in equation (2) then for 25°

$$\delta = \frac{9}{2000}\left[20.6 \times 10^{38}\mu\bar{\mu} - \frac{(\epsilon_0 - 1)(2\epsilon_0 + 1)}{9\epsilon_0}v + R\right] \quad (3)$$

It is now necessary to calculate $\mu\bar{\mu}$ from an assumed model and so obtain values for δ which we can compare with experiment.

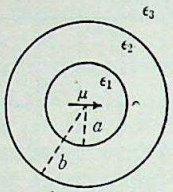
Consider a point dipole of moment μ at the center of a sphere (the dipolar ion) of radius a and dielectric constant ϵ_1. Surrounding the sphere is a shell of inner radius a, outer radius b, and dielectric constant ϵ_2. The sphere and its shell are imbedded in a medium of dielectric constant ϵ_3.



Since no free charges are present, the electrostatic potentlal must satisfy Laplace's equation, $\nabla^2\psi = 0$ everywhere. Across the boundaries the potential and the normal component of the displacement vector must be continuous, *i. e.*, at the boundaries the following conditions must be satisfied

$$\psi_1 = \psi_2 \quad \epsilon_1 \frac{\partial\psi_1}{\partial r} = \epsilon_2 \frac{\partial\psi_2}{\partial r} \quad (r = a)$$
$$\psi_2 = \psi_3 \quad \epsilon_2 \frac{\partial\psi_2}{\partial r} = \epsilon_3 \frac{\partial\psi_3}{\partial r} \quad (r = b) \tag{4}$$

From the general solution of Laplace's equation in spherical coördinates for this spherically symmetric problem, namely

$$\psi = \sum_{n=0}^{\infty} \left(A_n r^n + \frac{B_n}{r^{n+1}} \right) P_n(\cos\theta) \tag{5}$$

the simplest solutions satisfying the conditions of the problem are taken. They are

$$\psi_1 = -Ar\cos\theta + (\mu/\epsilon_1 r^2)\cos\theta \tag{6a}$$
$$\psi_2 = -Br\cos\theta + (C/r^2)\cos\theta \tag{6b}$$
$$\psi_3 = (D/r^2)\cos\theta \tag{6c}$$

Applying the conditions (4) to equations (6) yields for the field inside the sphere (region 1)

$$A = \frac{2\mu}{\epsilon_1 a^3}\left[\frac{(\epsilon_2-\epsilon_1)(\epsilon_2+2\epsilon_3) - (2\epsilon_1+\epsilon_2)(\epsilon_2-\epsilon_3)\left(\frac{a}{b}\right)^3}{(2\epsilon_2+\epsilon_1)(2\epsilon_3+\epsilon_2) - 2(\epsilon_2-\epsilon_1)(\epsilon_2-\epsilon_3)\left(\frac{a}{b}\right)^3}\right] \tag{7}$$

and for the field in the shell region (2)

$$B = \frac{6\mu}{b^3}\left[\frac{\epsilon_3-\epsilon_2}{(2\epsilon_2+\epsilon_1)(2\epsilon_3+\epsilon_2) - 2(\epsilon_2-\epsilon_1)(\epsilon_2-\epsilon_3)\left(\frac{a}{b}\right)^3}\right] \tag{8}$$

Since $\bar{\mu}$ is the moment of the molecule and its shell of neighbors, then

$$\bar{\mu} = \mu + \frac{\epsilon_2 - 1}{4\pi}\frac{4\pi}{3}(b^3 - a^3)B \tag{9}$$

The second term on the right of the equation (9) comes from the electrostatic formula for the moment M of a region of volume v and dielectric constant ϵ in a field of intensity E, namely

$$M = \frac{\epsilon - 1}{4\pi} vE$$

In equation (9) μ does not equal the moment μ_0 of the molecule in free space, but rather

$$\mu = \mu_0 + \frac{\epsilon_1 - 1}{4\pi}\frac{4\pi}{3}a^3 A \tag{10}$$

Now μ and $\bar{\mu}$ act in the same direction so that $\mu\bar{\mu}$ is simply the product of equations (9) and (10). The equation for $\mu\bar{\mu}$ is considerably simplified if we take $\left(\frac{a}{b}\right)^3 << 1$. If, due to sorting, the outer radius of the shell is only three times that of its inner radius the quantity $(a/b)^3$ is sufficiently small so that the following equation holds to a good degree of approximation

$$\mu\bar{\mu} = \mu^2\left[1 - \frac{2(\epsilon_2-1)(\epsilon_2-\epsilon_3)}{(2\epsilon_2+\epsilon_1)(2\epsilon_3+\epsilon_2)}\right] \tag{11a}$$

where

$$\mu = \frac{\mu_0}{1 - \frac{2(\epsilon_1-1)(\epsilon_2-\epsilon_1)}{3\epsilon_1(2\epsilon_2+\epsilon_1)}} \tag{11b}$$

Equation (11b) shows that μ is practically independent of ϵ_3. It will be noticed from equation (11a) that $\mu\bar{\mu}$ is decreased when the dielectric constant of the shell, ϵ_2, is greater than that of the outer medium, ϵ_3. $\mu\bar{\mu}$ equals μ^2 only when $\epsilon_2 = \epsilon_3$ as would be the case for dipolar ions in a single solvent, for, example, pure water. As the dielectric constant of the medium ϵ_3 (written ϵ_0 in equations (2) and (3)) is reduced, $\mu\bar{\mu}$ approaches zero (ϵ_2 is generally large compared with unity and $\epsilon_1 = n^2$, the square of the refractive index of the solute) and so by equation (3) δ should approach zero (the other two terms in equation (3) not containing δ are relatively small). The effect on ϵ_3 of the sorting out of the higher dielectric constant constituent of the solvent mixture to form a shell about the dipolar ion has been neglected. This is a small effect, however, since the concentrations of the dipolar ions in the systems studied are very small compared with the concentration of the high dielectric constant constituent of the solvent mixture, so that the dielectric constant of the solvent would hardly be expected to be altered appreciably by this sorting process.

The media 1, 2 and 3 have been treated as continuous right up to the surface of the adjacent media. It is known[7,8] that in order to account for the dielectric properties of pure polar liquids it is necessary to examine a region near the surface of a molecule of the liquid where the dielectric constant cannot be considered equal to that of the bulk of the liquid. It turns out, however, that the cruder continuum model proves to be sufficiently detailed so as to agree with the general features of the observed dielectric properties of dipolar ions in mixed solvents.

Application of the Theory

In order to test the theory, the dielectric increment of pyridine betaine in mixtures of water and dioxane have been calculated. This may be evaluated by combining equations (3) and (11a) to

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

solve for δ. From the observed δ for pyridine betaine in pure water we calculate its dipole moment μ to be 16.9×10^{-18} e. s. u. In equation (11a) ϵ_1 is replaced by the square of the refractive index of pyridine betaine which is determined from a calculated molar refractivity R. The molar volume of pyridine betaine in water is $v = 99.6$ cc./mole.[6] The dielectric constant of water, ϵ_2, has the value 78.54.

The theoretical and experimental[3b] results are illustrated in the figure.

The deviations of the theoretical results from the observed suggest that the sorting of the water molecules by the dipolar ions is not complete and therefore the actual shielding effect is not as great as would be expected for a shell made up entirely of water molecules.

The writer wishes to thank Professor J. G. Kirkwood for his helpful suggestions.

Summary

A theory of the decrease in dielectric increment of dipolar ions with decrease in dielectric constant of the solvent mixture is presented. On the basis of electrostatic theory dipolar ions would be expected to sort out the solvent constituent of higher dielectric constant. The shell of material of higher dielectric constant thereby produced serves to act as an electrostatic shield thus decreasing the effective dipole moment (and therefore the dielectric increment) of the dipolar ion. The shielding effect becomes more prominent as the difference in dielectric of the shell surrounding the dipolar ion and that of the liquid in the bulk of the solution becomes greater.

This continuum treatment leads to results which reproduce the general features of the observed results.

Syntheses of Tyrosyltyrosyltyrosine and Tyrosyltyrosyltyrosyltyrosine.

BY ARCHIE E. BARKDOLL[1] AND WILLIAM F. ROSS[2]

In relation to certain protein studies in progress in this Laboratory, there were desired polypeptides containing three, four and additional residues of the amino acid *l*-tyrosine[3] bound one to another with none but tyrosyl residues within the chain. For this reason the syntheses of tyrosyltyrosyltyrosine and tyrosyltyrosyltyrosyltyrosine have been carried out according to the procedures to be described in this paper.

The starting material was the compound O-acetyl-N-carbobenzoxytyrosyltyrosine ethyl ester, I, prepared according to the method of Bergmann, *et al.*,[4] which involves the coupling of O-acetyl-N-carbobenzoxytyrosyl chloride with the ethyl ester of tyrosine. This product may be applied in several ways toward the synthesis of the desired polypeptides. Its hydrogenation yields tyrosyltyrosine ethyl ester, II, to the free amino group of which additional tyrosine residues may be coupled through the action of the chloride or azide of a suitable tyrosine derivative.

The preparation of O-acetyl-N-carbobenzoxytyrosyl-O-acetyltyrosyl chloride, which after reaction with II would lead directly to a derived tetrapeptide, was first investigated. O-Acetyl-N-carbobenzoxytyrosyl-O-acetyltyrosine was obtained in good yield by the saponification and subsequent acetylation of I, but attempts to convert it satisfactorily into the chloride failed. The reaction of the free acid with phosphorus pentachloride yielded an oil, which in exploratory experiments with tyrosine ethyl ester gave no useful products. It appears probable that the failure of this approach was due to an attack on the peptide linkage by the phosphorus pentachloride. Similar results were obtained by Pacsu and Wilson,[5] who studied the action of phosphorus pentachloride and of thionyl chloride on carbobenzoxyglycylglycine.

The azide of N-carbobenzoxytyrosyltyrosine coupled with II, would also yield a derivative of the tetrapeptide. This line of approach was next investigated. N-Carbenzoxytyrosyltyrosine hydrazide was obtained readily by the action of hydrazine hydrate on I. The corresponding azide was prepared and, without isolation, added in ethyl acetate solution to a similar solution of the ester, II. The failure to isolate any definite product and the inaccessibility of the two reagents employed led finally to the simple, direct approach of adding single tyrosine residues stepwise to peptide esters of increasing length.

This procedure, although laborious and time-consuming, led finally to the desired products. For its consummation O-acetyl-N-carbobenzoxytyrosyl chloride was coupled with tyrosyltyrosine ethyl ester, to give O-acetyl-N-carbobenzoxytyrosyltyrosyltyrosine ethyl ester, III. The latter was converted by hydrolysis to the carbobenzoxytripeptide, IV, which was catalytically reduced to the desired tripeptide, V. Repeating this process, addition of another

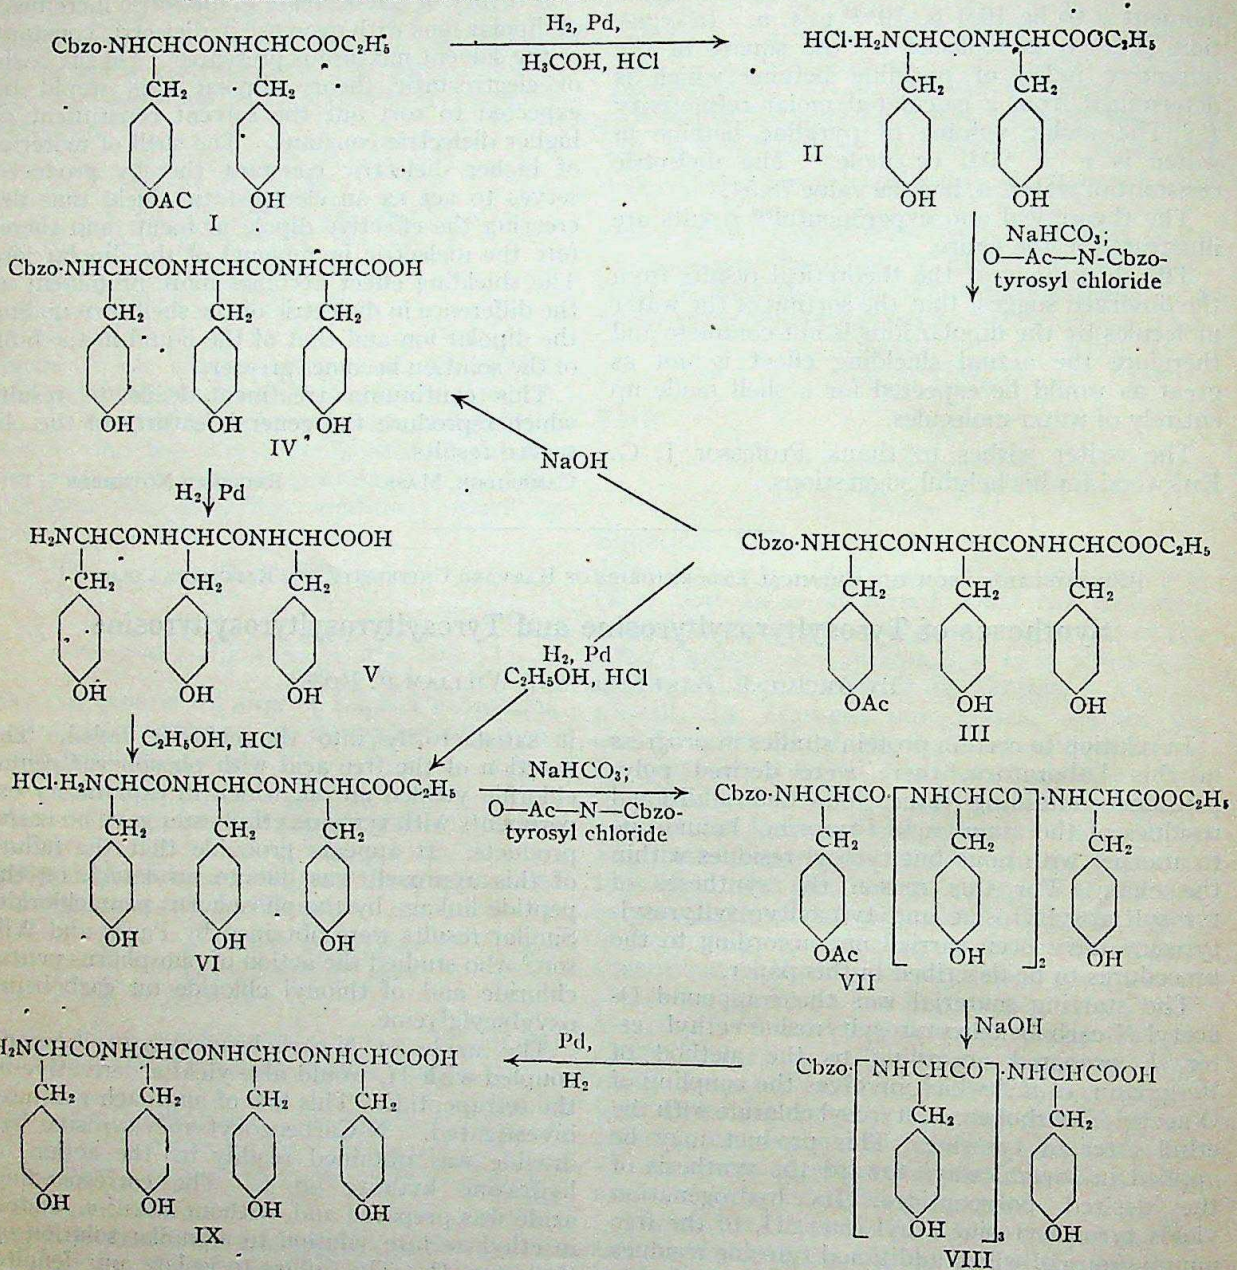
TABLE I

SYNTHESES OF TYROSYLTYROSYLTYROSINE AND TYROSYLTYROSYLTYROSYLTYROSINE



tyrosine residue to the tripeptide ester, VI, yielded the tetrapeptide, tyrosyltyrosyltyrosyltyrosine, IX. An outline of the entire procedure is given in Table I.

It will be noted that catalytic reduction of O-acetyl-N-carbobenzoxytyrosyltyrosine ethyl ester, III, in absolute ethanol containing hydrogen chloride leads directly to an unacetylated product. A parallel case was observed by Bergmann and Fruton[6] in the reduction of O-acetyl-N-carbobenzoxytyrosylglycine ethyl ester, and analogous behavior of derivatives of oestrone has been observed by Miescher and Scholz.[7] The removal of the O-acetyl group during reduction has been verified by the synthesis of tyrosyltyrosine ethyl ester hydrochloride by an unambiguous method. O-Acetyl-N-carbobenzoxytyrosyltyrosine ethyl ester, I, was saponified to N-carbobenzoxytyrosyltyrosine and this was esterified with diazoethane. The resulting ester was reduced to tyrosyltyrosine ester hydrochloride, II, identical with that obtained by the reduction of the acetylated derivative, I. In addition, the dipeptide ester hydrochloride was prepared by the esterification of tyrosyltyrosine.

The O-acetyl group was lost also during the reduction of O-acetyl-N-carbobenzoxytyrosyltyrosyltyrosine ethyl ester, III, to tyrosyltyrosyl-

tyrosine ethyl ester hydrochloride, VI. The same product was formed by the direct esterification of tyrosyltyrosyltyrosine with absolute ethanol and dry hydrogen chloride. This esterification is of interest in view of the report of Pacsu and Wilson[8] that attempts to prepare the ester hydrochlorides of several tripeptides were unsuccessful because of cleavage of the peptide chain. For example, alanylglycylglycine on esterification was converted to a mixture of the ester hydrochlorides of glycine and alanylglycine.

The O-acetyl group, however, is not removed when glacial acetic acid is substituted for methanolic hydrogen chloride, the carbobenzoxy derivative reduced, and gaseous hydrogen chloride then added. In this way, O-acetyl-N-carbobenzoxytyrosine methyl ester gave O-acetyltyrosine methyl ester hydrochloride, and O-acetyl-N-carbobenzoxytyrosine gave O-acetyltyrosine hydrochloride.

The availability of the series consisting of tyrosine, tyrosyltyrosine, tyrosyltyrosyltyrosine and tyrosyltyrosyltyrosyltyrosine makes possible a comparison of the physical and chemical properties of the various members. Most striking is the change in solubility with the number of tyrosine residues within the molecule. Tyrosine itself is almost insoluble in water, tyrosyltyrosine and the tripeptide are freely soluble, but the tetrapeptide only slightly soluble in the cold. There is an increasing solubility in either ethyl or methyl alcohol as the number of residues is increased. Both the tri- and tetrapeptides give positive tests with Millon reagent.

The absorption spectra of the first three members of the series have also been determined.[9] All three compounds contain the same chromophoric group, the phenolic ring, so that little qualitative difference would be anticipated. This expectation is confirmed by the experimental curves of Fig. 1 and the data of Table II. There is only a slight quantitative shift toward the red with increasing molecular weight; this may be associated with the increasing size of the molecule to which the chromophores are bound in each case. The proportionality between the extinction coefficient and the number of tyrosine residues per molecule is also evident from the last column of the table.

TABLE II

For these experiments buffered solutions of *p*H 4.5 were employed. The value of 2750 Å. for λ max of tyrosine agrees with that of Enselme and Pozzi[10] for this amino acid in a solution of *p*H 5.95.

Substance	Mol. wt.	$E_{molar,\ max.}$	λ max, Å.	$E_{molar,\ max./1350}$
l-Tyrosine	181.2	1350	2750	1.00
Tyrosyltyrosine	344.4	2850	2760	2.11
Tyrosyltyrosyl-tyrosine dihydrate	543.6	4160	2765	3.08

The Removal of the Carbobenzoxy Group by Alcoholic Hydrogen Chloride.—In addition to the usual catalytic hydrogenation method for the removal of the carbobenzoxy group from amino acids and polypeptides, several others have been found valuable for special cases such as the reduction of sulfur containing carbobenzoxy derivatives. Thus sodium in liquid ammonia has been employed by Sifferd and du Vigneaud,[11] and phosphonium iodide in glacial acetic acid by Harington and Mead.[12] Also, White[13] removed the carbobenzoxy group by treatment with aqueous hydrogen chloride at 60°. We have observed that the action of an absolute ethanol solution of hydrogen chloride also serves to liberate the carbobenzoxy group, with the simultaneous formation of the corresponding ester hydrochloride.

In an attempt to prepare N-carbobenzoxytyrosyltyrosine ethyl ester by the action of absolute ethanol and dry hydrogen chloride at 0° on N-carbobenzoxytyrosyltyrosine, it was found that a major portion of the acid had been converted by esterification of the peptide carboxyl and fission of the carbobenzoxy group to tyrosyltyrosine ethyl ester hydrochloride, while only a small amount of the desired carbobenzoxy ester was obtained. A similar experiment with O-acetyl-N-carbobenzoxytyrosyltyrosine ethyl ester gave the same products.

The action of absolute ethanolic hydrogen chloride on carbobenzoxyglycine at 0° likewise yielded a mixture of glycine ester hydrochloride and carbobenzoxyglycine ethyl ester. But, if

the absolute alcohol solution of the acid was saturated at room temperature with dry hydrogen chloride and refluxed for an hour, glycine ester hydrochloride was obtained to the exclusion of carbobenzoxyglycine ester. The simplicity of this procedure for removing the carbobenzoxy group and the concomitant ester formation suggest its further application in synthetic work.

Experimental

The tyrosine employed in this work was natural *l*-tyrosine of $(\alpha)^{20}D$ −9.0° (in 5.8 *N* hydrochloric acid, $C = 3.613$). Consequently all the compounds to be described are of the *l* configuration, although the prefix *l* is omitted throughout for the sake of economy.

The palladium black catalyst was prepared according to the method of Tausz and von Putnoky.[14] It was kept either in the dry state or as a suspension in distilled water.

The analyses have been variously performed by Mr. M. Brown, Dr. Carl Tiedcke, Miss E. Werble, and one of the authors (A. E. B.).

N-Carbobenzoxytyrosyltyrosine Ethyl Ester.—The ethyl ester was prepared by the addition of somewhat less than one equivalent of diazoethane–ether solution to a solution of N-carbobenzoxytyrosyltyrosine hydrate (0.97 g.) prepared by the method of Bergmann,[4] in 15 cc. of methanol. The sirupy residue remaining after concentration of the solution *in vacuo* was dissolved in ethyl acetate and unreacted acid extracted with dilute sodium bicarbonate. The ethyl acetate solution was dried over anhydrous sodium sulfate, the solvent removed *in vacuo*, and the residue recrystallized several times from ethyl acetate–petroleum ether to yield 260 mg. of the pure ester in the form of colorless, silky needles melting at 159–160.5°.

Anal. Calcd. for $C_{28}H_{30}O_7N_2$: C, 66.38; H, 5.97; N, 5.53. Found: C, 65.96, 65.88; H, 6.11, 6.17; N, 5.62.

All melting points are uncorrected.

Tyrosyltyrosine Ethyl Ester Hydrochloride.—Five grams of O-acetyl-N-carbobenzoxytyrosyltyrosine ethyl ester, prepared by the method of Bergmann,[4] was dissolved in 110 cc. of 0.2 *N* absolute ethanolic hydrogen chloride and reduced at atmospheric pressure in the presence of 1.4 g. of palladium black catalyst. The product, recovered after concentration by the addition of ether, represented an almost quantitative yield. For analysis it was recrystallized twice from absolute alcohol–absolute ether in the form of microscopic clusters of platelets; it melted at 216° (dec.).

Anal. Calcd. for $C_{20}H_{25}O_5N_2Cl$: C, 58.50; H, 6.16; Cl, 8.68. Found: C, 58.25, 58.41; H, 6.05, 6.23; Cl, 8.55.

An identical product was obtained by dissolving 100 mg. of tyrosyltyrosine[4] in 10 cc. of absolute ethanol saturated with dry hydrogen chloride at 0°. After two days at 7° the crystalline ester hydrochloride was obtained by concentration and addition of ether. It melted at 217° and showed no depression of the decomposition point when mixed with the product described above.

The same product, melting at 216°, was obtained by the catalytic reduction of N-carbobenzoxytyrosyltyrosine ethyl ester in absolute ethanolic hydrogen chloride.

N-Carbobenzoxytyrosyltyrosine Methyl Ester.—Methylation of N-carbobenzoxytyrosyltyrosine hydrate with diazomethane in methyl alcohol solution gave the ester, which, after several recrystallizations from ethyl acetate–ligroin, formed small needles and rosets melting at 174–175°.

Anal. Calcd. for $C_{27}H_{28}O_7N_2$: C, 65.84; H, 5.73; N, 5.68. Found: C, 65.62; H, 5.57; N, 6.27.

Tyrosyltyrosine Methyl Ester Hydrochloride.—Obtained by the catalytic reduction of N-carbobenzoxytyrosyltyrosine methyl ester, this product melted at 210° after three recrystallizations from absolute methanol–absolute ether.

Anal. Calcd. for $C_{19}H_{23}O_5N_2Cl$: C, 57.79; H, 5.87; Cl, 8.98. Found: C, 57.84, 57.49; H, 6.09, 6.03; Cl, 9.17.

O-Acetyl-N-carbobenzoxytyrosyl-O-acetyltyrosine.—Three grams of finely powdered O-acetyl-N-carbobenzoxytyrosyltyrosine ethyl ester was added to 21 cc. of 1 *N* sodium hydroxide. After shaking for an hour at room temperature, the solution was filtered, and 1.11 cc. of acetic anhydride in 12 cc. of dioxane added. After fifteen minutes at room temperature, the solution was acidified to congo red with 1 *N* hydrochloric acid. The solid thus formed was collected on the filter, washed with water and recrystallized three times from hot acetone–water, to give white tufts of needles melting at 209–210°. The acid was insoluble in cold acetone, and in either hot or cold water, but was moderately soluble in boiling acetone.

Anal. Calcd. for $C_{30}H_{30}O_9N_2$: C, 64.05; H, 5.37; N, 4.98. Found: C, 63.94, 63.82; H, 5.20, 5.35; N, 5.30.

O-Acetyl-N-carbobenzoxytyrosyltyrosyltyrosine Ethyl Ester.—Tyrosyltyrosine ethyl ester hydrochloride (4.24 g.) was dissolved in 35 cc. of water, 25 cc. of pure ethyl acetate was added and the mixture cooled in ice. The free ester was liberated by the addition of 1.70 g. of sodium bicarbonate. It settled out as a thick paste after several minutes of shaking. This was filtered off, pressed as dry as possible on the filter, and then dissolved in 75 cc. of purified dioxane. To this solution 25 cc. of ethyl acetate was added and the resulting solution dried for an hour at 0° over anhydrous potassium carbonate. After filtration the solution was stored at 0° for about an hour, during the preparation of O-acetyl-N-carbobenzoxytyrosyl chloride.

The latter was prepared essentially according to the procedure of Bergmann[4]: 7.20 g. of the finely powdered free acid was suspended in 72 cc. of anhydrous ether, and cooled in an ice–salt-bath; to the suspension was then added 4.20 g. of finely powdered phosphorus pentachloride. The flask was shaken in ice until the white crystalline acid chloride had completely formed. This was filtered off, washed with a 1:2 mixture of anhydrous ether–petroleum ether and dried in an evacuated desiccator at 0° over phosphorus pentoxide. It was used for coupling with the ester as soon as possible.

For this purpose, 2.28 g. of O-acetyl-N-carbobenzoxytyrosyl chloride dissolved in 20 cc. of purified, anhydrous ethyl acetate was added to the tyrosyltyrosine ethyl ester solution as prepared above. Immediate formation of a precipitate of tyrosyltyrosine ester hydrochloride occurred. After standing at room temperature for nine hours, the latter was removed, and the solution concentrated *in vacuo* to a thick yellow sirup which was crystallized by the slow addition of ethyl acetate. After two recrystallizations from hot acetone–ether the product was obtained as a white microcrystalline powder, m. p. 211°. The yield of the crude product, calculated from the weight of amino acid ester hydrochloride recovered, was 78%.

Anal. Calcd. for $C_{39}H_{41}O_{10}N_3$: C, 65.81; H, 5.81; N, 5.90. Found: C, 65.94, 65.80; H, 6.35, 6.15; N, 5.92.

Tyrosyltyrosyltyrosine Ethyl Ester Hydrochloride.—A sample of 2.06 g. of O-acetyl-N-carbobenzoxytyrosyltyrosyltyrosine ethyl ester was dissolved in 40 cc. of anhydrous dioxane by warming, and 160 cc. of absolute ethanol, 7 cc. of 2 *N* absolute ethanolic hydrogen chloride and 2 g. of palladium black catalyst were added. After completion of the hydrogenation, which followed, the filtered solution was concentrated *in vacuo* to a thick sirup which was taken up in 15 cc. of water and treated with 10 cc. of ethyl acetate and 0.8 g. of sodium bicarbonate in order to transfer the ester to the organic phase. After washing the aqueous phase with several additional 10-cc. portions of ethyl acetate, the combined ethyl acetate extracts were dried thirty minutes at 0° over anhydrous potassium carbonate and filtered. When dry hydrogen chloride gas was passed over the surface of the filtrate, the hydrochloride formed as a light yellow sirup which slowly

(14) Tausz and von Putnoky, *Ber.*, **52**, 1573 (1919).

crystallized. The yield of product was 66%. In order to purify a sample for analysis it was necessary to repeat the procedure of transferring the liberated ester to ethyl acetate and adding hydrogen chloride. Hemispherical nodules of crystals ranging up to 2 mm. in diameter were obtained; m. p. 231–231.5° (dec.) with previous coloring and sintering. Attempts to crystallize the compound directly from alcohol–ether gave an oil which crystallized but slowly and retained any impurities present.

Anal. Calcd. for $C_{29}H_{34}O_7N_3Cl$: C, 60.88; H, 5.99; Cl, 6.11. Found: (dried at 100° *in vacuo*) C, 60.67, 60.20; H, 6.82, 6.25; Cl, 6.12.

The same product was obtained by esterification of 150 mg. of tyrosyltyrosyltyrosine in absolute ethanol solution with hydrogen chloride. The procedure was similar to that followed for tyrosyltyrosine ethyl ester, except that the viscous sirup obtained on concentration of the solution was crystallized by allowing it to stand under ethyl acetate for several days; yield, 158 mg. The m. p. was 230–231° (dec.) and a mixture of the product with the tripeptide ester hydrochloride, of m. p. 231–231.5° (dec.), prepared by the reduction of O-acetyl-N-carbobenzoxytyrosyltyrosyltyrosine ethyl ester, gave no depression.

N-Carbobenzoxytyrosyltyrosyltyrosine.—This derivative was obtained by saponification of 1.5 g. of O-acetyl-N-carbobenzoxytyrosyltyrosyltyrosine ethyl ester in 8.5 cc. of 1.1 *N* sodium hydroxide. It formed as a gel when the solution was acidified to congo red, and was finally crystallized as sheaves and rosets of needles from warm methanol; m. p. 182–183°, yield, 1 g.

Anal. Calcd. for $C_{35}H_{35}O_9N_3$: C, 65.51; H, 5.49; N, 6.55. Found: C, 65.45, 65.49; H, 5.56, 5.61; N, 6.49.

Tyrosyltyrosyltyrosine Dihydrate.—To a solution of 400 mg. of N-carbobenzoxytyrosyltyrosyltyrosine in 20 cc. of methanol were added 30 cc. of water, 0.4 g. of palladium black catalyst and a small drop of glacial acetic acid. Removal of the carbobenzoxy group was complete after hydrogenation for thirty minutes. The filtered solution was concentrated *in vacuo* at a bath temperature not exceeding 35°. The peptide crystallized in the form of microscopic white prisms after the removal of approximately half of the solvent. After further concentration, the solid was removed and recrystallized twice from hot water to give fine prisms of m. p. 181–182° in a yield of 150–200 mg.

Anal. Calcd. for $C_{27}H_{29}O_7N_3 \cdot 2H_2O$: C, 59.65; H, 6.11; N, 7.73; H_2O, 6.65. Found: C, 59.54, 59.53; H, 5.92, 6.14; N, 7.90; H_2O, 6.63.

The tripeptide was slightly soluble in cold alcohol and water, somewhat soluble in hot alcohol and quite soluble in hot water. The anhydrous material, formed by drying at 100° over phosphorus pentoxide *in vacuo*, was hygroscopic, tending to revert to the dihydrate on exposure to the air.

N-Carbobenzoxytyrosyltyrosine Hydrazide Hydrate.—The hydrazide was obtained from O-acetyl-N-carbobenzoxytyrosyltyrosine ethyl ester by reaction with hydrazine hydrate in ethanol solution. It melted at 246° (dec.) after recrystallization from pyridine, and lost one molecule of water on drying over phosphorus pentoxide for one hour at 100° (1 mm.).

Anal. Calcd. for $C_{26}H_{28}O_6N_4 \cdot H_2O$: C, 61.16; H, 5.94; N, 10.97; H_2O, 3.53. Found: C, 61.13; H, 5.96; N, 11.09; H_2O, 3.42.

It has already been pointed out that attempts to use the corresponding azide in coupling experiments with tyrosyltyrosine ethyl ester were without success.

O-Acetyl-N-carbobenzoxytyrosyltyrosyltyrosyltyrosine Ethyl Ester.—O-Acetyl-N-carbobenzoxytyrosyl chloride was prepared as described in the preparation of the O-acetyl-N-carbobenzoxy tripeptide, except that in this case it was desirable to have extremely pure chloride on account of the difficulty of purifying the tetrapeptide. Therefore, just as the crystals of chloride began to form, the solution was filtered, the precipitate discarded and the chloride to be used in the coupling obtained from further crystallization in the filtrate.

374 mg. of O-acetyl-N-carbobenzoxytyrosyl chloride was dissolved in 10 cc. of anhydrous ethyl acetate and the solution added to that containing the ester from 1.14 g. of tyrosyltyrosyltyrosine ethyl ester hydrochloride. The latter had been prepared in the same manner as the tyrosyltyrosine ester in the synthesis of the tripeptide. The solution became turbid, and an oil deposited. After standing for two days, this oil had solidified and was found to be a mixture of the tripeptide ester hydrochloride and the desired O-acetyl-N-carbobenzoxy tetrapeptide ester. The two were separated by extraction of the former from the solid with 0.5 *N* hydrochloric acid and crystallization of the tetrapeptide ester from hot acetone–ether. The yields were 233 mg. and 624 mg., respectively. The m. p. of the latter was 235.5–236.5° (dec.).

Anal. Calcd. for $C_{48}H_{50}O_{12}N_4$: C, 65.89; H, 5.76; N, 6.40. Found: C, 65.53; H, 5.80; N, 6.43.

N-Carbobenzoxytyrosyltyrosyltyrosyltyrosine.—A sample of 590 mg. of finely powdered O-acetyl-N-carbobenzoxytyrosyltyrosyltyrosyltyrosine ester was saponified by treatment with 6 equivalents of 1 *N* sodium hydroxide for thirty minutes at room temperature. The free acid was precipitated as an amorphous jell on acidification to congo red. After filtering, washing, and drying, it weighed 530 mg. It was finally obtained as a white solid, appearing under the microscope as ill-formed rosets of crystals, by the slow concentration of a methanol solution in a partially evacuated desiccator over phosphorus pentoxide. The final yield was 201 mg. and the product melted at 224–225° (dec.) with previous darkening at 220°. The acid contained a molecule of methanol which was lost on drying over phosphorus pentoxide at 100° (1 mm.).

Anal. Calcd. for $C_{44}H_{44}O_{11}N_4 \cdot CH_3OH$: CH_3OH, 3.83. Found: (dried *in vacuo* at 100°) 3.70. Calcd. for $C_{44}H_{44}O_{11}N_4$: C, 65.65; H, 5.51; N, 6.96. Found: C, 65.35; H, 5.62; N, 6.38.

On standing in the air, the dried acid rapidly absorbed 1% of its weight of moisture. The acid was insoluble in water and 5% sodium bicarbonate, but soluble in 1 *M* sodium hydroxide and hot methanol.

Tyrosyltyrosyltyrosyltyrosine.—A sample of 118 mg. of N-carbobenzoxy tetrapeptide methyl alcoholate was catalytically hydrogenated in methyl alcohol solution containing a small drop of acetic acid. Concentration of the filtered solution gave a viscous sirup which formed a noncrystalline glassy solid on standing. The latter we were unable to obtain in a clearly crystalline form in spite of many efforts. The analytical sample was obtained as a glass-like solid by treating the tetrapeptide in methanol solution with activated carbon, followed by concentration *in vacuo* and drying over phosphorus pentoxide one hour at 65° (1 mm.).

Anal. Calcd. for $C_{36}H_{38}O_9N_4$: C, 64.46; H, 5.71; N, 8.35. Found: C, 63.45; H, 5.72; N, 7.15.

The tetrapeptide was insoluble in cold water, hot and cold dioxane, ethyl acetate, and acetone, but was soluble in cold 5% sodium carbonate, 0.5 *N* hydrochloric acid, absolute methanol and ethanol, and glacial acetic acid. It could be precipitated from absolute ethanol solution in an amorphous condition by the addition of ether.

Purification of Materials for Determination of Absorption Spectra.—A. Tyrosine: Six grams of tyrosine, obtained from the University of Illinois, was recrystallized five times from boiling distilled water, carbon being employed during the first two recrystallizations: yield 2.42 g. The material was dried for two hours over phosphorus pentoxide at 100° (1 mm.).

B. Tyrosyltyrosine: The dipeptide was prepared by the method of Bergmann, *et al.*[4] After two recrystallizations from hot ethanol–water, the peptide was obtained in the form of small, colorless prisms melting at 285–288° (dec.), with preliminary sintering. The material was dried over phosphorus pentoxide for two hours at 100° (1 mm.).

C. Tyrosyltyrosyltyrosine Dihydrate: An analytical sample of tripeptide dihydrate (300 mg.) which gave correct analyses but which had a very faint yellow tint, was

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

recrystallized three times from hot distilled water, 25 mg. of activated carbon being used in the first recrystallization. There was obtained 220 mg. of white clusters of prisms, m. p. 180–181°. As the anhydrous tripeptide was quite hygroscopic, the stable hydrate was air-dried to constant weight and employed for the spectral analysis.

O-Acetyl-N-carbobenzoxytyrosine Methyl Ester.—A 9.91-g. sample of recrystallized O-acetyl-N-carbobenzoxytyrosine was esterified in methyl alcohol with diazomethane. The product after two recrystallizations from ether melted at 73–74.5°.

Anal. Calcd. for $C_{20}H_{21}O_6N$: C, 64.66; H, 5.70; N, 3.77. Found: C, 64.68, 64.77; H, 6.00, 5.81; N, 4.13.

Tyrosine Methyl Ester Hydrochloride from the Reduction of O-Acetyl-N-carbobenzoxytyrosine Methyl Ester.—Three grams of O-acetyl-N-carbobenzoxytyrosine methyl ester, dissolved in 30 cc. of 0.27 *N* absolute methanolic hydrogen chloride, was reduced in the presence of palladium black catalyst. From the reaction solution was obtained 1.75 g. of fine needles, which after two recrystallizations from absolute methanol–absolute ether melted at 187° (dec.). A mixed melting point with authentic tyrosine methyl ester hydrochloride showed no depression.

Anal. Calcd. for $C_{10}H_{14}O_3NCl$: C, 51.83; H, 6.09. Found: C, 51.63, 51.55; H, 6.15, 6.31.

O-Acetyltyrosine Methyl Ester Hydrochloride.—One gram of O-acetyl-N-carbobenzoxytyrosine methyl ester was dissolved in 40 cc. of glacial acetic acid and hydrogenated in the presence of palladium black catalyst. The filtered solution was saturated with dry hydrogen chloride and concentrated *in vacuo* at a bath temperature of 25° until the hydrochloride crystallized. There was obtained 0.68 g. of O-acetyltyrosine methyl ester hydrochloride, which melted at 201° (dec.), after two recrystallizations from hot glacial acetic acid–ether.

Anal. Calcd. for $C_{12}H_{16}O_4NCl$: C, 52.65; H, 5.89; Cl, 12.95. Found: C, 52.47, 52.50; H, 5.77, 5.97; Cl, 12.8.

O-Acetyltyrosine Hydrochloride.—O-Acetyl-N-carbobenzoxytyrosine dissolved in glacial acetic acid was reduced with palladium black catalyst in the usual manner. The reduction product separated as a white, flocculent precipitate which was dissolved by saturating the solution with dry hydrogen chloride and heating on the steam-bath. The solution was filtered and the hydrochloride obtained as small white needles by cooling the filtrate and resaturating it with hydrogen chloride. Three recrystallizations from glacial acetic acid–hydrogen chloride gave a product melting at 223° (dec.).

Anal. Calcd. for $C_{11}H_{14}O_4NCl$: C, 50.87; H, 5.43; Cl, 13.65. Found: C, 50.81, 50.66; H, 5.53, 5.40; Cl, 13.21.

Action of Absolute Alcoholic Hydrogen Chloride on N-Carbobenzoxytyrosyltyrosine.—Anhydrous N-carbobenzoxytyrosyltyrosine (1.16 g.) was dissolved in 15 cc. of absolute ethanol, and the solution saturated at 0° with dry hydrogen chloride and stored in ice for thirty-one hours. By concentrating the alcohol solution and diluting it with ether, altogether 590 mg. of tyrosyltyrosine ethyl ester hydrochloride, m. p. 214°, was obtained. By allowing the mother liquor and washings to evaporate spontaneously overnight white needles of N-carbobenzoxytyrosyltyrosine ethyl ester were formed; weight 189 mg. After recrystallization from ethyl acetate–petroleum ether the latter melted at 159°, and gave no depression on admixture with an authentic sample.

Action of Absolute Alcoholic Hydrogen Chloride on O-Acetyl-N-carbobenzoxytyrosyltyrosine Ethyl Ester.—Five grams of O-acetyl-N-carbobenzoxytyrosyltyrosine ethyl ester was treated with 90 cc. of ethanolic hydrogen chloride as described in the preceding section. The product consisted of 2.0 g. of tyrosyltyrosine ethyl ester hydrochloride, m. p. 216° (dec.) and 1.2 g. of an impure product melting at 132–160°. The latter, which appeared to be composed of the starting material and N-carbobenzoxytyrosyltyrosine ethyl ester, we were unable to purify further.

N-Carbobenzoxyglycine Ethyl Ester.—The ester from 14 g. of glycine ethyl ester hydrochloride was coupled in ethyl acetate solution with 20.2 g. of carbobenzoxy chloride, employing the customary technique. The product was purified by vacuum distillation, b. p. 147–151° (0.5–1.0 mm.), and 17.8 g. was obtained. It formed beautiful long needles which were readily recrystallized from aqueous ethanol, m. p. 35.5–36.5°.

Anal. Calcd. for $C_{12}H_{15}O_4N$: C, 60.74; H, 6.37; N, 5.90. Found: C, 60.45, 60.72; H, 6.26, 6.46; N, 5.96.

Action of Absolute Alcoholic Hydrogen Chloride on Carbobenzoxyglycine.—A solution of 3 g. of carbobenzoxyglycine[15] in 15 cc. of absolute ethanol was saturated with dry hydrogen chloride at 0° and stored at this temperature for 42 hours. By cooling and seeding the solution there was obtained altogether 1.25 g. of glycine ester hydrochloride, which melted at 144.5–145° alone and at 143.5–144.5° when mixed with an authentic sample. The concentrated mother liquor was dissolved in ether, and the resulting solution dried over sodium sulfate and concentrated on the steam-bath. The light yellow residual oil was crystallized from alcohol–water to give 0.86 g. of carbobenzoxyglycine ester, m. p. 35.5°. This gave no depression in a mixed m. p. determination with an authentic sample.

An ethanolic hydrogen chloride solution of 10 g. of carbobenzoxyglycine was refluxed for one hour while a slow stream of dry hydrogen chloride was passed through the solution. 5.80 g. of glycine ester hydrochloride melting at 143–144° was obtained, and no carbobenzoxyglycine ester could be recovered from the mother liquor. This represents an 87% yield.

Summary

1. Tyrosyltyrosyltyrosine and tyrosyltyrosyltyrosyltyrosine have been synthesized.

2. The ultraviolet absorption specta of tyrosine, tyrosyltyrosine and tyrosyltyrosyltyrosine are compared.

3. The use of alcoholic hydrogen chloride for the removal of the carbobenzoxy group is described.

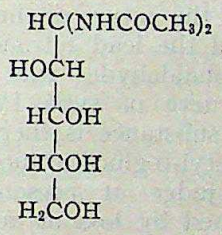
Lead Tetraacetate Oxidations in the Sugar Group. VIII.[1] The Preparation and Proof of Structure of N-Acetyl-D-glucofuranosylamine[2]

BY ROBERT C. HOCKETT AND LEONARD B. CHANDLER[3]

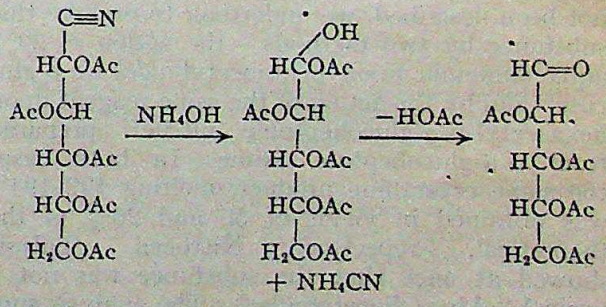
In 1893, Alfred Wohl[4] published his method of degrading an aldose to the next lower member of the series. The action of acetic anhydride and fused sodium acetate upon the D-glucose oxime which had been described by Jacobi[5] produced an acetylated D-gluconic acid nitrile which in turn lost CN^- when treated with an ammoniacal solution of silver oxide. This unusual hydrolysis of a cyanide group as a pseudohalogen instead of to the carboxyl group, produced a compound with one less carbon atom. However, instead of obtaining D-arabinose directly in a free state, Wohl obtained the pentose in a combination with two molecules of acetamide. This product, usually called by the unsatisfactory name "D-arabinose diacetamide," showed a composition and properties consistent with the formula



The open-chain structure was accepted as a matter of course in the era[4] when both sugars and their oximes were regarded as compounds of this type. As the realization grew, however, that the majority of sugar derivatives have cyclic structures,[6] these acetamide condensation products eventually became recognized as representatives of the relatively rare class of acyclic sugar derivatives.[7] The absence of a ring has been further confirmed in several cases by observation of the number of acetyl groups introduced on complete acetylation[8,9] as well as by study of the behavior of the substances toward lead tetraacetate.[10]

It was shown by Maquenne[11] that silver ions are not necessary for the removal of the cyanide group and that aqua ammonia alone will bring about the reaction in one instance. In this Laboratory Maquenne's observation has been confirmed and the effectiveness of 29% ammonia alone has been shown in a number of other cases.[8]

Interesting questions arise concerning the mechanisms of the several reactions which convert pentaacetyl-D-gluconic nitrile into "D-arabinose diacetamide." It is noteworthy that no tendency of free sugars to condense directly with acetamide has been observed either in this Laboratory or elsewhere[7] in spite of a number of efforts to effect such a combination under various conditions. The implication is that some form of sugar other than the pyranose is present at the instant of combination with acetamide. Such a form of D-arabinose could conceivably be the tetraacetyl *aldehydo*-D-arabinose which might be present in a transitory manner, *if* the hydrolysis of nitrile group proceeds at a greater speed than ammonolysis of the acetate groups. The latter, so long as present, will prevent cyclization to furanose or pyranose.



There are two objections to this theory. First, we have been unable to combine pentaacetyl *aldehydo*-D-glucose with acetamide in this Laboratory under any conditions found so far. Second, in the Wohl reaction no acetamide is present until it has been formed by the action of ammonia upon acetate groups in the molecule. We must therefore assume that two acetyl groups are converted to acetamide prior to condensation. If acetyl groups must also serve to prevent cyclization until after condensation has occurred, we must also assume that the groups at the two and three positions undergo ammonolysis more rapidly than those in the four and five positions. Thus 4,5-diacetyl *aldehydo*-D-arabinose may be the true intermediate.

The non-combination of the fully acetylated aldehydo sugars with acetamide may indicate either (1) that removal of acetyls from positions two and three activates the carbonyl in a necessary manner or, (2) that an alkaline medium is necessary for the condensation. If this is true, the "sugar diacetamide" is obviously formed as a result of a delicate balance among the rates of several concurrent reactions.

In either case, fully acetylated *aldehydo*-sugars ought to be converted by aqua ammonia into the open-chain diacetamide condensation products. Deulofeu[9] obtained "L-erythrose diacetamide" by the action of ammonia in ethanol upon triacetyl-aldehydo-L-erythrose and Brigl, Mühlschlegel and Schinle[7] obtained an analogous "D-glucose dibenzamide" by the action of ammonia in methanol upon pentabenzoyl-*aldehydo*-D-glucose. An attempt in this Laboratory, to prepare "D-xylose diacetamide" has resulted in failure. The action of aqua ammonia upon crystalline tetraacetyl-*aldehydo*-D-xylose,[12] has yielded no crystalline products. Neither have we been able to obtain D-gulose oxime or pentaacetyl-D-gulonic nitrile in a crystalline state.

Since "D-glucose diacetamide" had apparently not been described, we undertook to prepare this substance by two methods: the action of 29% aqua ammonia upon pentaacetyl-*aldehydo*-D-glucose[13] and by the action of the same reagent upon hexaacetyl-D-α-glucoheptonic nitrile[14] prepared from D-α-glucoheptose oxime. In both cases the same crystalline product, melting 192–194°, was obtained in yields of 56 and 26% of the theoretical, repectively. Nitrogen analysis showed at once that the substance was not a typical "aldose diacetamide." The analysis supported formulation as an N-acetyl-D-glucosylamine. Such a compound had previously been reported by Brigl and Keppler and by Niemann and Hays.[15] Their product, prepared by the action of ketene upon D-glucopyranosylamine, was shown by oxidation with periodic acid and hypobromite to a dibasic acid with one less carbon atom, to contain a pyranose ring.

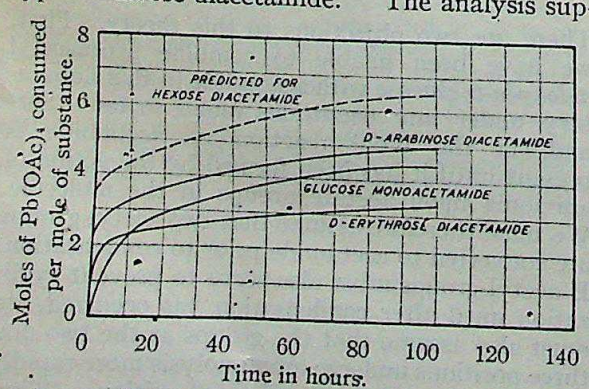

Fig. 1.

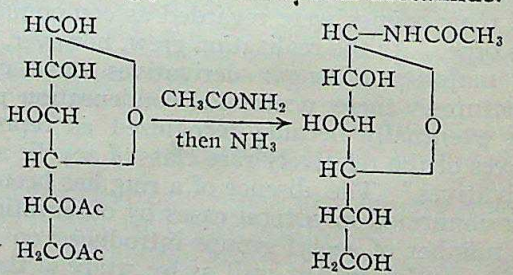
COMPARISON OF N-ACETYL-D-GLUCOSYLAMINES

	Melting point, °C. (uncor.)	Specific rotation
Hockett and Chandler	192–194	+86.9 (*C*, 1.584; H_2O; 25°)
Niemann and Hays (Brigl and Keppler)	255	−22.4 (*C*, 1.24; H_2O)

COMPARISON OF PENTAACETYL-D-GLUCOSYLAMINES

Hockett and Chandler	82.5–84.5	+32.7 (*C*, 1.062; $CHCl_3$; 25°)
Niemann and Hays (Brigl and Keppler)	160–161	+17.7 (*C*, 0.76; $CHCl_3$; 22°)

To determine the nature of the ring in our isomer, we applied the lead tetraacetate oxidation method.[16] Formaldehyde was produced and an oxidation curve of type IV was obtained (Fig. 1). The substance is therefore considered to be an N-acetyl-D-glucofuranosylamine. It is impossible to judge at present whether this product is formed by loss of acetamide from a typical "hexose diacetamide"[17] or by direct condensation of a glycofuranose with acetamide.



We describe D-α-glucoheptose oxime apparently for the first time. It was previously prepared in this Laboratory by Mr. André Laus (unpublished research) in 1936.

We wish to thank Professor M. L. Wolfrom of The Ohio State University for seed crystals of three compounds used in this study and Dr. Morris Zief of this Laboratory for optical measurements on glucoheptose oxime.

pentaacetyl-*aldehydo*-D-glucose (m. p. 110–118°), prepared by the method of Wolfrom[13] was treated with 110 cc. of 29% aqua ammonia at 50–60° for three hours. The solvents were then removed under reduced pressure and the remaining sirup was treated again with 110 cc. of ammonia solution. After concentration to a sirup, the latter was treated with 50 cc. of absolute ethanol which caused separation of fine crystals weighing 2.2 g.; yield, 56%. Recrystallized from about five parts of water with addition of eighteen parts of absolute alcohol, the crystals reached a maximum melting point of 189–191° (uncor.) (with decomposition) when heated at the rate of two degrees a minute. They rotated[18] +86.7° (*C*, 3.937; H_2O; 22.4°). A slow mutarotation[15] to +85.8° occurred in ten days. The compound is moderately soluble in hot water, slightly soluble in ice-cold water and in hot dry methanol, and insoluble in absolute ethanol, ether, pyridine, acetone and chloroform. It reduced Fehling solution only slowly on continued boiling.

Anal. Calcd. for $C_8H_{15}O_6N$: C, 43.3; H, 6.84; N, 6.34. Found: C, 42.4, 42.2, 43.2; H, 6.39, 6.73, 6.26; N, 6.34, 6.49.

Pentaacetyl-D-glucofuranosylamine.—A sample of 1.56 g. (0.00707 mole) of N-acetyl-D-glucofuranosylamine was treated with a mixture of 7.5 cc. (0.0789 mole) of acetic anhydride and 6 cc. (0.0740 mole) of pyridine at 75–80° for three hours. Solution was complete in thirty minutes and then slight discoloration occurred. After three hours, 5 cc. of pyridine was added and the solution was concentrated under diminished pressure (bath temp., 55°) to a sirup. This sirup was several times dissolved in absolute alcohol and reconcentrated to get rid of pyridine. The resulting yellow sirup was dissolved in 10 cc. of acetone and filtered through carbon to decolorize. The filtrate was treated with 10 cc. of dry ether and then with petroleum ether to turbidity. Crystals weighing 1.46 g. (53% of the theoretical) separated in a refrigerator. These prisms, once recrystallized from the same solvents, melted 82.5–84.5° (uncor.) and rotated[18] +32.7° (*C*, 1.620; $CHCl_3$; 25°). They are readily soluble in acetone, chloroform, methanol and ethanol, somewhat soluble in warm water, very slightly soluble in boiling ether or cold water, and insoluble in petroleum ether.

Anal. Calcd. for $C_{16}H_{23}O_{10}N$: N, 3.60; acetyl, 44.3. Found: N, 3.76, 3.77; acetyl, 44.2.

Pentaacetyl-D-glucofuranosylamine was also made by heating at 90° for ninety minutes with four parts of acetic anhydride and one-quarter part of anhydrous sodium acetate. The mixture was poured on ice, and the product was dissolved in chloroform, which was shaken repeatedly with sodium bicarbonate solution, was washed with water, dried over sodium sulfate and evaporated. The sirup remaining was crystallized as described above.

Attempted Condensation of Pentaacetyl-*aldehydo*-D-glucose with Acetamide.—After ten hours of boiling under reflux, a solution of the glucose derivative and of acetamide in chloroform was found to contain the starting materials unchanged.

D-α-Glucoheptose Oxime.—Nineteen grams (0.0906 mole) of D-α-glucoheptose (m. p. 188–190°) made as described by Haworth, Hirst and Stacey,[19] was treated with a methanol solution of 0.129 mole of hydroxylamine overnight at room temperature. A little unreacted sugar remaining the next morning was dissolved by warming a short time on the steam-bath. The solution was then concentrated to a sirup (diminished pressure) and was dissolved in a minimum volume of dry methanol. A crystalline product weighing 17 g. (85% of the theoretical) soon separated which melted at 89–91.5°. Recrystallized from water, it melted at 100–101° (uncor.).

Anal. Calcd. for $C_7H_{15}O_7N$: N, 6.22. Found: N, 6.33, 6.30.

The substance shows a slight mutarotation in water. The initial rotation[18] of −6.3° (*C*, 1.589; H_2O; 22°) reaches 0.9° in seventy hours. Because of the low magnitude of these rotations, no accurate rate constant has been obtained.

Hexaacetyl-D-α-glucoheptonic Nitrile.—Thirteen grams (0.0578 mole) of D-α-glucoheptose oxime (m. p. 89–91°) was treated with 69 cc. of acetic anhydride and 5 g. of anhydrous sodium acetate. Heat was evolved as the oxime dissolved. Finally the mixture was digested for an hour at 100° and then poured on ice. The precipitated gum soon solidified after excess acetic acid had been neutralized with sodium bicarbonate. Filtered, decolorized, and recrystallized from hot ethanol, 13.5 g. of product (51% of the theoretical) was obtained. After recrystallization to constant properties, the elongated prisms melted 85.5–87.5° (uncor.) and rotated[18] +24.3° (*C*, 3.893; $CHCl_3$; 24.8°). Zemplén and Kiss, who prepared the compound by another method,[14] reported a melting point of 112.5–113.5° but a closely agreeing rotation +24.6° at 21°. Possibly two crystal modifications exist.

Anal. Calcd. $C_{19}H_{25}O_{12}N$: C, 49.5; H, 5.44; N, 3.05. Found: C, 49.8, 49.8; H, 5.47, 5.47; N, 3.26. Acetyl determination by the method of Kunz and Hudson[20] resulted in hydrolysis of the cyanide group as well as the acetyls: calcd. for seven CH_3CO, 65.6; found, 63.6 (60 min.), 64.7 (75 min.) and 65.6 (120 min.).

N-Acetyl-D-glucofuranosylamine from Hexaacetyl-D-α-glucoheptonic Nitrile.—A sample of 10.5 g. (0.0229 mole) of the nitrile was heated for three hours at 50° with 125 cc. of 29% aqua ammonia. The solution was then concentrated to a sirup (diminished pressure) which was given a second treatment with ammonia. The sirup obtained by a second concentration was dried by adding absolute alcohol and redistilling solvent-free. The dried sirup was dissolved in a little absolute ethanol and ether was added to turbidity. Crystals separated in a yield of 1.3 g. or 26%. Recrystallized as described above, the small prisms attained a melting point of 192–194° (uncor.) and rotated[18] +86.9° (*C*, 1.584; H_2O; 25.1°). The two samples when mixed showed no depression of melting point.

Anal. Calcd. for $C_8H_{15}O_6N$: C, 43.4; H, 6.84; N, 6.34. Found: C, 43.4, 43.8; H, 6.94, 7.12; N, 6.25.

Rate of Oxidation of N-Acetyl-D-glucofuranosylamine by Lead Tetraacetate.—The measurement was carried out under the standard conditions described by Hockett, Dienes and Ramsden.[21]

Detection of Formaldehyde on Oxidation of N-Acetyl-D-glucofuranosylamine by Lead Tetraacetate.—A sample of 0.10 g. (0.0005 mole) of the glucose derivative was dissolved in 10 cc. of water in a small distilling flask. A volume of 15 cc. of approximately 0.05 molar lead tetraacetate in glacial acetic acid was added from a buret. After ten minutes, a receiver was attached and packed in dry-ice. The liquids were distilled under reduced pressure into this receiver. To the distillate was added 30 cc. of a saturated solution of 2,4-dinitrophenylhydrazine in 2 *N* hydrochloric acid (about 0.2 g. of the hydrazine). The precipitate of formaldehyde 2,4-dinitrophenylhydrazone melted at 166° (cor.).

Summary

An N-acetyl-D-glucofuranosylamine has been prepared in two ways: by the action of aqua ammonia upon pentaacetyl-*aldehydo*-D-glucose and upon hexaacetyl-D-α-glucoheptonic nitrile. The physical properties of the new compound are recorded along with those of the corresponding pentaacetyl-D-glucofuranosylamine and of D-α-glucoheptose oxime.

(18) All rotations in this paper refer to specific rotations of the D line of sodium at 20° unless otherwise stated. Concentrations are stated in grams of solute in 100 cc. of solution.

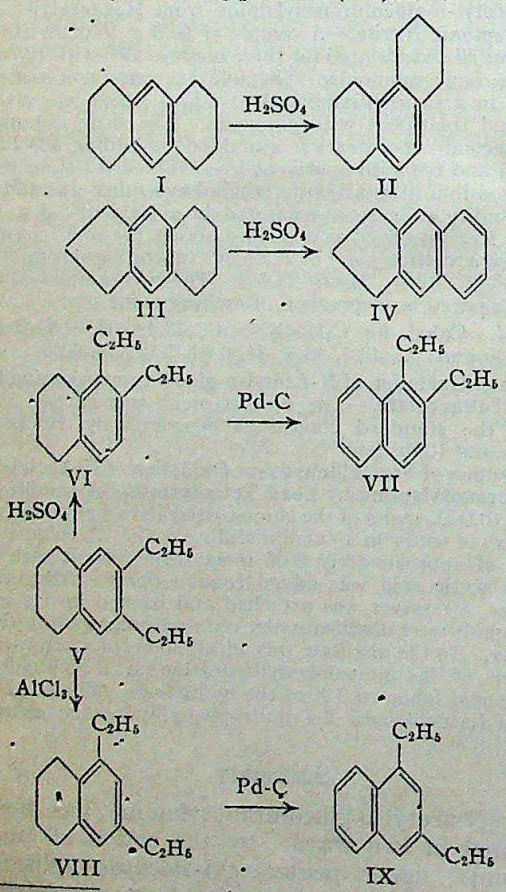
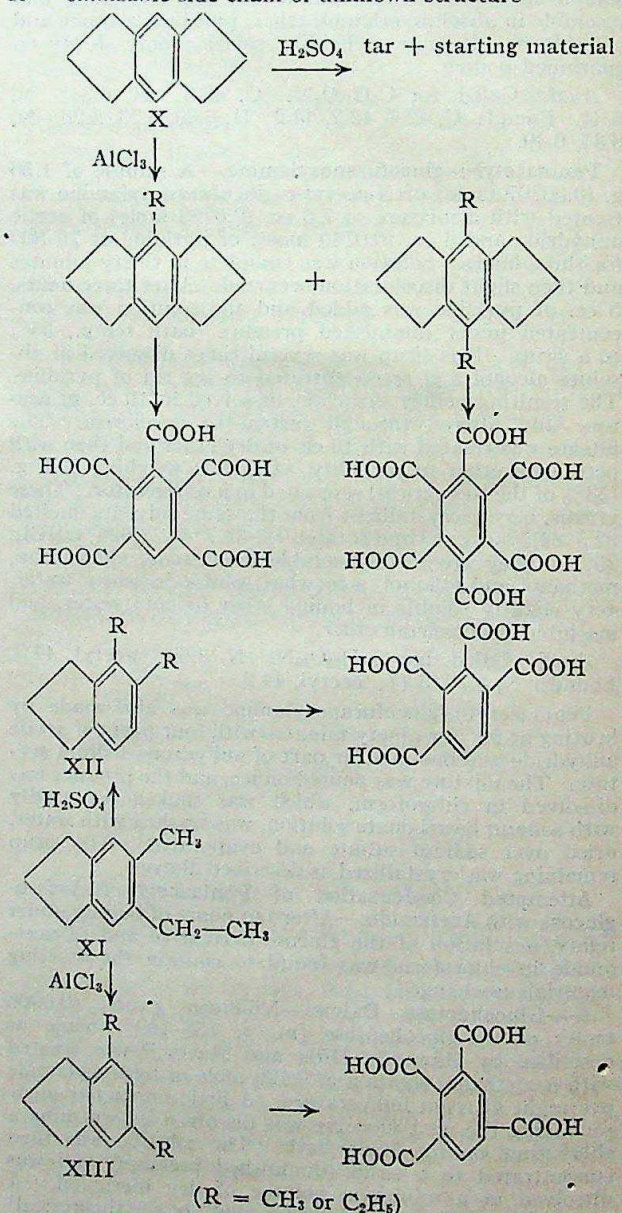
The Jacobsen Rearrangement. VIII.[1] Cyclic Systems; Mechanism

BY RICHARD T. ARNOLD AND RODERICK A. BARNES[2]

For many purposes it is convenient to regard hydrindene and tetralin as *o*-dialkylbenzenes. If this view is accepted, then one might suppose that the tri- and tetramethylene rings in these substances would undergo rearrangement when the molecule is subjected to conditions which bring about a migration of simple alkyl groups. Therefore it was of interest to study the Jacobsen rearrangement of hydrocarbons derived from tetralin and hydrindene. During the course of this investigation octahydroanthracene (I), 5,6,7,8-tetrahydrobenz[f]indan (III),[3] 6,7-diethyltetralin (V), 5-ethyl-6-methylhydrindene (XI), and *s*-hydrindacene (X) (Ring Index 1459) have been prepared and their reactions with sulfuric acid and aluminum chloride (in three cases) investigated.





The only example of a Jacobsen rearrangement involving a cyclic system which so far has been

reported is the conversion of octahydroanthracene into octahydrophenanthrene.[4] The results obtained in our work are in charts.

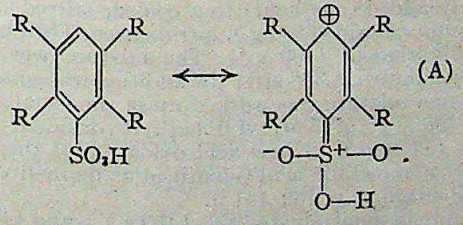
Discussion

No satisfactory and adequate explanation has yet been proposed for the mechanism of the Jacobsen rearrangement.[5]

In their original paper, Mills and Nixon[6] pointed out that in hydrindene the two bonds linking the trimethylene group to the benzenoid ring are probably distorted toward one another and that such a distortion should affect the aromatic character of the benzenoid ring. A very important result which must accompany such a deflection of these valence bonds is the reduction in the steric influence of the methylene groups adjacent to the benzene ring.[7]

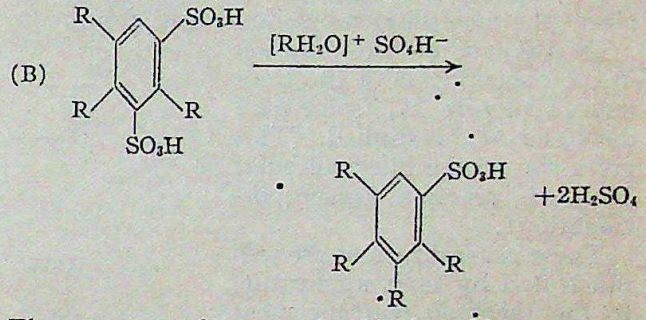
As the chart of reactions shows, successful Jacobsen rearrangements have been effected with compounds I, V and XI to give products with the expected orientations (*i. e.*, 1, 2, 4, 5- to 1, 2, 3, 4-). Compound III was not rearranged but was dehydrogenated by the action of sulfuric acid. No products from the rearrangement of X could be detected. In every case where possible (V and XI), aluminum chloride brought about a change in the orientation of the alkyl groups from the 1, 2, 4, 5-position to the 1, 2, 3, 5-position in a manner identical to that observed with simple tetraalkylbenzenes.

The evidence so far accumulated indicates that the Jacobsen rearrangement proceeds via an initial sulfonation and that it is the sulfonic acid which undergoes the rearrangement.[5] If the statement at the close of the footnote[7] is accepted, then it becomes apparent that in the sulfonic acids derived from I, V and XI, the sulfonic acid group is sterically more hindered than it is in the sulfonic acids from III and X. This steric factor is important because it controls in part the contribution of structure "A" to the resonance.[8,9]



(A)

The contribution of "A" to the resonance is less in the sulfonic acids derived from I, V and XI than it is in the sulfonic acids derived from III and X. As a result the benzene rings in the former compounds are more susceptible to attack by cationoid reagents than are those in the latter compounds. Furthermore, it has been shown[10] that the most hindered sulfonic acid groups are those most readily hydrolyzed by acid solutions. It follows, therefore, that in a disulfonic acid of type "B" the sulfonic acid grouping subject to the greatest hindrance will be the one to be preferentially replaced by cationic reagents.



The entrance of a second sulfonic acid group and the replacement of the original sulfonic acid group by an alkyl cation is an essential feature of the Jacobsen rearrangement. This conclusion together with the other considerations mentioned above lead to the following generalizations with regard to the mechanism of the Jacobsen reaction:

(1) The rearrangement of alkyl groups can occur only if the initial sulfonic acid group is

(7) A systematic investigation of the relative steric influence of the methylene group when present in a methyl group, a six-membered ring (as in tetralin), and a five-membered ring (as in hydrindene) has been under way for some time in this Laboratory and will be continued as conditions permit. This work has already indicated that the steric effect of these groups decreases in the order in which they are mentioned above.

sufficiently hindered sterically by two ortho substituents so that the contribution of form "A" to the resonance is diminished.

(2) The resulting steric inhibition of resonance allows for the formation of a disulfonic acid.

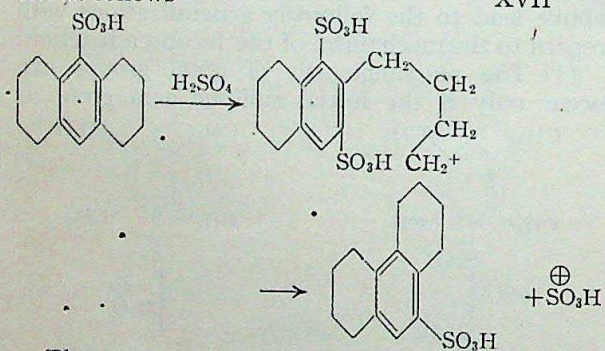
(3) This latter reaction takes place preferentially in the meta position to the first sulfonic acid group and leads to the elimination of an alkyl cation or the opening of a saturated ring to form an intermediate having a cationic terminal carbon atom.

(4) The cationic alkyl group preferentially replaces the most hindered sulfonic acid group.

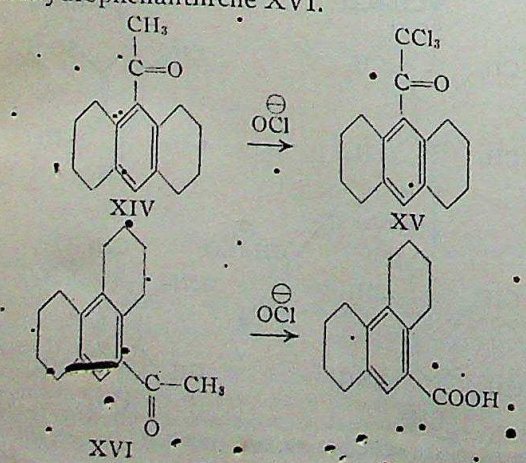
(5) Because of a diminution in the contribution of the resonance structure "A," some para disulfonic acid is formed. This gives rise to the intermolecular Jacobsen reaction (disproportionation).

These generalizations are well illustrated by their application to the Jacobsen rearrangement of durene already shown.

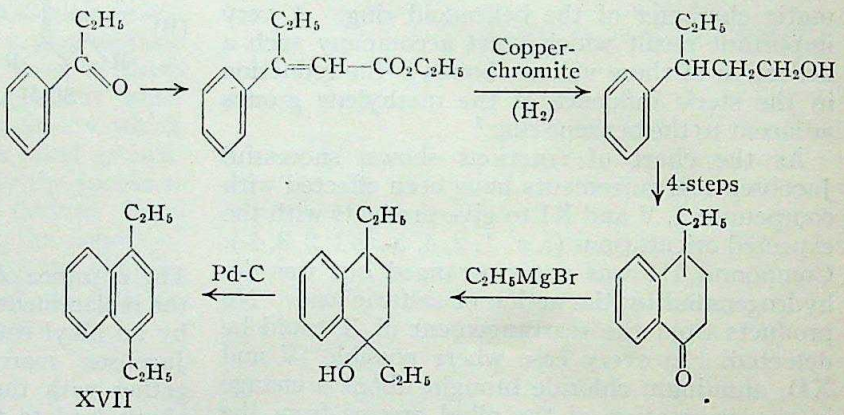
When applied to the specific case of octahydroanthracene, the rearrangement can be written as follows



There can be little doubt that the 9-position in octahydroanthracene is hindered to a rather considerable degree since 9-acetyloctahydroanthracene XIV when subjected to the haloform reaction yields a trichloromethyl ketone XV. As expected such is not the case with 9-acetyloctahydrophenanthrene XVI.



Incidental to this study, all of the possible diethylnaphthalenes having the two alkyl groups in a single ring have been synthesized. The 1,2-, 2,3- and 1,3-diethylnaphthalenes resulted from the catalytic dehydrogenation of the corresponding tetralins (VI, V and VIII) by means of palladium–charcoal catalyst. The structures of the tetralins employed were established by nitric acid oxidation to the known benzenetetracarboxylic acids; these were identified as their tetramethyl esters. 1,4-Diethylnaphthalene was prepared via the following sequence of reactions



The resulting hydrocarbon XVII (m. p. 16.5–17°) formed a picrate melting at 91–93°. These physical properties are quite different from those reported for 1,4-diethylnaphthalene by Frösche and Harlass.[11]

Experimental

5-Methylhydrindene.—A mixture of freshly distilled 5-chloromethylhydrindene (50 g.), absolute alcohol (200 cc.) and palladium on barium sulfate catalyst (1.5 g.) was shaken with hydrogen (45–50 lb. pressure) at room temperature. When the reaction was complete (twenty minutes), the catalyst was removed by filtration. From four such runs there was obtained on fractionation 154 g. of hydrocarbon (96%); b. p. 86–88° (19 mm.). Platinum oxide also is an effective catalyst.[12]

5-Ethyl-6-methylhydrindene.—Acetic anhydride (102 g.) was slowly added (one hour) to a cooled, stirred mixture of aluminum chloride (223 g.), nitrobenzene (500 cc.) and 5-methylhydrindene (100 g.). The mixture was stirred for ninety minutes at 30° after the addition was completed. The reaction mixture was worked up in the usual manner to give 106.8 g. of 5-acetyl-6-methylhydrindene; b. p. 152–158° (11 mm.). Nitric acid oxidation of the ketone gave only pyromellitic acid (identified as its methyl ester; m. p. and mixed m. p. 139–141°).

A mixture of amalgamated zinc (450 g.), water (450 cc.), concentrated hydrochloric acid (900 cc.), acetic acid (450 cc.) and the ketone (100 g.) was refluxed for fifty hours during which time 800 cc. of hydrochloric acid was added in portions. There was obtained 70.7 g. of hydrocarbon; b. p. 112–116° (11 mm.).

Anal. Calcd. for $C_{12}H_{16}$: C, 89.93; H, 10.07. Found: C, 89.70; H, 10.25.

5-Propionylhydrindene.—Propionic anhydride (130 g.) was added to a cooled, stirred mixture of aluminum chloride (292 g.), nitrobenzene (500 cc.) and hydrindene (118 g.). The mixture was worked up as described above for 5-acetyl-6-methylhydrindene. There was obtained 139 g. of ketone; b. p. 159° (12 mm.).

Anal. Calcd. for $C_{12}H_{14}O$: C, 82.72; H, 8.10. Found: C, 82.97; H, 8.33.

The oxime melted at 95–96°.

Anal. Calcd. for $C_{12}H_{15}ON$: C, 76.15; H, 7.99. Found: C, 76.26; H, 7.78.

Diethyl 5-Hydrindenylmethylmalonate.—Sodium (46 g.) was dissolved in one liter of absolute ethanol. Malonic ester (320 g.) was added and this was followed by the slow addition (two hours) of 5-chloromethylhydrindene (200 g.). The mixture was gently refluxed for five hours, made acidic (litmus) with 1:1 hydrochloric acid, and then the alcohol was removed by distillation. The residue was poured into water, separated, and distilled; b. p. 158–165° (3 mm.); weight 225 g.

Anal. Calcd. for $C_{17}H_{22}O_4$: C, 70.30; H, 7.65. Found: C, 70.28; H, 7.77.

β-5-Hydrindenylpropionic Acid.—(a) A mixture of 5-propionylhydrindene (35 g.), dioxane (110 cc.), sulfur (14 g.) and concentrated ammonia saturated with hydrogen sulfide (140 cc.) was heated in a closed iron pipe at 150–155° for twenty-four hours. The residue after removing the solvents was refluxed for two hours with potassium hydroxide (200 cc., 15%). The alkaline solution was treated with norite, filtered, and acidified. The liberated acid was extracted with benzene. Distillation in a sausage flask at 4 mm. pressure followed by recrystallization from dilute acetic acid gave 26 g. of acid; m. p. 85–86°.

Anal. Calcd. for $C_{12}H_{14}O_2$: C, 75.76; H, 7.41. Found: C, 75.64; H, 7.45.

(b) Saponification of diethyl 5-hydrindenylmethylmalonic ester followed by decarboxylation gave the same acid in a more impure condition; yield 91%; m. p. 78–80°. It was impossible to raise this melting point appreciably by recrystallization. A mixed melting point determination of the two samples gave m. p. 82–84°.

5-Hydrindacene-1-one.—Phosphorus pentachloride (5.21 g.) was added in portions to a solution of pure β-5-hydrindenylpropionic acid (4.76 g.) in dry benzene (50 cc.). Upon cooling to room temperature stannic chloride (3.7 cc.) dissolved in benzene (6 cc.) was added dropwise during an interval of forty-five minutes. Decomposition with dilute hydrochloric acid gave the ketone; yield 3.84 g.

Anal. Calcd. for $C_{12}H_{12}O$: C, 83.68; H, 7.03. Found: C, 83.36; H, 7.18.

***s*-Hydrindacene.**—A mixture of amalgamated zinc (140 g.), water (115 cc.), hydrochloric acid (230 cc.), acetic acid (86 cc.), toluene (115 cc.) and 5,6-cyclopenteno-1-indanone (20 g.) was refluxed for thirty-six hours during which time an additional 200 cc. of hydrochloric acid was added. There was obtained on distillation of the toluene layer 15.1 g. of hydrocarbon; b. p. 116–120° (9 mm.). Recrystallization from ethanol gave long prisms; m. p. 52–54°.

Anal. Calcd. for $C_{12}H_{14}$: C, 91.08; H, 8.92. Found: C, 90.92; H, 8.59.

This hydrocarbon on nitric acid oxidation gave only pyromellitic acid (methyl ester; m. p. 139–141°).

6,7-Diethyltetralin.—This hydrocarbon was prepared essentially by the method of Fleischer and Siefert.[13] Proof of its structure was established by nitric acid oxidation to pyromellitic acid.[14]

5,6,7,8-Tetrahydrobenz[f]indan.—This hydrocarbon was prepared according to the directions published by Sen-Gupta.[15]

4,9-Dibromo-5,6,7,8-tetrahydrobenz[f]indan.—The hydrocarbon (1.0 g.) was dissolved in acetic acid and a solution of bromine in acetic acid was added dropwise until a permanent reddish solution resulted. After a few minutes sodium bisulfite (0.2 g.) in 50 cc. of water was added. The white precipitate was collected and recrystallized from ethanol; m. p. 141.5–142.5°.

Anal. Calcd. for $C_{13}H_{14}Br_2$: C, 47.3; H, 4.27. Found: C, 47.5; H, 4.36.

3-Phenylpentanol-1.—Ethyl β-ethylcinnamate (200 g.) was hydrogenated at 250° with an initial pressure of 2800 pounds in the presence of 35 g. of copper chromite (37 KAF). The reduction was complete in six hours. Fractionation gave 137.4 g. of 3-phenylpentanol-1; b. p. 145–148° (26 mm.).[16]

1-Ethyltetralone-4.—This cyclic ketone was prepared from 3-phenylpentanol-1 by use of the method of Levy.[16]

1,4-Diethylnaphthalene.—A solution of the above ketone (5.6 g.) dissolved in dry ether (25 cc.) was slowly added to a solution of ethylmagnesium bromide prepared from 5.5 g. of ethyl bromide. After thirty minutes the mixture was decomposed with dilute hydrochloric acid. The ether layer, after removal of the ether, left a residue of crude carbinol (6.4 g.). This carbinol was heated for two hours at 225° with palladium-charcoal (0.2 g., 10%) in a current of carbon dioxide. After cooling, the product was taken up in ethanol (50 cc.), filtered, and treated with 5 g. of picric acid while the solution was warm. On cooling, the picrate separated; m. p. 91–93°. The hydrocarbon was regenerated by shaking the picrate with ether and ammonia. Evaporation of the ether layer and distillation gave 4.1 g. of hydrocarbon; b. p. 165° (25 mm.); m. p. 16.5–17°.

Anal. Calcd. for $C_{14}H_{16}$: C, 91.25; H, 8.75. Found: C, 91.70; H, 9.04.

9-Acetyl-1,2,3,4,5,6,7,8-octahydrophenanthrene.—In the preparation of 6-acetyltetralin from tetralin (132 g.) acetic anhydride (82 g.), aluminum chloride (300 g.) and dry carbon bisulfide (400 cc.) there were obtained 69.2 g. of 6-acetyltetralin and 11 g. of 9-acetyloctahydrophenanthrene (m. p. 50.5–51.5).[17] The structure of the latter was established by conversion to the corresponding 9-octahydrophenanthrene carboxylic acid; m. p. 236–238°. Schroeter[18] reports 239–240°.

9-Acetyloctahydroanthracene.—A solution of acetic anhydride (11.3 g.) in tetrachloroethane (25 cc.) was added slowly to a cooled solution of aluminum chloride (30 g.) and octahydroanthracene (9.3 g.) in tetrachloroethane (100 cc.). The solution was stirred in an ice-bath for two hours after the addition was completed, and the mixture was decomposed with dilute hydrochloric acid. Fractionation gave 7.8 g. of ketone; b. p. 169° (3 mm.). Crystallization from methanol gave a white solid; m. p. 72–72.5°.

Anal. Calcd. for $C_{16}H_{20}O$: C, 84.16; H, 8.83. Found: C, 84.09; H, 8.86.

9-Trichloroacetyloctahydroanthracene.—An aqueous solution of potassium hypochlorite from 15 g. of bleaching powder (H. T. H.) was shaken vigorously with 1.0 g. of acetyloctahydroanthracene. The solution became warm and, on cooling, a precipitate (1.4 g.) melting at 123.5–124.5° was isolated. The trichloro ketone crystallized with one molecule of water.

Anal. Calcd. for $C_{16}H_{17}OCl_3 \cdot H_2O$: C, 57.59; H, 5.14. Found: C, 57.61; H, 5.17.

2,3-Diethylnaphthalene.—One gram of 6,7-diethyltetralin was heated with palladium-charcoal (0.1 g., 10%) at 200–240° for three hours. The product was taken up in a small quantity of ethanol, filtered, and treated with a saturated solution of picric acid in ethanol. The precipitated picrate melted at 126–128°. The regenerated hydrocarbon was liquid at room temperature.

Action of Sulfuric Acid on the Hydrocarbons

(A) Octahydroanthracene.—The reported rearrangement to octahydrophenanthrene[4] was confirmed.

(B) 5,6,7,8-Tetrahydrobenz[f]indan.—The hydrocarbon (11.8 g.) and concentrated sulfuric acid (47 g.) were heated at 118°. Sulfur dioxide was continuously evolved.

On cooling the mixture was poured into 250 cc. of water and treated with calcium oxide (27 g.). After filtering, the filtrate was treated with sodium carbonate to remove the excess calcium ion. Evaporation of the aqueous filtrate gave a semicrystalline mass. This was steam distilled at 145–150° in the presence of dilute sulfuric acid. One gram of starting hydrocarbon and one gram of benz[f]-indan (m. p. 92–93°) were recovered. The latter formed its well known picrate, m. p. and mixed m. p. 116–118°.

(C) **6,7-Diethyltetralin.**—Eighteen grams of the hydrocarbon in sulfuric acid (80 cc.) was heated gradually while being stirred. At 60° complete solution was effected. The mixture was then heated at 95° for fifteen minutes and allowed to cool. Steam distillation at 150° gave 4.9 g. of liquid hydrocarbon. Oxidation of a portion of this material with nitric acid gave only mellophanic acid (methyl ester—m. p. and mixed m. p. 129–131°). Dehydrogenation of the hydrocarbon with palladium-charcoal gave 1,2-diethylnaphthalene a liquid hydrocarbon whose picrate melted at 105.5–107°.

(D) **5-Ethyl-6-methylhydrindene.**—Ten grams of the hydrocarbon was heated with 40 cc. of sulfuric acid at 90° for thirty minutes. Steam distillation as described above gave 1.4 g. of volatile hydrocarbon. Nitric acid oxidation gave only mellophanic acid (methyl ester—m. p. and mixed m. p. 129–131°).

(E) ***s*-Hydrindacene.**—Three grams of the hydrocarbon and 20 g. of sulfuric acid were heated at 70° for three minutes. More drastic conditions (*i. e.*, higher temperatures, etc.) gave only unidentifiable tarry materials. The solution was cooled and a solid sulfonic acid separated. To the total contents of the flask acetic acid (2 cc.) and sulfuric acid (5 cc.) were added and the temperature was raised to 98° and held there for one hour. Steam distillation gave the starting hydrocarbon (m. p. 52–53°) as the sole product. Considerable tarry residue remained in the distilling flask.

Action of Aluminum Chloride on the Hydrocarbons

(A) **6,7-Diethyltetralin.**—Thirteen grams of hydrocarbon and aluminum chloride (1 g.) was heated on the steam-bath for two and one-half hours and then allowed to stand several days at room temperature. After decomposition with water followed by ether extraction there was obtained on fractionation at 11 mm. three cuts boiling at 124–140°, 142–152°, and 155–168°. The first cut on oxidation with nitric acid gave impure prehnitic acid (identified as its methyl ester—m. p. and mixed m. p. 109–110°). Fraction II (b. p. 142–152°) gave fairly pure prehnitic acid. Dehydrogenation of this fraction with palladium–charcoal gave a naphthalenic hydrocarbon whose picrate melted at 100–101°. This hydrocarbon must be 1,3-diethylnaphthalene.

(B) **5-Ethyl-6-methylhydrindene.**—Treatment of 20 g. of hydrocarbon with aluminum chloride (2.0 g.) as described above gave on fractionation at 15 mm. the following cuts: I, 80–100° (1 g.), II, 100–120° (7 g.), III, 120–140° (10 g.), IV, 140–180° (0.5 g.) and V, 215–230° (0.8 g.). Fraction III gave prehnitic acid on nitric acid oxidation (identified as its methyl ester) and fraction V gave benzenepentacarboxylic acid (pentamethyl ester—m. p. and mixed m. p. 146–148°).

(C) ***s*-Hydrindacene.**—The hydrocarbon (1.5 g.) was treated with aluminum chloride (0.5 g.) as described above. The reaction product was oxidized with nitric acid and the resulting carboxylic acid mixture was esterified with diazomethane. Penta- and hexacarbomethoxybenzenes were isolated; m. p. 146–148° and 184–186°, respectively.

Summary

1. The Jacobsen rearrangement has been studied with cyclic hydrocarbons related to hydrindene and tetralin.

2. The action of aluminum chloride on 6,7-diethyltetralin, 5-ethyl-6-methylhydrindene, and *s*-hydrindacene is reported.

3. A new and convenient synthesis of pure 1,4-diethylnaphthalene is described.

4. A mechanism for the Jacobsen rearrangement is proposed and discussed.

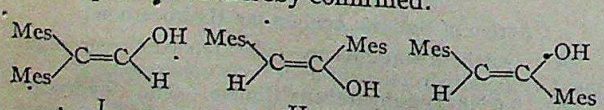
Vinyl Alcohols. IX.[1] Esters of 1,2-Dimesitylvinyl Alcohols

BY REYNOLD C. FUSON, L. J. ARMSTRONG[2] AND W. J. SHENK, JR.

For the dimesitylvinyl alcohol produced by the dehydration of hydromesitoin or isohydromesitoin[1] three structures are possible—1,1-dimesitylvinyl alcohol (I) and the *cis* (II) and *trans* (III) forms of 1,2-dimesitylvinyl alcohol. The present paper is concerned with the last two of these. Although it has not been possible to prepare these enols, evidence has been accumulated which shows both to be unstable and thus entirely different from the dehydration product. The structure, 1,1-dimesitylvinyl alcohol, (I), previously assigned to this product is thereby confirmed.



One of the methods employed in attempts to make enols II and III consisted in the condensation of mesitylmagnesium bromide with mesitylketene (IV). The possibility of preparing enols from ketenes was suggested by the work of Gilman and Heckert,[3] who found that the enolate formed by the addition of the Grignard reagent to diphenylketene was converted by the action of benzoyl chloride to the corresponding enol benzoate. Hydrolysis of this ester produced the enol, which immediately ketonized. It seemed possible that a more stable enol could be made by the condensation of a Grignard reagent with mesitylketene. Although this ketene could not be isolated it was prepared in solution and to the solution was added mesitylmagnesium bromide. The enolate (V) reacted with benzoyl chloride to yield a benzoate (VI) of desoxymesitoin (VII). The structure of the benzoate was established by

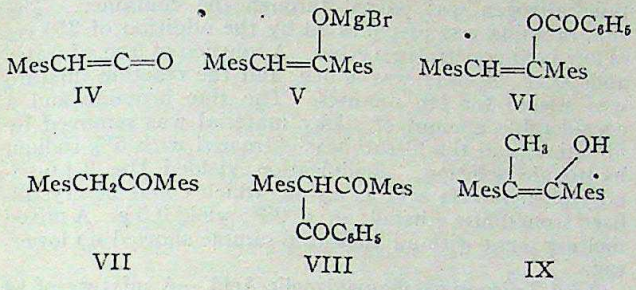
hydrolysis, which generated desoxymesitoin. That the benzoylation product was not the 1,3-diketone (VIII) was shown by its failure to



generate methane in the Kohler–Richtmyer apparatus.[4]

An attempt to synthesize the new benzoate from desoxymesitoin led to an interesting result. Desoxymesitoin was treated with ethylmagnesium bromide, and benzoyl chloride was added to the solution of the resulting enolate. The benzoate formed in this way was not identical with that from the ketene. It had similar chemical properties, however. It likewise gave no gas in the Grignard machine[4] and yielded desoxymesitoin when hydrolyzed. Evidently the two benzoates are *cis–trans* isomers. It also becomes certain that neither the *cis* (II) nor the *trans* (III) 1,2-dimesitylvinyl alcohol is stable with respect to the keto form. This result stands in marked contrast to the stability of the propenol, IX,[5] and that of 1,1-dimesitylvinyl alcohol (I).

Two acetates have also been prepared from desoxymesitoin. One of these had been made earlier by Barnes, Cooper, Tulane and Delaney[6] by heating desoxymesitoin with acetic anhydride and potassium acetate. It melted at 106° and, presumably, has the *trans* configuration. A low-melting acetate (67–68°), presumably the *cis* modification, was prepared by the action of acetyl chloride on the enolate formed by treating desoxymesitoin with ethylmagnesium bromide.

As might be expected, the synthesis of highly hindered ketenes offered difficulty. Mesitylketene was obtained in solution by the action of zinc on α-bromomesitylacetyl bromide. However, attempts to isolate it yielded only the dimer.

An attempt to prepare 2,4,6-triethylphenylketene by the same method led to similar results. The ketene could not be isolated. However, when water was added to the solution the hydration product of the ketene, 2,4,6-triethylphenylacetic acid, was formed.

An attempt to prepare mesitylketene from mesitoyldiazomethane likewise gave only the hydration product, mesitylacetic acid. Similar results were obtained in attempts to prepare 2,4,6-triisopropylphenylketene.

Experimental

α-Bromomesitylacetyl Bromide.—A mixture of 50 g. of mesitylglycolic acid[7] and 30 cc. of phosphorus tribromide was heated on the steam-bath for six hours. The lower layer was removed and distilled *in vacuo;* b. p. 138–139° (9 mm.); yield 65%.

Mesitylketene Dimer.—A solution of 26 g. of α-bromomesitylacetyl bromide in 50 cc. of absolute ether was added rapidly, with stirring, to a suspension of 15 g. of granulated zinc in 150 cc. of boiling absolute ether. The mixture was boiled for thirty minutes. The zinc bromide was precipitated from the yellow solution by the addition of 700 cc. of low-boiling petroleum ether. The solution was filtered and the solvent evaporated rapidly. The ketene dimer was purified by recrystallization first from a chloroform–petroleum ether mixture and then from methanol. It formed colorless crystals, melting at 197–200°, which were insoluble in 5% sodium hydroxide solution and in 5% hydrochloric acid.

Anal.[8] Calcd. for $C_{22}H_{24}O_2$: C, 82.48; H, 7.56; mol. wt., 320. Found: C, 82.36; H, 7.85; mol. wt. (ebullioscopic in chloroform), 325.

***trans*-1,2-Dimesitylvinyl Benzoate.**—A solution of mesitylketene was prepared according to the foregoing directions from 55 g. of α-bromomesitylacetyl bromide and 25 g. of zinc in 200 cc. of dry ether. After the reaction mixture had been heated under reflux for ten minutes, 800 cc. of low-boiling petroleum ether was added to precipitate the zinc bromide formed during the reaction. To the resulting solution was added a solution of mesitylmagnesium bromide prepared from 20 g. of bromomesitylene and 2.4 g. of magnesium in 50 cc. of dry ether. The reaction mixture was stirred for twenty minutes at room temperature. Twenty cubic centimeters of benzoyl chloride was then added, and stirring was continued for an hour at room temperature. The solution was filtered and shaken with 200 cc. of 5% sodium hydroxide solution and 20 cc. of alcohol to remove the excess benzoyl chloride. The ether–petroleum ether layer was washed successively with water, 10% potassium bicarbonate solution and water. It was dried over calcium chloride, and most of the solvent was removed by evaporation. When allowed to stand overnight the solution deposited the benzoate in clusters of white needles. These were collected on a filter, washed with low-boiling petroleum ether and recrystallized from methanol; m. p. 147–148°; yield, 5 g.

Anal. Calcd. for $C_{27}H_{28}O_2$: C, 84.34; H, 7.34. Found: C, 84.09; H, 8.00.

The benzoate was insoluble in 5% sodium hydroxide solution and 5% hydrochloric acid. Analysis in the Grignard machine[4] showed the absence of active hydrogen. When treated with copper acetate in ether the benzoate failed to yield a copper derivative.

Hydrolysis of the Benzoate.—One gram of the benzoate was dissolved in a solution made from 40 cc. of ethanol, 2 g. of sodium and 2 cc. of water. This solution was heated under reflux for two and one-half hours, cooled, diluted with an equal volume of water and extracted twice with ether. The ether solution was washed with water and dried over calcium chloride. Evaporation of the solvent left a solid residue. It was recrystallized from a mixture of methanol and water; m. p. 91–92°; yield 0.5 g. A mixture with an authentic specimen of desoxymesitoin showed no lowering of the melting point.

Enolization of Desoxymesitoin.[9]—Desoxymesitoin yielded 0.96 mole of methane in the Grignard machine,[4] but when the reaction mixture was treated with water the original ketone was recovered. Enolizing agents such as alcoholic alkali, sodium ethoxide and sodium amide likewise failed to produce a stable enol.

***cis*-1,2-Dimesitylvinyl Benzoate.**[9]—To the Grignard reagent, prepared from 0.7 g. of magnesium, 1.9 g. of ethyl

Digitized by Arya Samaj Foundation Chennai and eGangotri

bromide and 20 cc. of dry ether, was added a solution of 2.3 g. of desoxymesitoin in 25 cc. of dry ether. The mixture was heated under reflux for one hour. An ether solution of 2 cc. of benzoyl chloride was added, and the refluxing continued for three hours. The decomposition of the mixture and the isolation of the product were conducted in the usual way. The benzoate was purified by recrystallization from methanol. It formed fine, white platelets melting at 104–105.5°.

Anal. Calcd. for $C_{27}H_{28}O_2$: C, 84.34; H, 7.34. Found: C, 84.31; H, 7.34.

cis-1,2-Dimesitylvinyl Acetate.[9]—The preceding synthesis was repeated, acetyl chloride being used in place of benzoyl chloride. The vinyl acetate boiled at 188–193° (4 mm.) and melted at 68–69°. It was purified by recrystallization from methanol.

Anal. Calcd. for $C_{22}H_{26}O_2$: C, 81.94; H, 8.12. Found: C, 81.91; H, 8.26.

Mesitylglyoxal Monohydrazone.—This compound was prepared by the procedure used by Nenitzescu and Solomonica[10] for the synthesis of the monohydrazone of benzil. A solution of hydrazine acetate, prepared from 54 g. of hydrazine sulfate and 77 g. of anhydrous sodium acetate in 250 cc. of water, was boiled for five minutes. The sodium sulfate was precipitated by the addition of 250 cc. of ethanol and removed by filtration. The hydrazine acetate solution was added rapidly from a dropping funnel to a warm solution of 58 g. of mesitylglyoxal in 100 cc. of ethanol. The mixture was heated for ten minutes under reflux. When cold it deposited the hydrazone in white crystals. The yield of crude product was 90%. The monohydrazone was purified by recrystallization from a mixture of ether and low-boiling petroleum ether; m. p. 129–131°.

Anal. Calcd. for $C_{11}H_{14}N_2O$: C, 69.44; H, 7.42. Found: C, 69.40; H, 7.60.

Mesitoyldiazomethane.—A mixture of 5 g. of mesitylglyoxal monohydrazone and 6 g. of yellow mercuric oxide was added to a flask containing a mixture of 500 cc. of low-boiling petroleum ether, two drops of saturated alcoholic potassium hydroxide solution and 3 g. of finely ground calcium sulfate. The mixture was stirred for three hours at ice-bath temperatures. The solid material was removed by filtration and washed with a little ether. Evaporation of the solvent from the filtrate and washings left the diazomethane in yellow crystals. The yield of crude product was 75%. It crystallized from methanol in fine, yellow needles; m. p. 59–61°, with decomposition.

Anal. Calcd. for $C_{11}H_{12}N_2O$: C, 70.21; H, 6.43. Found: C, 70.36; H, 6.19.

In an attempt to prepare mesitylketene a solution of 5 g. of mesitoyldiazomethane in 50 cc. of dry benzene was dropped slowly into a 10-cc. modified Claisen flask placed in a metal bath held at 100–110°. After the benzene had been distilled nitrogen was passed in and the residue distilled *in vacuo*. No sharp fraction could be obtained; the material in the receiver was a yellow, resinous mass.

Mesitylacetic Acid.—One gram of mesitoyldiazomethane was treated for thirty minutes with 100 cc. of boiling water. The solution was allowed to cool, 3 g. of potassium carbonate was added and the mixture extracted twice with ether. Acidification of the carbonate solution yielded 0.3 g. of mesitylacetic acid; m. p. 165–166°.

2,4,6-Triethylphenylacetic Acid.—Thirty-five grams of 2,4,6-triethylphenylglycolic acid[5] was mixed with 15 cc. of phosphorus tribromide and the mixture allowed to stand overnight on the steam-bath. An additional 5 cc. of phosphorus tribromide was added and the heating continued for twelve hours. The organic layer was distilled *in vacuo*, yielding 27 g. of α-bromo-2,4,6-triethylphenylacetyl bromide; b. p. 140–142° (5 mm.).

A solution of 20 g. of α-bromo-2,4,6-triethylphenylacetyl bromide, 50 cc. of dry ethyl ether and 50 cc. of dry butyl ether was added dropwise, with stirring, to a mixture of 5 g. of granulated zinc and 30 cc. of dry ethyl ether. The addition required five minutes, and the mixture was stirred and warmed for ten minutes longer. During this time nitrogen was passed through the container. The zinc bromide was precipitated by the addition of 350 cc. of low-boiling petroleum ether. A solution of 5 cc. of water and 50 cc. of ether was added, and the reaction mixture was stirred for ten minutes. The zinc bromide and a considerable amount of sticky material was removed by filtration, and the filtrate was extracted with 5% sodium hydroxide solution. Acidification yielded the 2,4,6-triethylphenylacetic acid as an oil, which could be crystallized from dilute ethanol; m. p. 98°; yield 0.5 g. A mixed melting point with an authentic sample showed no lowering.

2,4,6-Triisopropylphenylglycolic Acid.—A mixture of 84 g. of selenium dioxide and 700 cc. of 95% ethanol was heated at 50° until the solid had dissolved. Methyl 2,4,6-triisopropylphenyl ketone (153 g.)[11] was added and the mixture heated under reflux, with stirring, for seven hours. The selenium was removed by filtration, and the solvent was distilled. The 2,4,6-triisopropylphenylglyoxal distilled at 138–143° (7.5 mm.). The yield was 77% of the theoretical.

A mixture of 95 g. of the glyoxal and 1 l. of 10% potassium hydroxide solution was heated on a steam-bath for twenty-four hours and acidified with hydrochloric acid. The 2,4,6-triisopropylphenylglycolic acid dissolved with difficulty in dilute potassium hydroxide solution. The solution was washed repeatedly with ether and acidified with hydrochloric acid. The glycolic acid was recrystallized twice from 66% acetic acid; m. p. 163–164° (cor.); yield 73%.

Anal. Calcd. for $C_{17}H_{26}O_3$: C, 73.34; H, 9.42. Found: C, 73.60; H, 9.62.

Methyl 2,4,6-Triisopropylphenylglycolate.—This ester was obtained in 65% yield by heating the acid for three hours with methanol which had been saturated previously with hydrogen chloride. It was recrystallized from ligroin; m. p. 94–95°.

Anal. Calcd. for $C_{18}H_{28}O_3$: C, 73.93; H, 9.65. Found: C, 73.80; H, 9.73.

Saponification with aqueous alkali converted it to the original acid.

Dioxolone from 2,4,6-Triisopropylphenylglycolic Acid.—A mixture of 9 g. of the acid, 40 cc. of acetone and 2 cc. of concentrated sulfuric acid was stirred for thirty minutes at ice-bath temperatures. The dioxolone was obtained in beautiful, white crystals melting at 165–165.5°; yield 75%.

Anal. Calcd. for $C_{20}H_{30}O_3$: C, 75.43; H, 9.50. Found: C, 75.59; H, 9.82.

Treatment of the dioxolone with hydrazine hydrate converted it to the corresponding hydrazide. A solution of 1.5 g. of the dioxolone, 50 cc. of absolute ethanol and 2 g. of hydrazine hydrate was heated for four hours under reflux. The product was recrystallized from a ligroin–benzene solution (7:3). It formed white crystals melting at 156–157°.

Anal. Calcd. for $C_{17}H_{28}O_2N_2$: C, 69.82; H, 9.65; N, 9.58. Found: C, 70.22; H, 9.32; N, 9.85.

The Hydrazone of 2,4,6-Triisopropylphenylglyoxal.[12]—The procedure was similar to that given for the mesityl analog. From 62.4 g. of the glyoxal there was obtained 59 g. (90%) of the hydrazone, melting at 147–151°, with decomposition. It was recrystallized repeatedly from dilute ethanol. The hydrazone formed white cubes melting at 153–154°, with decomposition.

Anal. Calcd. for $C_{17}H_{26}N_2O$: C, 74.41; H, 9.55. Found: C, 74.38; H, 9.65.

2,4,6-Triisopropylphenylacetic Acid.—(a) A finely ground mixture of 7 g. of yellow mercuric oxide, 2.5 g. of

anhydrous calcium sulfate and 5 g. of the hydrazone of 2,4,6-triisopropylphenylglyoxal was covered with 75 cc. of dry ether and stirred for twelve hours at room temperature. The ether was decanted through a filter paper and the black residue washed by decantation with a total of 100 cc. of dry ether. Removal of the ether left the diazo compound as a yellow powder, which decomposed explosively at 125°. After recrystallization from methanol it was found to decompose at 104°; yield 4.5 g.

It was covered with water and a pinch of silver oxide was added. The mixture was boiled for thirty minutes. Eight grams of potassium hydroxide pellets was added and the boiling continued for fifteen minutes. A solid was removed by filtration and recrystallized from ether. It formed pale yellow crystals melting at 204–205°. This substance was not identified. When the filtrate was acidified the 2,4,6-triisopropylphenylacetic acid was precipitated. It was recrystallized from 75% acetic acid and then from ligroin; m. p. 146–146.5°. A mixture with an authentic specimen of the acid (see below) showed no depression in melting point.

(b)[13] The hydrolysis of 2,4,6-triisopropylbenzyl cyanide could not be effected satisfactorily with 50–80% sulfuric acid. The method of Redemann and Lucas[14] for the saponification of esters, however, was found to be suitable. A mixture of 67 g. of the pure nitrile, 500 cc. of diethylene glycol, 100 g. of potassium hydroxide and 20 cc. of water was heated under reflux for twelve hours and poured into water. The 2,4,6-triisopropylphenylacetic acid, precipitated by acidification of the mixture, was recrystallized from aqueous ethanol; m. p. 144–145°; yield 85%.

Anal. Calcd. for $C_{17}H_{26}O_2$: C, 77.80; H, 9.99. Found: C, 78.08; H, 9.67.

Hydrolysis of the nitrile with potassium hydroxide and ethanol produced 2,4,6-triisopropylphenylacetamide. It was recrystallized from ethanol; m. p. 170–171°.

Anal. Calcd. for $C_{17}H_{27}NO$: C, 78.11; H, 10.41. Found: C, 78.15; H, 10.57.

2,4,6-Triisopropylbenzyl Cyanide.[11]—2,4,6-Triisopropylbenzyl chloride, prepared by the chloromethylation of 1,3,5-triisopropylbenzene,[15] was converted to the corresponding cyanide by treatment with cuprous cyanide. A mixture of 149 g. of the chloride, 57.8 g. of cuprous cyanide and 60 cc. of dry pyridine was heated at 210–220° for ninety minutes. When the mixture had cooled to 150° it was poured into a mixture of 500 g. of ice and 200 cc. of ammonium hydroxide. The mixture was allowed to stand overnight, and the crude nitrile was collected on a filter and distilled, b. p. 129–130° (4 mm.); m. p. 81–82°; yield 64%.

Anal. Calcd. for $C_{17}H_{25}N$: C, 83.89; H, 10.35. Found: C, 83.40; H, 10.26.

Summary

Methods of synthesis of hindered aldoketenes have been studied.

The *cis* and *trans* enol benzoates of desoxymesitoin have been prepared. Hydrolysis was found to convert them to desoxymesitoin, showing that the *cis* and *trans* enols of desoxymesitoin were unstable and ketonized rapidly. The corresponding *cis* and *trans* acetates were also prepared. These results confirm the conclusion reached earlier that the dehydration product of hydromesitoin or isohydromesitoin is 1,1-dimesitylvinyl alcohol.

URBANA, ILLINOIS RECEIVED MARCH 13, 1944

The Relation of Estrogenic Activity to Structure in Some 4,4′-Dihydroxydiphenylmethanes[1]

BY E. EMMET REID AND EDITH WILSON[2]

Estrogenic activity has been noted by Dodds and Lawson[3] in some 4,4′-dihydroxydiphenylmethanes, $(HOC_6H_5)_2CRR'$. It seemed worthwhile to prepare a number of these to see how the estrogenic activity varies with the size and character of the groups R and R′. Two series have now been made: one, in which R is methyl and R′ varies from methyl to hexyl, and the other, in which R and R′ are identical and vary from methyl to amyl. Besides these several compounds of different types, including the double one, $(HOC_6H_4)_2C(CH_3)CH_2CH_2C(CH_3)(C_6H_4OH)_2$, from acetonyl-acetone have been studied. In order to have comparable estrogenic data, the known compounds have been prepared and tested along with the new. For better chemical characterization the benzoates of all of them have been prepared. The results are in Table I. The activities of the members of the second series are plotted in Fig. 1. When our work was nearly completed, an article by Campbell[4] covering part of the same ground appeared.

The activity reaches a peak in the first series with the methyl-propyl and in the second series a much higher peak at the propyl-propyl, which is ten times as potent as any of the others. The activities for ethyl-propyl and for propyl-butyl are borrowed from Campbell. For comparison the data for the corresponding *trans*-4,4′-dihydroxy-α,β-dialkylstilbenes[5] are plotted in Fig. 1, but they are in rat units per milligram while ours are in the same units per gram. The ethylene derivatives are around a thousand times as active as the methane derivatives, yet the shapes of the two curves are strikingly alike except that the maximum is at the ethyl-ethyl in the one and at the propyl-propyl in the other. The rise is gradual through the methyl-ethyl in the one and through the ethyl-propyl in the other. In both

TABLE I

MELTING POINTS AND ACTIVITIES

R	R′	M. p., °C.	Rat u./g.	Benzoate m. p., °C.
Methyl	Methyl[3,6,7,8]	155	28	161
Methyl ethyl	[6,8,9,10,11]	124	80	143
Methyl	Propyl[6,8,10,11,12]	149	200	120
Methyl	Butyl[7]	Liq.	40[2]	72
Methyl	Amyl	101	35	118
Methyl	Hexyl	88	50	114
Methyl	*i*-Propyl	194	50	204
Methyl	*i*-Butyl[6,11]	153	200	116
Ethyl	Ethyl[6,10,12]	204	200	163
Propyl	Propyl[6,12]	154	2000	142
Butyl	Butyl[6]	170.5	20	129.5
Amyl	Amyl	148.5	10	94
c-Pentanone[6,8,11]		157	66	205
c-Hexanone[6,11,13,14]		184	50	198
4-Me-Hexanone[10,11,13]		179	200	149.5
Methyl	Phenyl[6,11,14,15]	188	0	150.5
Methyl	*p*-MeO phenyl	245	55	221
Benzyl	Benzyl[16]	193	0	223
$(CH_3C{\cdot}CH_2{\cdot})_2$[17]		302 d	200	247

the activities drop off sharply as soon as the maxima are passed. Symmetry seems to play an important part; the maxima are at ethyl-ethyl and propyl-propyl. So far as the same compounds are concerned our results agree well with those of Campbell except that our value for propyl-propyl is much higher.

The methyl-*i*-butyl is considerably more active than the methyl-*n*-butyl. A methyl group in the 4-position in the cyclohexanone derivative raises its activity, so does the *p*-methoxy group in the methyl-*p*-methoxyphenyl. The double compound from acetonyl-acetone shows as much activity as any except the propyl-propyl. This is remarkable considering its high molecular weight and low solubility.

The estrogenic activities were determined by Dr. Geschickter and Dr. Byrne by the standard method.

The melting points of the compounds of the two series show alternation, as do those of their benzoates.

Experimental

The method of preparation was the same for all. The ketone and three equivalents of phenol were put into a glass-stoppered bottle and concentrated hydrochloric acid equal to about one-fifth of the phenol added. The mixture stood, with occasional shaking, until the reaction seemed to be complete, which took from a day or two for the simpler ketones up to twenty weeks for some others. Hydrogen chloride was passed into the slow ones from time to time. The condensations went much faster if, instead of using aqueous hydrochloric acid, the ketone–phenol mixture was saturated with hydrogen chloride, but the products so obtained were harder to purify. The mixtures turned red in any case, but the purified compounds were colorless. The reaction product was poured into hot water, the unused reactants driven off with steam, and the residue filtered off or collected in ether according to its physical state. The yields were high, 90% or better, even with the higher ketones if they were given time enough. Acetic acid, chloroform, acetone and toluene were used as solvents. The low melting compounds were hard to purify as they tended to separate from solvents as liquids. Some could be obtained pure only by saponification of the recrystallized benzoates. The benzoates were made by the Schotten–Baumann method. All melting points were determined with the aid of a thermometer calibrated for 3-inch immersion. The analyses of new compounds are in Table II.

TABLE II

ANALYSES

R R′	Carbon, % Calcd.	Carbon, % Found	Hydrogen, % Calcd.	Hydrogen, % Found
Methyl amyl	80.28	79.41	8.45	8.51
Methyl hexyl[a]	80.54	78.50	8.72	8.64
Benzoate	80.61	79.91	6.77	6.53
Amyl amyl	81.17	80.98	9.41	9.50
Methyl *i*-propyl	79.69	79.53	7.81	7.99
4-Methyl-*c*-hexanone	81.13	81.10	7.47	8.02
Methyl *p*-MeO-phenyl	78.75	78.39	6.25	6.45
Benzyl benzyl	85.26	85.70	6.31	6.34
$(CH_3CCH_2—)_2$	79.19	79.30	6.60	6.79

[a] The low carbon is probably due to adsorbed water. On account of the low m. p. the compound was difficult to dry. The benzoate gave satisfactory figures.

Summary

A number of 4,4′-dihydroxy-diphenylmethanes, $(HOC_6H_4)_2CRR'$, have been prepared and their

Single Bond Energies. V. The Association of Ketyls

BY H. E. BENT AND A. J. HARRISON[1]

The compound formed by the addition of an alkali metal to an aromatic ketone is highly colored and by some investigators[1a] has been assigned the formula

$$R_2{=}C(\text{—}O\text{—}Na)\text{—}$$

although evidence has been advanced[2] to show that the compound should not be considered to be a free radical but is associated and should be represented as a pinacolate

$$\begin{aligned} R_2{=}C\text{—}O\text{—}Na \\ | \\ R_2{=}C\text{—}O\text{—}Na \end{aligned}$$

We have attacked this problem by the method used in studying hexaphenylethane and triphenylmethyl reported by Ziegler and Ewald.[3] They found that on diluting a solution of hexaphenylethane the deviations from Beer's law could be explained satisfactorily by assuming an equilibrium between the ethane and the free radical and also assuming only the free radical to be colored.

Benzophenone was chosen as the first compound to be studied since it is the simplest aromatic ketone. Fluorenone was chosen as the second compound due to the presence of a five-membered ring. Peculiarities in five-membered rings have been found in the acidity of very weak acids,[4,5] the dissociation of free radicals[6] and the addition of sodium to single bonds.[7]

A solution of the ketyl is prepared by shaking the ketone in ether solution with 0.6% sodium amalgam. A portion of this solution is used to rinse the apparatus, removing adsorbed water. Fresh solution is then poured into the cell in which the optical density is to be determined. In order to avoid the errors inherent in an analysis one sample is used for a whole series of measurements, dilution being accomplished by means of the apparatus shown in Fig. 1. This device is carefully calibrated to determine the amount of hold up in the annular space when a solution is poured through it. The total volume of ether is determined at the beginning of the experiment. This permits one to pour a known fraction of the solution through the dilution device and then to distill the ether back, condensing it in the solution which had been retained in the annular space, thus diluting the solution by a known fraction. Two or three dilutions may be carried out with one cell before the solution becomes too dilute to measure with precision. Another sample of the solution is removed and the sodium determined analytically.

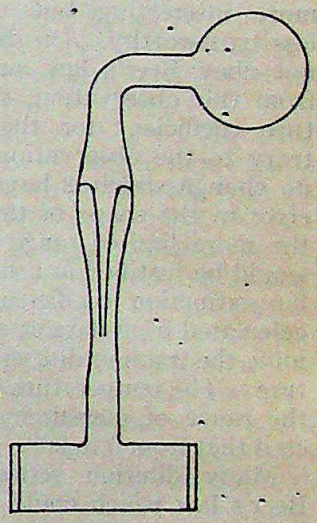

Fig. 1.—Dilution device. The solution is diluted without exposing to air by inverting the whole apparatus. A certain fraction of the liquid is retained in the annular space around the capillary. The apparatus is then returned to its original position without pouring solution back from the flask. On cooling the cell solvent distills from the flask back into the cell.

Measurements of the optical density were carried out with a spectrophotometer, previously described,[8] which illuminates the cell with monochromatic light and gives high precision. All cells were of Pyrex glass with fused plane glass windows mounted in Dewars.

The experimental results from the study of fluorenone indicate that it gives rise to a ketyl which obeys Beer's law within the accuracy of our experimental measurements. A series of measurements at room temperature gave ratios for the optical densities which agreed very closely with the values for the dilution ratio. In order to find evidence for association if possible at lower temperatures a series of dilutions were carried out, measurements being made at −112°, using solid carbon disulfide as the cooling agent. These measurements also showed close agreement with Beer's law. Since one would expect a temperature coefficient for the process of dissociation which would greatly increase the frac-

tion dissociated at room temperature as compared with −112°, we may conclude that this compound exists essentially 100% in the form of a free radical at room temperature.

On lowering the temperature of a solution of this ketyl there is an increase in the molecular extinction coefficient which by itself might be taken as evidence for dissociation! The series of dilutions at the lower temperature, however, give no such evidence. Examination of the absorption curve indicates that the percentage change in the molecular extinction coefficient is not constant on lowering the temperature but depends upon the wave length, there being an increase in the maximum and a narrowing of the band. Hence one is not justified in taking the value of the molecular extinction coefficient at infinite dilution at one temperature and using this with values at other temperatures to calculate the fraction dissociated.

The results with benzophenone are perhaps more interesting but unfortunately somewhat less trustworthy. On dilution, the solution does not obey Beer's law and as one would predict from this observation, there is a large temperature coefficient for the optical density. Contrary to the observations on fluorenone there is no change which is larger than our experimental error in the shape of the absorption curve, over the more limited range of 20°. In this case we would be justified in using a value of the molecular extinction coefficient of the pure ketyl as calculated from data at one temperature to determine the fraction dissociated at another temperature. The temperature coefficient is so large that the range of measurement did not need to exceed that from 0 to 20°.

Many dilution series gave deviations from Beer's law which could not be explained by the simple assumptions made at the beginning of this paper. In practically every case the dilute solution was darker than could be accounted for by any experimental error or by the dissociation of the pinacolate into the free radical. We are inclined to believe that in these series some excess ketone was present, produced by hydrolysis, the ketyl reacting with minute traces of water firmly held on the glass apparatus even after evacuating and washing with ketyl solution. We have observed that the addition of ketone to the ketyl does destroy the blue color. If one assumes that an unstable compound is formed containing one molecule of ketone and two of ketyl, possibly forming a chelate ring, it is possible to account for our experimental data quantitatively. The possible presence of the disodium derivative of the ketone has been considered but can be ruled out by a consideration of the difference between the absorption curves for the mono- and the di-sodium derivatives. The strong maximum for the latter at a wave length of 510 is sufficiently far from the wave length used of 630 to permit one to say from a study of the latter curve that only an extremely small amount of the disodium derivative could have been present.

In some series of dilutions, especially those carried out with fresh solutions which had been in contact with the glass for too short a time to react with much water, the deviations from Beer's law could be quantitatively accounted for by a simple equilibrium between pinacolate and free radical. Using these runs alone values have been calculated for the equilibrium constant.

The results on the two ketyls mentioned above are not what one would predict from a consideration of the behavior of similar hydrocarbon free radicals. The relatively small association of triphenylmethyl as compared with phenylfluoryl indicates that the removal of two hydrogen atoms and the connection of two benzene rings by a carbon–carbon bond favors association. In the study of the ketyls described in this paper the effect is just the opposite.

The explanation of this apparent inconsistency is probably to be found in the assumption that phenylfluoryl has more resonance than triphenylmethyl. The converse has usually been assumed in accounting for phenylfluoryl being less stable as a free radical than triphenylmethyl.[9] If one considers the symmetry of the free radical alone one would be led to this conclusion. If on the other hand we assume that phenylfluoryl has more resonance, then we must also assume that the greater tendency to associate is due to a smaller amount of steric hindrance. This is in accord with the observation of Cline[10] that diphenyldifluoryl can be hydrogenated with much less ease than hexaphenylethane, indicating a smaller amount of steric hindrance in the undissociated molecule. The hydrogenation experiment gives an answer to the question of steric hindrance without the complication of resonance which appears in the process of dissociation to give a free radical.

The details of the way in which this extra resonance appears in the free radical phenylfluoryl have been suggested to one of the writers by R. W. Stoughton. It is evident from the illustration below that whereas the odd electron can appear on only alternate carbon atoms in triphenylmethyl, in phenylfluoryl the odd electron can appear on every carbon of the fluoryl group and hence we have a much larger number

(9) Pauling and Wheland, *J. Chem. Phys.*, **1**, 373 (1933), have concluded that one can give a reasonable explanation for a smaller amount of resonance in the fluoryl radical and thus explain the smaller amount of dissociation without recourse to steric hindrance. Muller and Janke, *Z. Elektrochem.*, **45**, 386 (1939), come to similar conclusions. No experimental data were available in 1933 to suggest the need of any other explanation. The data of Muller and Janke do not agree with ours on the two ketyls under consideration. Although it is true that Muller and Janke were working in more concentrated solutions it seems hardly likely that this would reverse the relative ease of dissociation of the two compounds.

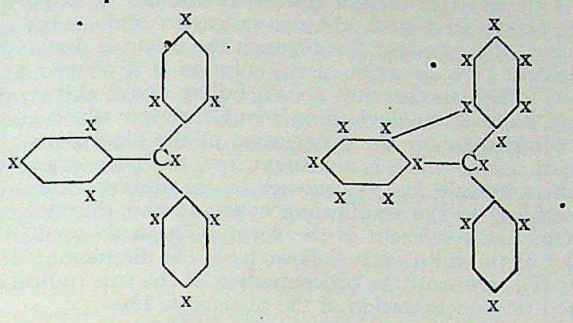
of resonating structures. A double bond appears between two rings in some cases.



We will now summarize the above discussion and then proceed to indicate the way in which our conclusions aid in understanding the peculiarities of five-membered rings referred to in the third paragraph of this paper. Our conclusions based upon evidence given above is that two phenyl groups attached to a single carbon differ in two important respects from the fluoryl group. In the first place the removal of two hydrogen atoms and the connection of the rings by a single bond produces a more compact group and reduces the probability of steric hindrance. In the second place the formation of a five-membered ring makes possible an increase in the stability of the group on account of the resonance resulting from an odd electron (or resulting from a free pair of electrons) taking up every position in each ring.[11]

As we will see, sometimes one and sometimes both factors are important in a given chemical reaction.

Taking up first a case where only steric hindrance is involved we consider the oxygenation of hexaphenylethane and diphenyldifluoryl. Resonance does not concern us in this reaction since the initial and final products are hydrocarbons involving no special resonance of the type found in free radicals. We would expect steric hindrance to weaken the carbon–carbon bond in the former compound more than in the latter and thus to cause more heat to be liberated in the former case than in the latter. The difference of 15 kcal. experimentally measured by Cline is in accord with this explanation.

An illustration involving chiefly resonance and little steric hindrance is that of the ketyls discussed in this paper. One cannot say with certainty that steric hindrance is of no importance but one would hardly expect it to be of great importance on account of the relatively small size of the O–Na group as compared with a benzene ring. If then resonance is of primary importance in determining the behavior of ketyls we would expect that the ketyl from benzophenone would dissociate slightly as compared with the ketyl derived from fluorenone. Experimentally, we have shown in this paper that this is the case, sodium fluorenone being entirely dissociated under conditions which give rise to only partial dissociation of sodium benzophenone.

Turning now to a case in which both factors are of significance we find an excellent illustration in the dissociation of hexaphenylethane and diphenyldifluoryl. We might expect that the greater steric hindrance in hexaphenylethane promoting dissociation would be offset by the greater resonance in phenylfluoryl. Actually we find that these two factors nearly compensate each other so that experimentally the difference is only about 8 kcal. as estimated by Conant,[6] leading to greater dissociation of hexaphenylethane. Subtracting this from the 15 kcal. difference for the heat of oxygenation gives 7 kcal. for the excess resonance of two phenylfluoryl radicals as compared with two triphenylmethyl radicals, or 3.5 kcal. for the difference between phenylfluoryl and triphenylmethyl.

A similar situation is to be found in the addition of sodium to hexaphenylethane and to diphenyldifluoryl. Here we might expect steric hindrance to favor the addition to the former compound and resonance to favor addition to the latter. Since steric hindrance is found to be more important than resonance in the case of simple dissociation, we might expect the same to be the case with the addition of sodium. Experimentally, Keevil[7] has shown that sodium adds more readily to the diphenyldifluoryl than to hexaphenylethane. This fact may be accounted for by bringing in the additional fact that in diethyl ether solution the sodium compounds are not dissociated into ions but exist as ion pairs. This indicates that the smaller ion will give rise to the more stable ion pair and hence sodium will react more readily with diphenyldifluoryl than with hexaphenylethane.[12]

Another way of expressing the same idea is to say that we are dealing here with a situation analogous to that described under hydrogenation. In the case of hydrogenation only steric hindrance was involved as no free radical was produced as a final product. Here, in the addition of sodium, we may be justified in saying that steric hindrance is of little if any significance compared with resonance which occurs in the negative ion. The reason for saying that steric hindrance may be of little or no importance here is that, although present in one molecule of the reactant it is also present in both molecules of the product and hence tends to cancel out.

Finally, a very striking example from the work of Conant and Wheland is to be found in the relative acid strengths of triphenylmethane and phenylfluorene. The essential reaction involved in those experiments is the substitution of a

(11) Resonance in an ion is to be treated in the same way as in the corresponding free radical as pointed out by Wheland, *J. Chem. Phys.*, 2, 479 (1934).

(12) One might expect to find a sodium to carbon distance which would determine the stability of the ion pair, but Kraus and Hawes have shown, THIS JOURNAL, 55, 2784 (1933), that this is not the case. Rather, it is the total size of the ion which determines the value of "a" of closest approach and hence the stability of the ion pair.

proton by an alkali metal ion. The inference based upon the foregoing discussion would be that steric hindrance would not be a factor in the acid where the hydrogen atom is localized on a single carbon but that it would be a factor in the ion pair formed as the product of the reaction and that it would operate in the same direction as resonance rather than against it as in one of the earlier examples. Thus we would expect from both of these factors that phenylfluoryl would behave as though it were a stronger acid than triphenylmethane. Experimentally, Conant and Wheland[4] have shown that it behaves as though it were stronger by a factor of 10^7. A revision of this value by McEwen[5] in extending the work of Conant and Wheland increases the value from 10^7 to 10^{12}. This would correspond to a free energy value of about 15 kcal. This is in the direction one would expect from resonance but larger than would be predicted by resonance alone. At least part of this difference is doubtless due to smaller steric hindrance in the ion pair.

Experimental

Experimental precautions have been discussed in previous papers of this series dealing with similar procedures. A high vacuum technique was employed to avoid contamination with air or water vapor. The ketones were purified, the ethyl ether distilled from a solution of sodium fluorenone and decomposition of ether avoided during sealing off from the vacuum line by condensing the ether vapor. The solution of the ketyl is found to be quite stable, a sample having been kept for more than a year without appreciable decomposition or change in color; sunlight and temperatures of 40° produce no appreciable decomposition. Nevertheless we sometimes observed a decrease in the optical density of solutions during rather short intervals of time. We attribute this to small amounts of water liberated from the rather large surface of glass exposed to the solution during the dilution experiments.

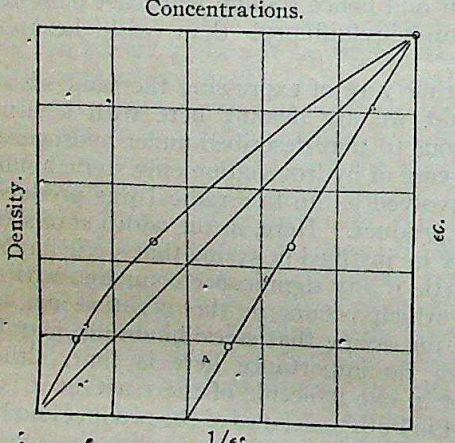

Fig. 2.—Deviations from Beer's law as shown by sodium benzophenone. Top curve is calculated from the equilibrium constant and the value of ϵ_∞. The points are experimental, only two of the three being required to evaluate K and ϵ_∞. Middle curve is what one would expect from Beer's law. Bottom curve is drawn through the experimental points, illustrating the way in which deviations from Beer's law can be expressed by a straight line. The triangles are for another series of measurements made on an older solution.

Typical experimental results on sodium benzophenone are shown in Fig. 2, the concentration scale being arbitrary. The straight line through the origin is drawn in to illustrate the behavior of the solution if it obeyed Beer's law. The experimental points, falling above this straight line, indicate the deviations from Beer's law which may be accounted for by the dissociation of the pinacolate. The third curve, which is a straight line, has been drawn to a different scale for convenience in calculating values proportional to the equilibrium constant and the molecular extinction coefficient of the ketyl. The scale used in the plot of the third curve follows from the discussion: If we let (R) represent the concentration of the free radical and (R_2) the concentration of the pinacolate then

$$K = (R)^2/(R_2) = \frac{2(\epsilon/\epsilon_\infty)^2 C}{1 - (\epsilon/\epsilon_\infty)}$$

in which C is the mole fraction of solute expressed as ketyl, ϵ_∞ is the molecular extinction coefficient of the pure free radical and ϵ is the apparent molecular extinction coefficient defined by the expression $\log I_0/I = \epsilon Cl$. I_0/I is the ratio of light intensities and l is the length of the cell expressed in centimeters. The ratio ϵ/ϵ_∞ gives the fraction of the material dissociated. The above expression for the equilibrium constant may be transformed into the more convenient expression

$$\frac{1}{\epsilon} = \frac{2\epsilon C}{\epsilon_\infty 2K} + \frac{1}{\epsilon_\infty}$$

which is the equation of a straight line if we plot the reciprocal of the apparent molecular extinction coefficient against the product of the molecular extinction coefficient and the concentration. The intercept gives the molecular extinction coefficient at infinite dilution and the slope gives, in combination with the intercept, the equilibrium constant. Actually, before we analyzed the solutions to determine the concentration we plotted the concentration, in arbitrary units, divided by the optical density against the optical density. The final analysis, giving the concentration, gives the appropriate factor for converting the equilibrium constant and the molecular extinction coefficient into absolute values.

The analysis of the solution was accomplished by extracting the ether solution with small portions of 0.5 N hydrochloric acid. This hydrolyzes the ketyl and gives an aqueous solution of sodium chloride. The method of McCance and Shipp[13] permits the determination of quantities of sodium of the order of 0.05 mg. Since we are dealing with very dilute solutions it seemed best to use a method capable of handling quantities of this order of magnitude. Subsequent experiments have shown our solutions to contain considerably larger quantities of sodium which would have made possible a more precise determination of the concentration. The optical density changes with time, but by standardizing the procedure and taking a measurement with the spectrophotometer one hour after the formation of the red color, results were obtained which indicate a possible accuracy of perhaps one or two per cent.

The results obtained with benzophenone, using only those series which give evidence by the straightness of the $1/\epsilon$ against ϵC plot that hydrolysis was unimportant, give values of K of $4 \pm 1 \times 10^{-5}$ and for ϵ_∞ of $7 \pm 2 \times 10^3$ when concentrations are converted into moles per liter. The calculation of the heat of the reaction may be carried out in a variety of ways, the most obvious of which is to calculate from dilutions at two temperatures two values of the equilibrium constant. This method gives results not too far out of line with the value reported below but probably is not as good a procedure as to take a solution of a given concentration quickly from the higher to the lower temperature. The possibility of reaction with water on the glass is minimized by this method and probably the results are more reliable. If one takes the change in

Digitized by Arya Samaj Foundation Chennai and eGangotri

optical density and calculates a value for the heat of the reaction assuming the associated material to be constant one obtains as a minimum value for the heat the quantity 3.3 ± 0.5 kcal. A still better method is to correct for the change in the concentration of the undissociated material using values for the equilibrium constant obtained from dilution experiments. This does not raise the value very much but leads us to report 4 ± 1 kcal. as the heat of the reaction. This value may be compared with 10 kcal. found by Ziegler and Ewald for the dissociation of hexaphenylethane.

Preliminary measurements on the sodium derivative of di-biphenyl ketone at 24 and 0° give no evidence of association at the lower temperature.

[a] Actual concentration 1.21 × 10^{-4} expressed as the mole fraction of the ketyl. Wave length 640 mμ. Cell length 1.4668 cm. [b] Values given in parentheses under runs 4 and 5 at −112 as "corrected" take into account the contraction of the ether on cooling from 20 to −112°. The increase in the corrected value over that found at 20° would suggest dissociation but this is not borne out by the dilution experiments. The difference is discussed in the text.

The data of Bent and Keevil[14] have been recalculated in order to obtain the value for the free energy of addition of sodium to benzophenone. As pointed out by them the existence of an appreciable amount of the ketyl in the form of the pinacolate will reduce the calculated value for the addition of sodium to the free radical. The change which we have found is scarcely of importance, the value being changed from −22.4 to −22.1 kcal., which is little more than the experimental error in the determination of Bent and Keevil.

Summary

The ketyl formed by treatment of fluorenone with sodium amalgam gives no evidence of associating to a pinacolate at either room temperature or −112°.

The shape of the absorption curve for sodium fluorenone is a function of temperature which rules out as a general procedure the using of a molecular extinction coefficient at one temperature in calculating with precision the fraction dissociated at another temperature.

Benzophenone forms a ketyl with sodium in ether solution which is associated at room temperature to a large extent to form a pinacolate. The dissociation constant for this reaction is found to be 4 ± 1 × 10^{-5} at 20°, concentrations being expressed as mole fractions.

Sodium benzophenone in ether solution has an apparent molecular extinction coefficient which decreases rapidly as the temperature is lowered. Combining such data with dilution experiments at 0° enables one to calculate a temperature coefficient for the dissociation constant and a corresponding heat of dissociation of 4 ± 1 kcal.

[a] The optical density was measured at a wave length of 630 mμ. The equilibrium constant is expressed as a mole fraction. The cell length in runs 1 and 2 was 0.6689 cm. and in run 3 was 1.4669 cm. [b] The concentration of the ketyl at the beginning of a run is based upon an analysis of the solution for sodium. The accuracy of the determination of sodium involves an error of probably not more than 5%. However, decomposition of ketyl before the first measurement of optical density and calculations of concentrations for some of the later runs from the optical density may involve an error in concentration of as much as 30%. Inasmuch as the value for the equilibrium constant is directly proportional to the value assumed for the concentration a corresponding error is present in the equilibrium constant. The relative values of the concentration, however, are known with an error of probably not more than 1%.

Photochemical Studies. XXXVII. Some Tests of Mechanism for the Photochemical Decomposition of Acetone

BY J. J. HOWLAND, JR.,[1] AND W. ALBERT NOYES, JR.

A study of the photochemical decomposition of acetone vapor was published several years ago.[2] Two important questions remain to be answered: (1) the importance of the decomposition of acetyl radical into methyl radical and carbon monoxide; (2) the homogeneity of this decomposition. Anderson and Rollefson[3] and Feldman, Ricci and Burton[4] as well as work in this Laboratory[5] have thrown much light on these important questions.

Spence and Wild[6] have published a discussion of earlier work[7] and have presented some new data. Comparisons were made between results obtained under different conditions, and some deductions made which may not have been justified.

It was claimed that the Herr and Noyes mechanism[2] explained the results only over a very narrow range of low intensities. The work herein presented was performed in an endeavor to answer some of the questions raised in the article of Spence and Wild.[6]

Herr and Noyes assumed a primary dissociation at all wave lengths whereas Spence and Wild assumed a primary dissociation only in the "continuum" below 2900 Å. The following steps have been proposed for the mechanism

(1)	$CH_3COCH_3 + h\nu = CH_3CO + CH_3$	ϕI_a
(2)	$CH_3CO = CH_3 + CO$	$b\phi I_a$
(3)	$CH_3CO = CH_3 + CO$	$k_2\ (CH_3CO)$
(4)	$2CH_3 + M = C_2H_6 + M$	$k_a\ (CH_3)^2\ (M)$
	walls	
(5)	$CH_3CO = 1/2(CH_3CO)_2$	$k_3\ (CH_3CO)/P$
(6)	$2CH_3CO + M = (CH_3CO)_2 + M$	$k_b\ (CH_3CO)^2\ (M)$
(7)	$2CH_3CO = (CH_3CO)_2$	$k_4\ (CH_3CO)^2$
(8)	$CH_3 + CH_3CO + M = CH_3COCH_3 + M$	$k_c\ (CH_3)(CH_3CO)\ (M)$
(9)	$CH_3CO + CH_3 = CH_3COCH_3$	$k_5\ (CH_3CO)(CH_3)$
(10)	$CH_3 + CH_3CO = C_2H_6 + CO$	$k_d\ (CH_3)(CH_3CO)$
(11)	$CH_3CO + M = CH_3 + CO + M$	$k_e\ (CH_3CO)\ (M)$
	walls	
(12)	$CH_3 = 1/2\ C_2H_6$	$k_6\ (CH_3)/P$

The Spence and Wild mechanism is based on equations 1, 4, 6, 8, 10 and 11 whereas the mechanism proposed by Herr and Noyes is based on 1, 2, 3, 5, 7, 9, and 12, although reaction 7 was not considered in deriving the rate equations.

Spence and Wild emphasize the following points: (1) At low intensities the ratio ethane/carbon monoxide in the reaction products approaches unity with increasing acetone pressure whereas in their experiments at very high intensities they found the ratio to rise with pressure. These effects are predicted if the exponents y and z are less than 0.5. (2) The Herr and Noyes mechanism does not account for the rise in the above ratio with increasing intensity. This can be explained by the introduction of reaction 6 or reaction 7, a suggestion made by Herr and Noyes.[2]

There is no evidence that reaction 10 is important under any conditions. In any case it is unnecessary since 3 has been clearly demonstrated.[3,4] Acetone was photolyzed in a flow system in which methyl radicals were removed by a lead mirror, and the remaining acetyl radicals passed through a section warmed to 45°.[4] New methyl radicals were produced as shown by the formation of $Pb(CH_3)_4$ at a second lead deposit.[4]

For wave lengths above 3000 Å. (the so-called "banded" region) Spence and Wild have proposed an elaborate scheme involving two kinds of excited acetone molecules

(13)	$CH_3COCH_3 + h\nu = CH_3COCH_3^*$	
(14)	$CH_3COCH_3^* = CH_3CO + CH_3$	$\tau = 10^{-8}$ sec.
(15)	$CH_3COCH_3^* + M = CH_3COCH_3^{**} + M$	
(16)	$CH_3COCH_3^{**} = CH_3COCH_3$	
(17)	$CH_3COCH_3^{**} = C_2H_6 + CO$	$\tau = 10^{-2}$ sec.
	walls	
(18)	$CH_3COCH_3^{**} = C_2H_6 + CO$	

This mechanism was based on the fact that apparent reduction in the mean distance from the positions of the absorbed quanta to the walls of the vessel causes a decrease in the ethane/carbon monoxide ratio. The authors also felt that results of the full mercury arc lamp could not be explained by adding the effects of the separate spectral regions. Thus the observed ratio rose to a maximum of 2 and then fell to 1.5 with increasing intensity whereas in the "continuum" alone it rose steadily toward a value of 2.5.

Spence and Wild also point out that the data of Herr and Noyes for 3130 Å. show no decrease in quantum yield of acetone disappearance with increasing intensity as was found to be true at 2537 Å. They conclude that a mechanism not involving free radicals was indicated for the "banded" region.

Spence and Wild believe that reaction 14 and the free radical reactions which follow are important only at low pressures whereas at higher pressures 15 predominates and ethane and carbon

monoxide would be formed by 17 or 18. These last two reactions are theoretically improbable.[8]

There is no sound basis for believing that there is a difference in primary process as the wave length is changed. The so-called "continuum" below 3000 Å. and the diffuseness of the bands above 3000 Å. may be explained in the first case as a great deal of overlapping of structure[9] and in the second case possibly by predissociation.[10]

A major objection to the mechanism embodied in reactions 13 to 18 is its inability to explain the rise of the quantum yields to unity as the temperature is raised to 100°.[2] Only a small rise of absorption coefficient is observed experimentally up to this temperature and hence pronounced absorption from higher levels in the ground state can scarcely be the correct explanation.

The present paper presents results designed to test the various mechanisms more thoroughly since the quantum yields as well as the ratio of the gaseous products have been determined. At short wave lengths and high intensities the mechanism of Spence and Wild predicts a rise in biacetyl yield and a fall of carbon monoxide yield. For long wave lengths their mechanism predicts a decrease in biacetyl with decrease in cell size at constant intensity. Also a smaller cell should cause the yield of acetone decomposed to rise. The mechanism of Herr and Noyes leads to the opposite conclusion in the first two instances and to a rise in acetone yield for a smaller cell at all wave lengths. Also the mechanism of Herr and Noyes leads to little change with wave length except that b in equation 2 should increase with decrease in wave length, leading to higher yields of everything except biacetyl.

Experimental Procedure

The apparatus used was nearly identical with that of previous work in this Laboratory[2,5] using the Manning[10] gas analysis technique. Merck reagent acetone was redistilled three times, dried with anhydrous calcium sulfate and then distilled at room temperature into a blackened trap which was kept at −78°. A Hanovia Uviarc mercury lamp was the source of radiation. Filters of cobalt and nickel sulfates and of potassium biphthalate gave very pure 3130 Å. light. With this light the absorption by acetone obeyed Beer's law within the experimental error of 1–2%. For the shorter wave lengths, the biphthalate filter was replaced by one of chlorine gas. The latter combination transmitted all the lines from 2320 to 2804 Å. in significant intensities.

A series of photographs of the spectrum of the mercury arc were made with and without the filters to determine their transmission for the various lines. Lines on the plates were matched at densities where the reciprocity law is approximately valid. Then from the known distribution of the intensity throughout the lines of the arc[11] and the absorption coefficients of acetone,[12] the percentage absorption was calculated at both 57 and 160 mm. pressure. The calculated percentages agreed with those measured by the photoelectric cell within 1%. The calculations also showed that the 2537 and 2654 Å. lines account for 68% of the incident light, and 83% of it is between 2480 and 2700 Å. It will be referred to as 25–2700 Å.

The polychromatic nature of this light discredits any conclusion drawn from the apparent variations in the quantum yields with pressure or cell size. Beer's law failed even for small percentages of absorption. This filter system was also used by Spence and Wild and was the only combination which made possible the high intensities at which they found the pressure effect reversal. Light intensity was measured by a plane quartz window photoelectric cell which was calibrated both by means of a uranyl oxalate actinometer[13] and by runs on acetone at 100° where the quantum yields are believed to be unity.[2] The observed light absorption was corrected for reflections back into the reaction vessel from its rear window and from the window of the photoelectric cell. Since for light of 3130 Å. each window reflects 7.3% of the light incident upon it, and the transmission of the 1.5-mm. rear window is about 0.88,[14] the true absorption is

$$I_a = I_a' + 0.129 I_t I_a'/I_0$$

where I_0 is the intensity at the rear of the front window, I_t is the intensity at the front of the rear window, and $I_a' = I_0 - I_t$. At 25–2700 Å.

$$I_a = I_a' + 0.138 I_t I_a'/I_0$$

The correction for loss at the rear window was incorporated into the photoelectric cell calibration.

One of the cylindrical quartz vessels was 2.35 cm. inside diameter × 20 cm. long; the second was 2.2 cm. × 1.00 cm. Their respective volumes were 87 cc. and 3.80 cc.

Assuming that carbon monoxide, ethane, and biacetyl are the only products, the yields of acetone decomposed were calculated by the relation

$$N_{CH_3COCH_3} = 2N_{C_2H_6} - N_{CO}$$

and those of biacetyl formed by

$$N_{(CH_3CO)_2} = N_{C_2H_6} - N_{CO}$$

Results and Discussion

In order to make comparisons of the two reaction cells, some data are given in the form of tables. Other results are shown graphically only. Since the variation of quantum yields and of C_2H_6/CO ratio with pressure at 3130 Å. are nearly identical with those of the earlier work at about a five-fold lower intensity, they are not plotted here.

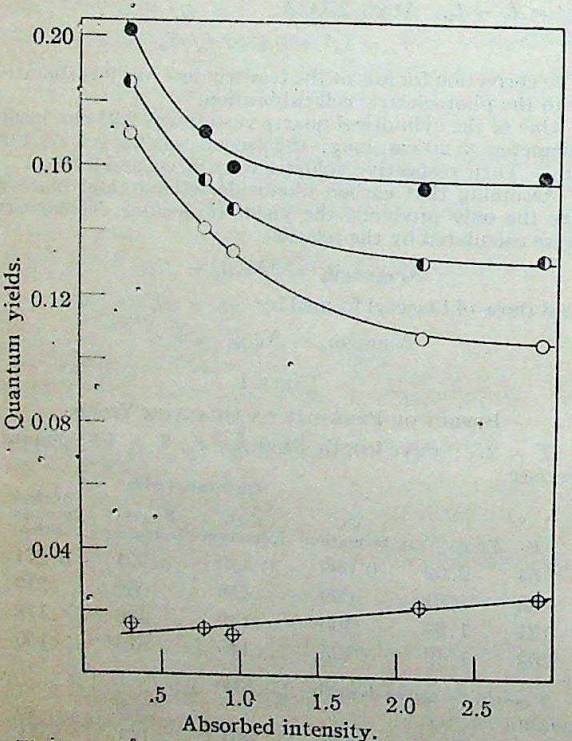

Fig. 1.—Effect of intensity on quantum yields: pressure, 120 mm.; wave length, 3130 Å.; O, carbon monoxide; ◐, ethane; -⊕-, biacetyl; ●, acetone.

It is apparent that the quantum yield of acetone decomposition does fall off with increasing intensity even at 3130 Å. A higher pressure was selected than in the earlier[2] runs in order that the reactions of excited acetone molecules should have predominated if the Spence and Wild mechanism were correct.

The experiments using the smaller reaction cell and 3130 Å. show the reverse of the effect previously reported.[6] In that comparison, however, use was made of three different sets of data, two by the authors, four years apart, and with different analytical methods, and the third by Herr and Noyes.[2] Unfortunately, the mean distance from points of absorption of quanta to the walls in the work of Herr and Noyes was taken as 1 cm., the estimate given by the authors.[2] To be consistent with the mean distances used for the other two vessels, the mean shortest distance of 0.4 cm. ($^1/_3$ of the radius) should lie between the 0.6 and the 0.25 cm. used for the other cells. In the data of Spence and Wild the rise in ethane/carbon monoxide ratio with this mean distance at constant intensity is only from 1.05 to 1.2. The results in the larger cells scatter badly, one value being 0.89.

Although the light intensity in the "continuum" was well into the range where the rise in C_2H_6/CO ratio was reported, the opposite effect was found. The older results for about the same light intensity are given in Table III. Their units of I_a are cc. × 10^5 of acetone decomposed/hr./cc. 100 of these units equals 12 × 10^{12} quanta/cc./sec. Their effect is not great except for the run at 32 mm.

TABLE III

RESULTS OF SPENCE AND WILD[5,6]

P, mm.	I_a	$N_{C_2H_6}/N_{CO}$
70	83.9	1.94
70	100.8	1.92
160	95.4	2.18
32	51.5	1.62
160	43.5	2.23

The drop in the yield of carbon monoxide with increasing pressure in the "continuum" favors the use of reaction (5). However, the apparent variation in quantum yields when using such polychromatic light should be viewed with suspicion. The combination of weaker absorption of acetone and greater sensitivity of the photoelectric cell at shorter wave lengths would be expected to cause an apparent drop in quantum yields with increased pressure (greater percentage absorption), since the increased absorption is actually less than measured and less than calculated by Beer's law.

The use of the smaller cell at 3130 Å. showed a slight increase in the yield of acetone decomposed as predicted by both mechanisms.

To attempt to explain satisfactorily results for an unfiltered arc is a nearly impossible and perhaps useless undertaking. Spence and Wild suggest that the fall in the C_2H_6/CO ratio with intensity increase at very high intensities is due to a reaction between excited acetone molecules resulting from absorption in the "banded" region and acetyl radicals produced by light of the shorter wave lengths.

(19) $CH_3COCH_3^* + CH_3CO = CH_3COCH_3 + CH_3 + CO$

They felt this to be necessary also because the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

ratio C_2H_6/CO was too much lower than for the case of "continuum" light only.

It should be pointed out that most of the drop in C_2H_6/CO ratio with increasing intensity occurs at intensities not attainable with filtered light. It is possible that the same effect would take place with "continuum" light of sufficiently high intensity.

The general conclusion from the present study is that there is no evidence which definitely indicates that the decomposition by light of 3130 Å. is anything but a free radical reaction, just as for shorter wave lengths. In the "continuum" region, either of the two mechanisms is satisfactory as far as its ability to explain the known facts is concerned. The scheme of Spence and Wild is more cumbersome in that it requires an additional step which can also be objected to on theoretical grounds. One test which might have decided between the two free radical mechanisms, the variation of the yield of CO with pressure at high intensity, was inconclusive because of the polychromatic nature of the light. The generally higher C_2H_6/CO ratios as a result of decreasing the reaction cell size, while not very pronounced, favor the use of a wall process for biacetyl formation as opposed to the supposition of pressure dependence for the decomposition of acetyl radical. One of those alternatives is sufficient to explain the general pressure effects.

Summary

1. The quantum yield of acetone decomposition falls off with increasing intensity at 3130 Å. just as it does around 2500 Å.

2. With all other conditions and techniques held constant, a decrease in the reaction cell size causes a rise in the C_2H_6/CO ratio regardless of the choice of intensity, pressure, and wave length.

3. The reported increase in the C_2H_6/CO ratio with increasing pressure at high intensity was not confirmed. The reverse effect resulted for all intensities.

4. Our previously modified mechanism is found to be adequate for correlation of the definitely established facts. Particularly, the use of reactions of excited acetone molecules at 3130 Å. seems unnecessary.

The Ionization Constants of Very Weak Acids. Acetoxime, Methyl Ethyl and Diethyl Ketoximes

BY CECIL V. KING AND ALEXANDER P. MARION

Difficulty has always been encountered in determining the ionization constants of very weak acids or bases. The conductance method fails when ionization is so small that conductance of water and its normal impurities become comparatively large, and the interpretation of conductivity in buffered solutions is uncertain. Hydrogen or other electrode measurements are useful in special cases, but usually only with very careful planning and interpretation. Rate measurements in which hydrogen or hydroxyl ion concentrations are determined from their catalytic effect on a suitable reaction have been often used. This method is capable of considerable refinement, and while not as accurate in general as other methods for the ordinary weak electrolytes, may be the best available for exceedingly weak ones. In the past salt effects have generally been ignored or inadequately treated. The purpose of the present work was to develop a method for determining acid dissociation constants of the order of 10^{-12} to 10^{-13} as a function of ionic strength with a reasonable degree of precision.

The Method.—A solution of acetoxime, unless in exceptionally pure water, would have an indefinite hydrogen ion concentration because the ionization is so small. A reaction sufficiently sensitive to hydrogen ion to be used in buffered solutions would probably be sensitive to general acid catalysis. The best procedure in such a case is to add the weak acid to a solution of strong base, and measure the extent of neutralization by means of a reaction only moderately sensitive to hydroxyl ion. From the rates the "hydrolysis constant" of the salt may be calculated.

For this purpose the catalyzed decomposition of nitrosotriacetonamine was chosen. The reaction has been studied in some detail by Francis and his co-workers,[1] by Brönsted and King[2] and by Kilpatrick.[3] The hydroxyl ion determination was first standardized by using solutions of sodium hydroxide, with sodium chloride to make up the ionic strengths desired. The previous work indicates that anions of even exceedingly weak acids do not catalyze the reaction, and the present work confirms this. The assumption is also made that in the specific salt effect, differences due to chloride, hydroxyl and weak acid anions are negligible.

Experimental

Eastman Kodak nitrosotriacetonamine, acetoxime and methyl ethyl ketoxime were used without further treatment (samples of the oximes redistilled before use gave no appreciable difference in rate). Diethyl ketoxime was prepared from diethyl ketone and hydroxylamine as described by Scholl.[4] The product was distilled under reduced pressure several times and finally the portion boiling at 75° at 15 mm. was retained. Various samples prepared in this way gave good agreement.

Fresh stock solutions of the oximes were prepared frequently by direct weighing into a volumetric flask, followed by addition of carbon dioxide-free water. Carbonate-free sodium hydroxide, kept in paraffin-lined bottles, was used throughout. Reagent grade sodium chloride was used and either weighed directly for experiments or made into stock solutions.

The rates were measured in an apparatus similar to that previously described.[2] In each experiment 60 cc. of solution was used, with 66 mg. of nitrosotriacetonamine (0.006 *M*). The thermostat was maintained at 24.9°. The first order rate constants were mostly evaluated as described by Guggenheim,[5] either graphically or by the least squares method.

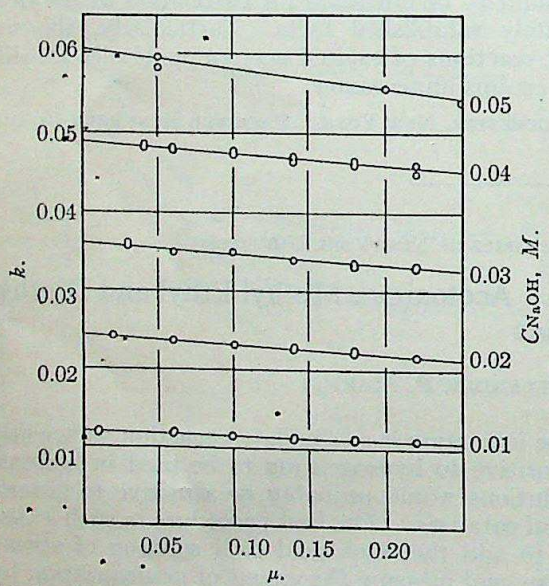

Fig. 1.—Salt effect (NaCl) in the catalytic decomposition of nitrosotriacetonamine.

The rate constants obtained in the standardization (*i. e.*, in solutions of sodium hydroxide and sodium chloride alone, $kt = 2.3 \log C_0/C$) are shown graphically in Fig. 1. The salt effect in this type of reaction is small and linear with ionic strength, and the straight lines represent the least square equations calculated from the experimental points

$$0.01\ M\ \text{NaOH}\quad k = 0.0120 - 0.0049\,\mu$$
$$.02\ M\ \text{NaOH}\quad k = .0243 - .0118\,\mu$$
$$.03\ M\ \text{NaOH}\quad k = .0360 - .0137\,\mu$$
$$.04\ M\ \text{NaOH}\quad k = .0488 - .0152\,\mu$$

The greatest deviation from these equations shown by any one experiment was 1.4%. Averaging the coefficients (divided by sodium hydroxide concentration) the general equation is obtained

$$k = (1.209 - 0.479\,\mu)C_{OH^-} \qquad (1)$$

which represents the rate satisfactorily in any solution used. The maximum deviation from the proceeding equations is 3% with 0.02 and 0.04 *M* sodium hydroxide at 0.22 ionic strength. In other solutions the divergence is 1% or less.

In Fig. 1 the straight line for 0.05 *M* sodium hydroxide represents equation (1) for this concentration, the circles a few check experiments made at a later date. In all succeeding work, equation (1) was used to calculate the hydroxyl ion concentration in any experiment.

The neutralization of a very weak acid by a strong base may be represented by the equation

$$HA + OH^- \rightleftarrows H_2O + A^-$$

The amount of hydroxyl ion which disappears may be taken as a measure of the amount of anion formed, and the unneutralized acid remaining can be found by difference. The "hydrolysis constant" of the salt (or its reciprocal) can then be calculated

$$1/K_h = K_{HA}/K_w = C_{A^-}/C_{OH^-}C_{HA} \qquad (2)$$

and if the water constant is known the dissociation constant K_{HA} follows. If K_{HA} is determined at various ionic strengths, suitable extrapolation will give K^0_{HA}, the true thermodynamic dissociation constant.

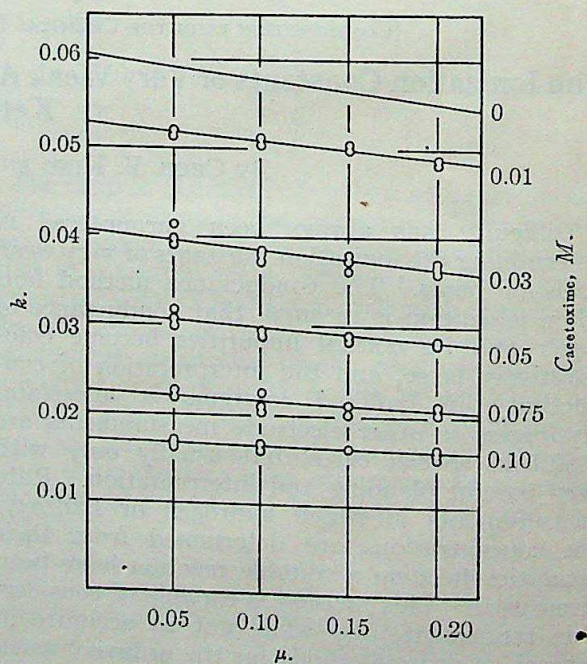

Fig. 2.—The effect of acetoxime and sodium chloride on the rate in 0.05 *M* sodium hydroxide.

The rate constants obtained for 0.05 *M* sodium hydroxide with various acetoxime concentrations are shown in Fig. 2. If dissociation constants are calculated from individual rate constants, the values vary widely—differences of 2% in rate constants lead to differences of approximately 20% in dissociation constants. In order to analyze the hundreds of experimental values obtained, each series was first plotted as in Fig. 2

(4) Scholl, *Ber.*, **21**, 509 (1888).

and since the salt effect is, within experimental error, linear, what seemed to be the best straight line was drawn through the points. A few values falling 3% or more from these lines were discarded and a linear equation was calculated, by the method of least squares, for each concentration. Later all results with 0.01 *M* oxime were discarded, since the small degree of neutralization leads to large errors in K_{HA}.

All the least square equations retained are given in Table I. From these values and equation (1), hydroxyl ion concentrations were calculated for ionic strengths 0, 0.05, 0.10, 0.15 and 0.20 (the first being, of course, a hypothetical value); and K_{HA}/K_w calculated from equation (2). The complete set of values for acetoxime and average values for the other oximes are given in Table II.

	.075	.0281 − .00600 μ

Although both K_{HA} and K_w vary exponentially with ionic strength, the ratio of the two shows only a small linear variation as is to be expected for weak electrolytes of the same valence type. Least square equations for average values of the ratio, valid at least to $\mu = 0.22$, are given in Table II.

TABLE II

THE RATIO K_{HA}/K_w FOR ACETOXIME AT VARIOUS IONIC STRENGTHS

C_{NaOH}	C_{oxime}	K_{HA}/K_w 0	0.05	0.10	0.15	0.20
0.05	0.03	38.3	38.7	39.4	40.2	40.9
	.05	35.6	35.6	37.2	38.1	39.1
	.075	37.7	38.0	38.6	39.1	39.7
	.10	40.5	39.5	38.9	38.1	37.4
0.03	.03	38.5	38.2	38.3	38.2	38.1
	.05	36.3	36.3	36.8	37.1	37.5
	.075	38.3	38.2	38.7	38.9	39.2
	.10	39.4	39.1	39.2	39.1	39.1
0.01	.03	40.3	40.9	41.9	42.9	44.0
	.05	39.7	39.8	40.3	40.7	41.2
	.075	39.4	39.3	39.5	39.6	39.8
	.10	38.0	38.8	40.2	41.4	42.9
Average, acetoxime		38.5	38.5	39.1	39.5	39.9
	$K_{HA} = K_w (38.3 + 7.6\,\mu)$					
Methyl ethyl		35.6	35.7	36.4	37.0	37.7
	$K_{HA} = K_w (35.4 + 11.0\,\mu)$					
Diethyl		25.4	25.9	26.5	27.0	27.7
	$K_{HA} = K_w (25.4 + 11.4\,\mu)$					

Rather than express K_{HA} as a semi-empirical function of ionic strength it seems more useful to calculate values of K_w from the data of Harned and Mannweiler[6] for sodium chloride solutions and tabulate corresponding values of K_{HA}. This is done in Table III. Although the values of K_w are given in terms of molalities ($m_H m_{OH}$) the deviation from molarities is very small up to 0.22 ionic strength.

TABLE III

IONIZATION CONSTANTS OF THE THREE KETOXIMES AS A FUNCTION OF IONIC STRENGTH AT 24.9°

μ	$K_w \times 10^{14}$	$K_{HA} \times 10^{13}$ Acetoxime	Methyl ethyl ketoxime	Diethyl ketoxime
0	1.00	3.83	3.54	2.54
0.01	1.22	4.68	4.33	3.11
.05	1.48	5.72	5.32	3.84
.10	1.63	6.37	5.95	4.33
.15	1.73	6.82	6.41	4.69
.20	1.80	7.17	6.77	4.98

No previous determinations of the ionization constants of methyl ethyl or diethyl ketoximes or of the "hydrolysis constants" of their salts were found in the literature. For acetoxime the value 6.0×10^{-13} at 25° has been cited by Scudder[7] based on the measurements by Lundén[8] of the

(6) Harned and Mannweiler, THIS JOURNAL, **57**, 1873 (1935).

rate of hydrolysis of ethyl acetate in solutions of barium hydroxide partially neutralized by the oxime. This agrees with our value at $\mu \sim 0.075$ but is based on $K_w = 1 \times 10^{-14}$ which is correct only at $\mu = 0$.

Summary

The rate of decomposition of nitrosotriacetonamine, catalyzed by hydroxyl ion, has been measured as a function of ionic strength at 24.9°, up to $C_{OH^-} = 0.05$ and $\mu = 0.22$ and may be expressed in the equation

$$k = (1.209 + 0.479\ \mu)\ C_{OH^-}$$

Using this catalytic reaction to measure hydroxyl ion concentration in solutions of sodium hydroxide partially neutralized by acetoxime, methyl ethyl and diethyl ketoximes, the acid dissociation constants of these oximes have been determined as a function of ionic strength.

The Ternary System Silver Bromate–Sodium Bromate–Water

BY JOHN E. RICCI AND JACK J. ALESHNICK*

Introduction.—The formation of a compound or of a solid solution of silver bromate and sodium bromate from aqueous solutions of the salts came to be suspected from certain difficulties encountered in attempts to determine bromate ion in the presence of sodium ion, using silver nitrate as precipitant. Estimated gravimetrically the precipitate was always too light. Volumetric determination of the excess of silver ion in the filtrate by the Volhard method revealed the same error, in that too much silver ion was found unprecipitated. These analytical errors appeared regularly and despite care in the original precipitation of the bromate ion with silver nitrate.

The equilibrium relations at room temperature in the ternary system consisting of silver bromate, sodium bromate and water were therefore investigated. The isotherm at 25° shows the formation of a 1:1 double salt capable of forming continuous solid solutions with silver bromate. The salts actually form two solid solutions: sodium bromate containing up to about 3% of silver bromate, and silver bromate containing up to 39.0%, a limit corresponding to the compound $AgBrO_3 \cdot NaBrO_3$.

The consequent contamination (which is of an equilibrium nature and therefore unavoidable) of silver bromate with sodium bromate whenever the silver salt is precipitated from solution containing sodium ion, and especially in the presence also of excess of bromate ion, not only explains the above-mentioned analytical difficulties in the attempted determination of bromate by precipitation as silver bromate, but also accounts, presumably, for the difficulty experienced in the preparation of pure silver bromate.[1-4] This difficulty is obvious from the great variation in the values of the aqueous solubility of the salt reported in the literature. In fact, even the C. P. grade of silver bromate used in the present experiments was found to contain about 1.8% of sodium bromate.

Such behavior on the part of silver bromate appears important not only in connection with possible applications of silver bromate in analytical procedures, but also because of its frequent use in experimental tests of theoretical principles involving solutions of electrolytes.[1-7]

Experimental Procedure

The solubility measurements were made by methods already described for similar determinations. The ternary complexes were made up by weight, using distilled water, C. P. sodium bromate and C. P. silver bromate. The sodium bromate was found to be of satisfactory purity (100.0 ± 0.1%) by iodometric titration using standard thiosulfate. The silver bromate was analyzed in several ways: (1) after reduction with sodium nitrite in the presence of nitric acid and of a small excess of sodium bromide, the precipitate of silver bromide was weighed and was found to correspond to 98.4% silver bromate. (2) After reduction with sulfur dioxide in the presence of nitric and hydrochloric acids, thus precipitating all the silver as silver bromide and chloride, the filtrate was evaporated, finally with sulfuric acid, and weighed, after recrystallization, as sodium sulfate; the sodium was evident in this residue, from ordinary flame tests. The result showed about 1.8% sodium bromate. (3) After reduction with sodium nitrite in the presence of nitric acid and of a small excess of silver nitrate, the precipitate of silver bromide was weighed, and, on the assumption that the original sample consisted of silver and sodium bromates, a purity of 98.0% silver bromate was calculated. These analyses were all done in duplicate and with blank corrections for reagents and apparatus. A value of 98.2% silver bromate and 1.8% sodium bromate was therefore assumed in calculating the compositions of ternary complexes prepared from the C. P. silver bromate.

It must be pointed out that these quantitative analyses of the silver bromate, with consequent correction of the compositions of the synthetic ternary complexes, were performed after a preliminary study of the ternary isotherm had indicated first of all the extensive formation of solid solution between the two salts, and, second, from certain consistent deviations of the tie-lines from the stoichiometric composition of the 1:1 compound, the probability of the presence of a definite amount of sodium bromate in the supposedly C. P. silver bromate.

The solubilities of "pure" silver bromate reported below were determined on samples of this C. P. salt which were repeatedly washed with considerable quantities of water. As may be seen from the ternary diagram, however, such a process of purification would be slow and incomplete. A purity of about 99.7% was finally thus attained, but it is evident that great accuracy cannot be claimed for these solubilities. The ternary diagram, however, and the reported relations of the two salts involved, are independent of the exact solubility of pure silver bromate, the ternary measurements possessing actually a very high degree of accuracy. They involve simply the weighing operations of

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

preparing the original complexes, and the sampling and analysis of the filtered liquid solutions at equilibrium. Because of the high concentration of bromate ion in these solutions, the silver ion concentration was so small as to be not even detectable in all but the last one or two complexes in Table I (at 25°). In these the silver bromate content was determined gravimetrically as silver bromide after reduction with sodium nitrite. In all other cases, it was sufficient simply to evaporate the solution to dryness and to assume the residue to be sodium bromate.

The composition of the solid phase was calculated by algebraic extrapolation of the tie-lines joining the composition of the saturated liquid solution with that of the total original complex.[8] Attainment of equilibrium was proved in almost all cases by repeated analysis of the solution after further stirring. The complexes were stirred for periods of two to eight weeks. The densities were determined by using calibrated pipets for the withdrawal of samples to be weighed for analysis.

Results

The results are presented in Table I, which includes the complete 25° isotherm and some data at 50 and 5°, and in Fig. 1, the usual graphical representation of the 25° isotherm. The compositions in Table I are given in terms of weight per cent.

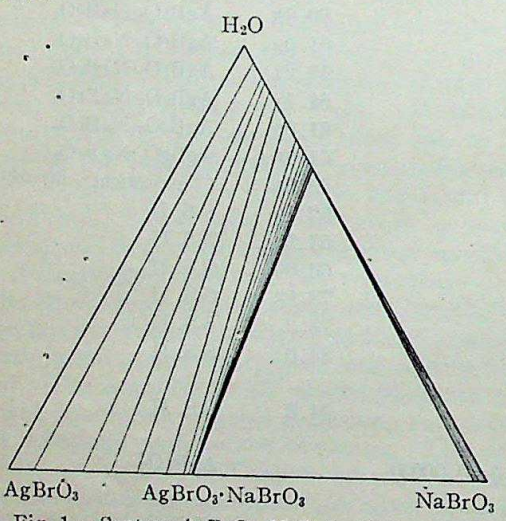

Fig. 1.—System $AgBrO_3$–$NaBrO_3$–H_2O at 25°.

The determinations at 25° show first of all a variable solid phase based on sodium bromate and containing up to 2.5–3.0% of silver bromate. This is seen in the first seven points, in which the liquid and solid compositions (the latter as determined by algebraic extrapolation) vary simultaneously and concomitantly. When this first solid solution (S.S.I.) reaches its limiting composition, a second solid phase evidently appears, and the liquid solution becomes isothermally invariant; the composition of this liquid solution, averaged from a great number of determinations, is 27.97 (±0.02) % sodium bromate, the percentage of silver bromate being analytically zero; its density is 1.260 (±0.001). The second solid is a saturated solid solution of the two salts containing, by extrapolation, 60.95 (±0.17)% silver bromate. This at any rate is the evidently constant composition of the solid in equilibrium with liquids ranging from 27.97 to about 22% sodium bromate, where, without the appearance of any break in the solubility curve, the solid composition begins to vary, gradually and continuously, increasing in silver bromate content until the composition of the pure salt is reached.

The second branch of the solubility curve therefore represents liquid solutions saturated with a second solid solution (S.S. II) starting at pure silver bromate, and whose limiting binary composition can be fixed very precisely because of the sharp convergence of the tie-lines at the binary limit. This sharp convergence indicates the existence of a definite compound, and the observed composition (by extrapolation of tie-lines) agrees very well with that theoretically required for the 1:1 compound, $AgBrO_3 \cdot NaBrO_3$, namely, 60.98% silver bromate.

Only a few determinations were made at 50°, so chosen as to verify the same general behavior. The isothermally invariant solution contains 35.24% sodium bromate as compared with 35.64%, the solubility of pure sodium bromate at this temperature. Since the relationship of these two points is the same as that of the corresponding points at 25°, it may be inferred that here too one of the solid phases is a solid solution of some small amount of silver bromate in sodium bromate. The second solid phase, as shown by the extrapolations, is again the compound, $AgBrO_3 \cdot NaBrO_3$, representing the limit of a solid solution presumably extending to pure silver bromate.

The nature of the limit of this second solid solution as a definite chemical compound, $AgBrO_3 \cdot NaBrO_3$, is of course corroborated by the constancy of the limiting composition at the two temperatures, 25 and 50°.

At 5° only the points of the isotherm have been determined; but the relation of the invariant point to the solubility of sodium bromate is still the same, indicating the probability of the same reaction and relationship between the salts at this as at the higher temperatures studied.

Discussion

The conclusion from this equilibrium study is that silver bromate precipitated in the presence of sodium ion and particularly in the presence also of excess of bromate ion, must be contaminated with sodium bromate. Mere recrystallization or digestion in water cannot be expected to purify it "completely" or analytically except through repeated and prolonged treatments. It may be suggested that this effect of sodium bromate is probably the reason for the disagreement in the published values for the solubility of this salt, and for the difficulties experienced by careful workers in attempting to obtain samples of constant and reproducible solubility. Thus, in a recent article on the silver–ammine ions, Vosburgh and McClure[4] state that their two different samples of the salt "gave appreciably different solubilities

(8) Hill and Ricci, THIS JOURNAL, 53, 4305 (1931).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

in water," and they do not consider these solubilities worth reporting.

The solubility here reported, of 0.204% at 25°, is not claimed to be final and accurate, and is to be compared with the following literature values (recalculated into units of weight per cent.)

Longi (1883)[9]	0.166 at 25°
Noyes (1890)[5]	.192 at 24.5°
Böttger (1903)[10]	.159 at 25°
Whitby (1910)[11]	.171 at 27°
Hill (1917)[1]	.195 at 25°
Reedy (1921)[2]	.196 at 25°
Dalton, Pomeroy and Weymouth (1924)[3]	.189–0.191 at 25°
Owen (1933)[6]	.192 at 25°
Neuman (1934)[7]	.192 at 25°

The highest values reported are those of Hill and of Reedy. The latter apparently took the greatest pains in purifying the salt by recrystallization. The present investigation shows that the presence of even small amounts of sodium bromate reduces considerably the solubility of silver bromate.

Reedy found that the purity of his silver bromate tended to be low, 99.6 to 99.8%, and he attributed this deviation from purity to the presence of air occluded in the crystals during precipitation. He even recommended the salt as a standard in iodimetry. But in view of the formation of a solid solution with sodium bromate, such use of silver bromate should obviously be undertaken only with serious precautions. The only other analysis of the silver bromate used for solubility work is given by Hill, who reported, without comment, that his salt gave 44.97 and 45.00% of silver (determined as silver chloride) as compared to the theoretical 45.75%. His sample was made by precipitation from potassium bromate and silver nitrate; the same reaction was used for the preparation of the material used in References 9, 10, 11, in which no analysis is given.

(9) Longi, *Gazz. chim. ital.*, **13**, 87 (1883).

Summary

1. The system silver bromate–sodium bromate–water has been studied in detail at 25°, and, partially, at 50° and 5°.

2. The salts form a definite compound, $AgBrO_3 \cdot NaBrO_3$, which forms a continuous solid solution with silver bromate. Sodium bromate also forms a solid solution containing up to 2.5–3.0% of silver bromate.

3. Some implications of these results on analytical procedures involving silver bromate are discussed. Precipitation of silver bromate from solutions containing sodium ion must result in an impure salt which can be purified by recrystallization only with difficulty.

4. The results may explain the great variation in the values of the solubility of silver bromate reported in the literature, and suggest that the samples of the salt used in various theoretical studies may have been contaminated with sodium bromate.

Mechanism of Peroxide Initiated Styrene Polymerization

BY HARRY F. PFANN[1] D. J. SALLEY[1a] AND H. MARK

Recent publications of Price and his co-workers[2] and of Kern and Kammerer[3] have succeeded in clarifying the mechanism of the peroxide initiated polymerization of styrene. Their results confirm and extend proposals advanced by Norrish,[4] Schulz[5] and others that the active centers for chain propagation are free radicals resulting from the decomposition of the peroxide as such or an addition compound between peroxide and styrene. As there appears to be continued interest[6,7,8] in this problem, the writers wish to present the following data obtained from experiments[9] in progress from 1940 to 1942, which were not published at that time due to the outbreak of the war.

In this work, halogen-containing polymer was prepared from styrene and *m*-bromobenzoyl peroxide. Non-combined initiator was removed by repeated extraction, and the presence of bromine in the polymer was demonstrated by combustion of the sample followed by determination of the halogen, as well as by measurement of the radioactivity of the polymer samples after neutron bombardment.

Experimental Procedure

Polymer samples were prepared by heating commercially pure styrene (Dow Chemical Company, 1941, $n^{25}D$ 1.5432, d^{24} 0.9025) with *m*-bromobenzoyl peroxide (m. p. 127–128°, 99% of theoretical active oxygen) in sealed glass tubes 33 mm. × 180 mm. immersed in an oil-bath at

140 ± 2°. Each tube was sealed off under vacuum (except Sample No. 100). The temperature of reactants was followed by use of a thermocouple placed in a well extending into the center of the reaction mixture. Heating was continued until *ca.* 50% of the styrene was polymerized, after which the reaction was quenched by sudden cooling.

Polymer was isolated by precipitation from benzene solution with methanol. A 5% solution of polymer in benzene was extracted three times by agitation with 15% aqueous sodium hydroxide at *ca.* 50° during one hour. The extracted polymer, precipitated with methanol, was digested in methanol on the steam-bath, and dried in a vacuum oven.

Chemical determination of the bromine content of the polymer was carried out by combustion in a macro combustion tube over a platinum gauze catalyst, absorption of the halogen in an alkaline sodium bisulfite solution, and gravimetric determination of silver bromide by a modification of the Pregl micro technique.[10] Combustion of the non-volatile polymer was attended by considerable difficulty, but the results tabulated represent fairly successful determinations.

Physical determination of the bromine content was carried out by measuring the intensity of the radioactive isotopes of bromine produced by irradiation with neutrons. Cast films of the polymer 1.0 sq. cm. by 1 mm. were subjected to neutron bombardment in the Columbia University cyclotron. Measurements of the resulting intensities were carried out with a mica-window type of Geiger counter tube. All counts were corrected for decay and for slight variation in the thickness of the specimens. The ratio of the corrected intensities gave the relative amounts of bromine present, and the absolute amount was obtained using one of the samples as the basis.

116	12.84	4	217	48.0

[a] Tube evacuated and filled with oxygen at 760 mm. before sealing.

indicated by the thermocouple, showing that there was a marked deviation from the isothermal condition of the heating bath. Comparison of samples 100 and 101 suggests that oxygen may act initially as an inhibitor, as it does, *e. g.*, in certain emulsion polymerizations.

In Table II are given the properties observed for the several polymer preparations. Sample 116-E-3 differed from 116-E-1 in that it was given three standard extractions and precipitations after polymerization. The essential constancy of the bromine content indicates that the halogen determined represents chemically bound, not associated or adsorbed, catalyst fragments. The agreement between the chemical and radioactive determinations appears quite satisfactory.

The analytically determined bromine content does not agree well with the value calculated from the viscosity average molecular weight, which calculation is based on the assumption of two initiator fragments per polymer molecule. This would be the case if chain termination is only effected through mutual saturation of two growing chains.[11,12]

Perhaps of more significance is the variation shown under "Comparison of Values." Polymer sample 104 was prepared with the smallest peroxide concentration at the lowest temperature, and it was found to have only 58% of the halogen calculated from viscosity measurements. Sample 116, prepared with greatest peroxide concentration and highest temperature, was found to have 166% of the calculated halogen content. Sample 104-E-1, of highest molecular weight, would be expected to have been subject to the greatest degree of chain transfer. A high incidence of chain transfer would result in a low concentration of initiator per polymer molecule.[13]

It must also be borne in mind that the viscosity average as contained in column three of Table II places less emphasis on the short chains than the counting of the bromine end-atoms does. If the

tion, the viscosity average is bound to give distinctly larger molecular weights than the counting of the end-groups. This may explain the high bromine content of the polymer prepared at 217° (sample 116-E) where the decomposition of the catalyst should be expected to be very fast and at the same time thermal activation would be most efficient.

Acknowledgment

The authors are anxious to express appreciation to the directors of the Stamford Research Laboratories of the American Cyanamid Company for extending to the junior author the use of the laboratories' facilities. Thanks are also extended to the staff of the Columbia University cyclotron for bombardment of the samples.

Summary

1. Styrene has been polymerized in the pure liquid phase at various temperatures and with various amounts of *p*-bromobenzoyl peroxide.

2. The bromine content of the polymer was determined gravimetrically and with the aid of a radioactive bromine isotope. The values obtained by the two methods agreed reasonably well with each other.

3. The polymers contain on the average between one and three bromine atoms per chain, if the viscosity average chain length is compared with the analytical bromine content.

4. It is shown that the radioactive tracer method can be fairly easily applied to this problem of polymer chemistry.

Rearrangement of Alkyl Halides[1]

BY FRANK R. MAYO[2a] AND ARTHUR A. DOLNICK[2b]

The addition of hydrogen bromide to a 1-alkene may yield either of two products, depending on the mechanism of addition.[3] The normal addition, giving a secondary or tertiary bromide, proceeds by an ionic or molecular mechanism. The abnormal addition, which is accelerated by oxygen and peroxides and is inhibited by certain antioxidants, proceeds by an atom-chain mechanism, giving a primary bromide. On the assumption that the rearrangement of an alkyl bromide proceeds by loss and readdition of hydrogen bromide, it was concluded that the rate of rearrangement should be affected by the same catalysts which influence the addition of hydrogen bromide. This paper describes the effects of such catalysts on the rearrangement of normal and isopropyl bromides to an equilibrium mixture. These readily available bromides were chosen because the carbon skeleton cannot rearrange and because a mixture of the halides is easily analyzed. For comparison with a representative pair of alkyl chlorides, experiments were made with *i*- and *t*-butyl chlorides. Data were also obtained on the two dibromoethanes.

Previous Work

When an alkyl bromide is strongly heated, it rearranges to give an equilibrium mixture of all the isomeric bromides which can be formed without rearrangement of the carbon skeleton. In spite of considerable work in the field, there is marked disagreement on the composition of some equilibrium mixtures, on the factors which influence the rate of approach to equilibrium, and on the mechanism of rearrangement.

In the liquid phase at 250°, normal and isopropyl bromides rearrange to give a mixture containing 30 and 70%, respectively, of these bromides.[4a] The proportion of primary bromide increases with the temperature[4a] and is smaller in the vapor phase.[4b] Equilibria between tertiary and isobutyl bromides have been more extensively investigated[5] in both the liquid and the vapor phase, but although the tertiary bromide always predominates, wide discrepancies in the composition of the equilibrium mixture have been reported; secondary butyl bromide (with rearrangement of the carbon skeleton) has also been detected.[5g] Equilibria between the four bromoisopentanes and between some isomeric dibromoalkanes have received less attention.[5a,6]

The rearrangement of the bromoisobutanes is retarded by the corresponding alcohols and by di-isobutylene.[5b] Michael has recently suggested[7]

that his earlier work[5a,b] shows an acceleration by oxygen. Aluminum,[5a,8b,d] zinc and mercuric[5b] bromides accelerate the rearrangement of several bromides. There is disagreement as to whether rearrangement is faster in the vapor than in the liquid phase[5a,b,e,8a] and as to the effect of various surfaces on the rate of rearrangement.[5a-c,6c] Difficulty in reproducing results has been mentioned frequently; catalytic effects have seldom been demonstrated by duplicate experiments, and frequent discrepancies between workers suggest that many conclusions are open to question. Typical of the state of the subject are the repeated claims,[5a,c,f,6c,8c] often refuted,[5e,6b,8f] that equilibrium is approached much faster from one side than from the other, that it can be approached only from one side, and that impurities[5b] determine the composition of the equilibrium mixture.

Rearrangement through loss and readdition of hydrogen bromide has been postulated,[4a,5d,6b,8a-c,9a] while those who favor an intramolecular rearrangement base their contentions upon failure to observe dissociation sufficient to account for rearrangement.[5a,b,f,g,8e,9b]

Alkyl chlorides, which rearrange with difficulty, have received comparatively little attention.[10]

Experimental

Conditions for Isomerization.—Generally, the propyl bromide[11] (3 cc. measured at room temperature) was heated for six hours at 250° in a sealed, heavy-walled, Pyrex tube (5.7 mm. inside diameter, 35 cm. long, 8–9 cc. capacity), enclosed in a close-fitting iron pipe. In runs where air was excluded, measured quantities of the dried bromide were distilled *in vacuo* into the cooled reaction tube containing the catalyst (if any), and sealed off (final pressure 10^{-4} mm. or less). When hydrogen bromide or propene was added, it was measured out in the vapor phase and condensed in the reaction vessel. For runs in the presence of air, the halides were pipetted into cooled (−80°) tubes and sealed off.

In the first third of the experiments, the reaction tubes were heated in a horizontal electric furnace, but when it was found that the temperature varied from 250° at the center to 210° at the ends of the tubes, the remaining experiments were carried out in boiling diphenyl ether (temperature 248–252°).[12] Tubes were introduced into the preheated furnace or bath; they attained the maximum temperature within fifteen minutes in the diphenyl ether-bath, more slowly in the furnace. In most of the experiments, the two methods of heating gave nearly identical results, but the runs without added catalysts or air tend to fall into two groups (Fig. 1). Less rearrangement was found in the electrically heated runs, ten out of eleven products having indices of refraction between 1.4328 and 1.4332. The halide presumably rearranged faster in the diphenyl ether-bath experiments because the temperature was higher and more rapidly attained.

Analysis of Reaction Products.—The heated tubes were cooled to −80° and opened. The products (usually colorless but containing hydrogen bromide) were washed several times with water, with concentrated sulfuric acid, and again with water. The percentage composition of the halide mixture (dried over potassium carbonate) was then estimated by determination of the index of refraction.[13] The analytical procedure was proved applicable by tests with known mixtures. It was found unnecessary to distil the rearrangement products of *n*-propyl bromide[14] except that those formed in the presence of aluminum bromide, catechol, or diphenylamine were vacuum-distilled before washing. In the experiments with bromobenzene, the bromopropanes were separated before washing by fractionation through a short Vigreux column. This procedure was found adequate with a known mixture. The chloroisobutanes were merely distilled before their refractive indices were determined. Because the dibromoethanes partially decomposed to hydrogen bromide and a black solid (amounting to about 15% of the product), the volatile products were distilled *in vacuo*, dried with anhydrous potassium carbonate, and fractionated through a small Vigreux column. Material boiling below 105° (mostly at 40–51°, probably ethyl and vinyl bromides) was rejected; the composition of the fraction boiling at 105–132° was determined by index of refraction.[15] Residue and hold-up were negligible.

Reagents.—One preparation of *n*-propyl bromide (made from *n*-propanol[16]), having the usual physical properties, rearranged unusually rapidly and was found to contain peroxides. This sample was washed with 2% aqueous potassium permanganate until no more reduction occurred; it was then washed until colorless with concentrated sulfuric acid. After treatment with aqueous potassium carbonate and then with water, the dried and distilled propyl bromide rearranged at the usual rate. Thereafter, all the propyl bromide (b. p. 749 mm. 70–71°, $n^{20}D$ 1.4341), from which about 75% of the runs were made, was treated in this manner. Isopropyl bromide (Eastman Kodak Co.) was washed with concentrated sulfuric acid and water, dried and fractionally distilled; b. p. 747 mm. 58.5–59.0°, $n^{20}D$ 1.4251. *t*-Butyl chloride,[17a] b. p. (739 mm.) 49.5°, $n^{20}D$ 1.3853, and isobutyl chloride,[10a,17b] $n^{20}D$ 1.3974, were prepared from the corresponding alcohols.

Catechol and diphenylamine were sublimed at reduced pressure; *n*-propanol, di-isopropyl ether, and bromobenzene were fractionally distilled. Anhydrous aluminum bromide was prepared from aluminum and reagent grade bromine[18] and stored and transferred in a dry atmosphere. The colorless salt dissolved rapidly and completely in alkyl halides with discoloration and development of heat.

Results

Rate Studies.—Since the equilibrium between the bromopropanes at 250° lies on the side of the secondary halide, isomerization of *n*-propyl bromide to the equilibrium mixture results in a greater change in composition and refractive index than would occur with its isomer. Conse-

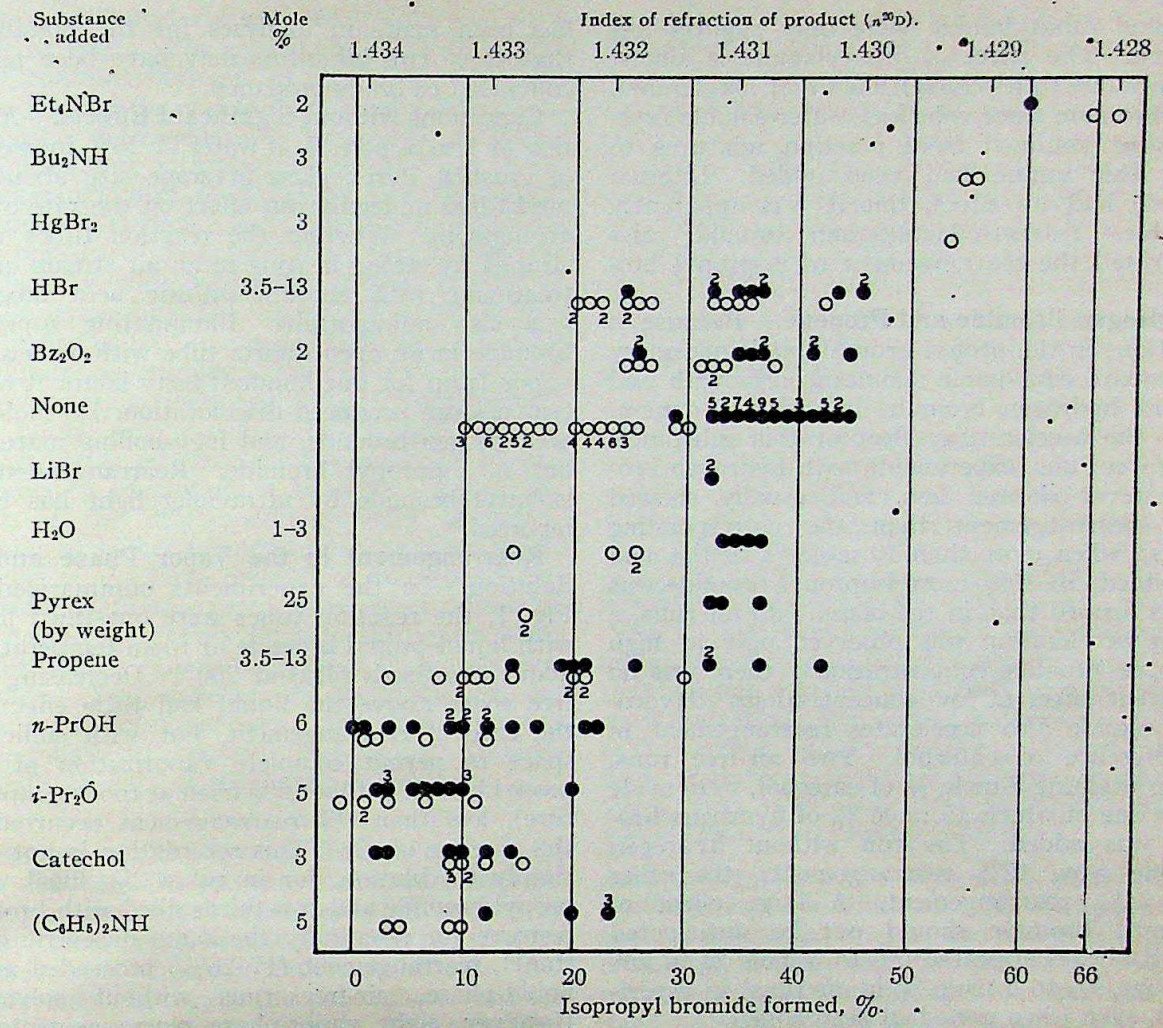

Fig. 1.—Extent of rearrangement of *n*-propyl bromide after six hours at 250°. Hollow circles represent experiments made in the absence of air; solid circles indicate presence of air. A number above or below a point shows the total number of duplicate experiments which gave the indicated result. The equilibrium mixture contains 66–67% isopropyl bromide.

quently, rate studies were carried out by heating the liquid primary bromide for six hours at 250°. Results are summarized in Fig. 1.

Oxygen and Peroxides; Precision of Results.—In the absence of air at 250°, 9–30% of *n*-propyl bromide rearranges during six hours to the secondary halide (Fig. 1), whereas 67% represents equilibrium. Using the same *n*-propyl bromide for each set, eight pairs of duplicate experiments gave products having a maximum difference in index of refraction of 0.0002 (2.2%) within each pair; hence catalytic impurities in the halides and the method of heating are probably responsible for the wide differences in the results obtained.

While the values actually overlap slightly, the rearrangement of *n*-propyl bromide (29–43%) is unmistakably faster in the presence of air than in its absence. Whenever air and air-free experiments were made simultaneously from the same sample of *n*-propyl bromide, 11–25% (average 17%) more rearrangement was always obtained in the presence of air. Hence the overlapping of air and air-free runs shown in Fig. 1 is due to variations in the *n*-propyl bromide or in heating. Oxygen is responsible for the accelerating effect of air: in simultaneous experiments, 9% rearrangement was found in a vaccum run, 18% and 42% were found after bubbling commercial nitrogen and oxygen, respectively, through the bromide samples before the reaction tubes were sealed. Air was also found to accelerate the rearrangement of isopropyl bromide.

Experiments with benzoyl peroxide yielded some charred material and erratic results. In view of the short life of the peroxide above 100°, the results are not considered to be significant.

Bromide Salts.—The powerful catalytic effect of aluminum bromide, which caused extensive side-reactions at elevated temperatures, was demonstrated by equilibrium studies at low temperatures. Addition of 2 mole % of tetraethylammonium bromide to reaction mixtures resulted in close approach to equilibrium (67% rearrangement) in six-hour runs at 250°;[19] mercuric bro-

(19) Only 17% rearrangement was found in the same time at 200°.

mide and dibutylamine were only slightly less effective. The effect of dibutylamine is almost certainly due to its conversion to an alkylammonium bromide since colorless, water-soluble crystals were obtained from reaction mixtures to which this amine had been added. Lithium bromide had no effect, but it was apparently insoluble. Tetraethylammonium bromide also accelerated the rearrangement of isopropyl bromide.

Hydrogen Bromide and Propene.—Because of variations in the propyl bromide, it is necessary to compare runs made simultaneously with and without hydrogen bromide, in order to demonstrate the accelerating effect of this substance. In air-free runs, experiments with hydrogen bromide never showed less, and usually showed more, rearrangement than the corresponding blanks; when more than 10 mole % of the acid was added, 10–15% more isopropyl bromide was always formed than in the blank. In air runs, a similar acceleration was observed only at high hydrogen bromide concentrations; there was no consistent effect at low concentrations. Hydrogen bromide also accelerates rearrangement in the presence of catechol. Two air-free runs, each containing 3 mole % of catechol, were made up, to one of which 15 mole % of hydrogen bromide was added. The run without hydrogen bromide gave 10% rearrangement; the other gave 34% rearrangement. A large effect of hydrogen bromide should not be anticipated since it always appeared (1/3 to 5 mole % in air-free runs, 1/3 to 2 mole % in air runs) in experiments, even when none had been added.

A small retarding effect of added propene can be shown in both the presence and absence of air. In ten experiments with added propene accompanied by simultaneous blank runs, nine rearranged 2–18% less (average 11%) than the blank, but a definite relation between the amount of alkene and the extent of rearrangement is not discernible.

Inhibitors.—Experiments with added catechol show that this antioxidant completely overcomes the accelerating effect of air on the rearrangement and reduces the effects of accidental catalysts in the *n*-propyl bromide. When simultaneous experiments were made with catechol, the air and air-free runs were identical (four pairs of experiments). In four pairs of experiments in the absence of air, the inhibitor had a marked retarding effect (12–16% rearrangement) only when the blanks rearranged rather rapidly (23% rearrangement), a slight effect when the blanks rearranged slowly (9–10% rearrangement). Diphenylamine proved to be a less effective inhibitor.

Figure 1 shows that *n*-propanol is also a fairly effective inhibitor. Di-isopropyl ether is the most effective; in the absence of air, it sometimes stops rearrangement completely. No allowance has been made in analyses for the possibility that these two inhibitors may have been partly converted to bromopropanes.

Conditions without Significant Effects.—Addition of 1 to 3 mole % of water or 25% by weight of crushed Pyrex glass (average size about 30 mesh) had no significant effect on the rate of rearrangment. Whether the reaction tubes were cleaned by strong heating in an air stream or by treatment with chromic–sulfuric acid mixture was also unimportant. Illuminating *n*-propyl bromide in an open quartz tube with a mercury vapor lamp for one hundred forty hours at room temperature produced discoloration, 1.5 mole % of hydrogen bromide, and high-boiling material, but no isopropyl bromide. Rearrangement of isobutyl bromide by ultraviolet light has been reported.[8c]

Rearrangement in the Vapor Phase and in Solution.—In the experiments summarized in Fig. 1, the reaction tubes were one-third filled with liquid propyl bromide at room temperature, about two-thirds filled at 250°. Decreasing the free space above the liquid had little effect on the rate of rearrangement, but with sufficient space to permit complete vaporization of the propyl bromide (tubes 2% filled at room temperature), less than 1% rearrangement occurred in the absence of air. This retardation is not due simply to dilution, for in tubes 2% filled with propyl bromide and two-thirds filled with bromobenzene (of essentially the same dielectric constant), rearrangement (17–26%) proceeded as in liquid-phase, air-free runs without solvents. However, eight vapor-phase rearrangements in the presence of air gave 12–31% (mean, 20%) rearrangement, just half the average of simultaneous liquid-phase blanks with air in small tubes. In six bromobenzene experiments with air present, 12–42% (mean, 25%) rearrangement was found.

Equilibrium between *n*- and Isopropyl Bromides.—As shown in Fig. 2, the same equilibrium mixture (containing 67% isopropyl bromide as compared with 70% reported by Brouwer and Wibaut[4a]) was obtained at 250° from both *n*- and isopropyl bromides, regardless of the presence or absence of tetraethylammonium bromide or air. With these catalysts, equilibrium could not be obtained within a reasonable time at or below 200°. Aluminum bromide could not be used at 250°, but gave equilibrium mixtures containing 85% isopropyl bromide at 70°, 91% at 26°.

Rearrangement of *i*- and *t*-Butyl Chlorides.—Isobutyl and *t*-butyl chlorides were unchanged after six hours at 250°, but each gave about 10% rearrangement in seven hours at 300°. Neither catechol nor air affects the rearrangement of isobutyl chloride. About 26% of this chloride rearranged in fifteen hours at 300°, in the presence or absence of air and/or 3 mole % of catechol. On the other hand, addition of 3 mole % of triethylammonium chloride increased rearrange-

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

ment of isobutyl chloride to 78 during seven hours at 300°. The equilibrium mixture apparently contains between 78 and 92% of tertiary chloride, but the value is uncertain due to the formation of considerable high-boiling material in runs starting with *t*-butyl chloride.

Rearrangement of Ethylene and Ethylidene Halides.—Ethylene and ethylidene chlorides were boiled with 2 mole % of aluminum chloride; ethylene bromide was refluxed with 1 mole % of aluminum bromide, and ethylidene bromide was heated to 100° in a sealed tube with 4 mole % of aluminum bromide. No rearrangement was observed over periods of six and one-half to ninety-four hours, but considerable halogen exchange occurred when ethylene chloride was refluxed with 23 mole % of aluminum bromide. Rearrangement of the dibromoethanes with aluminum bromide at higher temperatures was unsuccessful because of the large amount of tar formed, but less side reaction occurred when either dibromide was heated for twenty-eight to thirty-two hours at 250° with 4–5 mole % of tetraethylammonium bromide. Two experiments were carried out with each dibromoethane; the four products were found to contain 76–82% of ethylene bromide, 18–24% of ethylidene bromide.

Discussion

Correlation with Previous Work.—The present work supports the previous statements that rearrangement of alkyl bromides is accelerated by air and some metal bromides, and is retarded by alcohols and alkenes. With reference to previously disputed points, this paper shows that the rearrangement is much slower in the vapor than in the liquid phase, that there is no surface effect from glass, that reproducibility of results is highly dependent on catalysts and inhibitors present as impurities in the alkyl bromide, and that equilibrium can be approached from both sides. The analogies discussed below, as well as the formation of free hydrogen bromide in all experiments, point to rearrangement by loss and readdition of hydrogen bromide rather than by an intramolecular mechanism.

The Mechanisms of Rearrangement of Alkyl Halides.—Addition of hydrogen bromide to propene may occur by either of two mechanisms, each associated with different catalysts and each leading to a different propyl bromide.[3] Loss of hydrogen bromide from an alkyl bromide presumably occurs by the reverse processes. The present observations on the rate of rearrangement of the bromopropanes are entirely consistent with the view that rearrangement consists of loss and readdition of hydrogen bromide by the same two mechanisms, but here the two mechanisms can be distinguished not by the products formed, but only by analogy with the addition reaction. On this basis, the accelerating effect of oxygen on the rearrangement of the bromopropanes, and the counteracting effect of antioxidants,

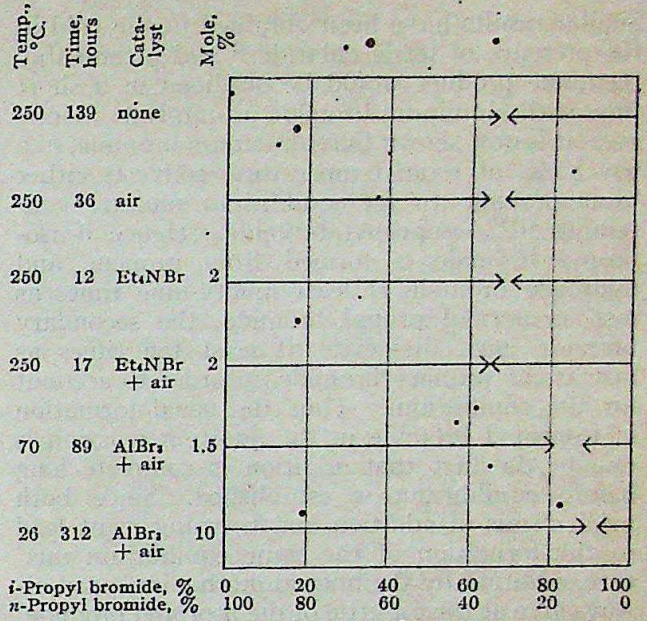

Fig. 2.—Liquid-phase equilibrium between *n*- and isopropyl bromides. Each line indicates the change undergone by a propyl bromide sample when heated under the stated conditions. The starting materials are indicated at the margins; the arrow heads show the final compositions. Experiments at 250 and 70° were carried out in sealed tubes; at 26°, open reflux condensers were used, with protection from moisture in the air.

are associated with the atom-chain mechanism of hydrogen bromide addition. The slight acceleration by hydrogen bromide and the greater effect of soluble bromide salts are associated with the normal, molecular mechanism of hydrogen bromide addition according to Markownikoff's rule. Substances which reduce the concentration of hydrogen bromide, such as propene, propanol and di-isopropyl ether, retard the rearrangement; the alcohol and ether may also retard the chain reaction. Since hydrogen chloride does not add to alkenes by the chain mechanism, both the absence of an oxygen effect and the presence of a catalytic effect of triethylammonium chloride are observed and expected.

As in many hydrogen bromide additions, the rearrangement of the bromopropanes seems to proceed by both mechanisms in the absence of air, as shown by the variable rates observed and their tendency to approach a lower limit in the presence of the antioxidant, catechol. The differences in the effectiveness of inhibitors, and the retardation or elimination of the molecular mechanism by diluting or operating in the vapor phase also have nearly identical counterparts in the addition reactions.[3]

Rates and Equilibria in the Formation and Rearrangement of Alkyl Bromides.—Hydrogen bromide adds rapidly to propene under ordinary conditions to give isopropyl bromide.[13] This isomer must be formed at least ninety-nine times as fast as *n*-propyl bromide since probably no more than 1% of the primary halide is present.

Digitized by Arya Samaj Foundation Chennai and eGangotri

Similar results have been obtained in the cold in the presence of ferric chloride,[20] and presumably the same product would be obtained in a short time with aluminum bromide as catalyst. However, it is now shown that aluminum bromide, in a few hours at room temperature, converts either bromopropane to an equilibrium mixture containing 91% isopropyl bromide. Hence if isopropyl bromide is formed from propene and hydrogen bromide at least ninety-nine times as fast as normal propyl bromide, the secondary bromide must dissociate at least ten times as fast as the primary bromide, in order to account for the equilibrium. Thus the usual formation of isopropyl bromide in the addition reaction is due to the fact that addition is complete long before equilibrium is established. Since both mechanisms of addition and rearrangement lead to the formation of the same equilibrium mixture, addition by the normal mechanism must always give at least a little of the *n*-propyl bromide; addition by the chain mechanism must always give some isopropyl bromide; and any catalyst which preferentially accelerates formation of one bromopropane must also preferentially favor the dissociation of the same bromopropane.

From the liquid-phase equilibrium data for normal and isopropyl bromides (the equilibrium mixture containing 91% of isopropyl bromide at 26°, 67% at 250°), calculation shows that the isomerization of primary to secondary halide evolves 2.2 kcal./mole.[21] Conn, Kistiakowsky and Smith[22] have justified the Markownikoff rule for the addition of halogen acids to alkenes because it predicts the formation of the thermodynamically more stable alkyl halides. While this generalization may well be correct for unsaturated hydrocarbons, it does not apply to vinyl bromide. Although in this case the normal addition of hydrogen bromide yields almost exclusively ethylidene bromide in the liquid phase at room temperature[15] or 100°,[23] or in the vapor phase at 200°,[23] the equilibrium mixture at 250° contains about 80% of ethylene bromide. Thus, here the abnormal addition yields the more stable of the two possible products.

The Redistribution Reaction.—Ethyl chloride and ethylene bromide react at room temperature in the presence of aluminum chloride to give a mixture containing ethyl bromide, ethylene chloride, ethylene chlorobromide, and the original halides.[24] Since it has now been shown that aluminum chloride does not rearrange the dichloro- and dibromoethanes below their boiling points, while replacement of one halogen by another occurs easily, the redistribution reaction of Calingaert, *et al.*, must involve a displacement reaction,[25] not loss and readdition of hydrogen halides.

Summary

The liquid-phase rearrangement of the bromopropanes to an equilibrium mixture has been studied. Many analogies between this reaction and the addition of hydrogen bromide to alkenes suggest that rearrangement of an alkyl bromide occurs by loss and readdition of hydrogen bromide and that the reactions proceed by two mechanisms. The first of these is a non-chain mechanism accelerated by soluble bromide salts or hydrogen bromide and retarded by substances which remove hydrogen bromide. The second is an atom-chain mechanism accelerated by oxygen and inhibited by antioxidants. Alkyl chlorides rearrange by the non-chain mechanism.

Since rearrangement of either propyl bromide is accelerated by catalysts for both mechanisms, the commonly observed formation of a single addition product from a halogen acid and an alkene is due to the fact that the first-formed addition product rearranges very slowly. Although the non-chain addition (in accord with Markownikoff's rule) usually yields the thermodynamically more stable isomer, the addition of hydrogen bromide to vinyl bromide is exceptional.

With the dihaloethanes, the replacement of one halogen by another in the presence of aluminum chloride or bromide proceeds much more easily than rearrangement.

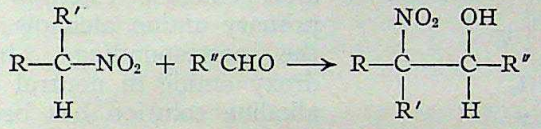
Preparation and Catalytic Reduction of 3-Nitrobutyl-2 *p*-Nitrobenzoate[1]

BY JULIAN R. REASENBERG AND G. B. L. SMITH

The commercial production of the nitroparaffins has greatly stimulated interest in the derivatives of these compounds.[2] Of these derivatives, the nitroalcohols and the corresponding amino alcohols are of prime importance because of their similarity in structure to compounds exhibiting physiological activity.

The reaction between nitroparaffins and aliphatic aldehydes to produce nitroalcohols was first described by Henry,[3] and since then has been studied extensively. A glance at the structure



of a nitroalcohol formed from a nitroparaffin higher than nitromethane and an aldehyde higher than formaldehyde, will indicate that the compound contains two asymmetric carbon atoms and should exist in diastereoisomeric forms. To date, only one case of the separation of the *erythro* and *threo* forms of an aliphatic nitroalcohol has been reported.[4]

The compound prepared from nitroethane and acetaldehyde, 3-nitrobutanol-2, fulfills these conditions and should exist as two chemical entities. However, careful fractionation of this compound by the authors as well as by Vanderbilt and Hass[4] has failed to show the presence of the diastereoisomerides.

Some of the fatty acid esters of the nitroalcohols have been described. Vanderbilt and Hass[4] have prepared the acetates of a wide variety of nitroalcohols by allowing them to react with acetic anhydride. Tyndall[5] has prepared the propionates, butyrates, and isobutyrates of these compounds. The nitroalcohols and corresponding esters in which the nitro group is linked to a secondary carbon atom are relatively unstable. Boiling water or 0.1 *N* sodium bicarbonate decomposed the esters of 3-nitrobutanol-2 into the acid and 3-nitrobutene-2.[4,5]

3-Nitrobutanol-2 was prepared by a method similar to that described by Vanderbilt and Hass[4] although the method was developed independently before the publication of the method of Vanderbilt and Hass. The product could be purified by vacuum distillation without decomposition although it has been reported to decompose explosively at times upon low pressure distillation.[6] On standing for several months in a sealed container it decomposed somewhat with the formation of nitrobutene. Attempts to prepare the nitrobenzoate by the usual chemical methods resulted in failure until a low temperature acylation in the presence of pyridine was performed. The product so obtained was a white solid with a wide melting point range, 80–85°. After eight to ten recrystallizations from alcohol the product melted sharply at 107–108°. This purification could also be effected with greater ease by a partial and stepwise treatment of the alcoholic solution with sodium hydroxide. Two successive treatments with 10% of the theoretical amount of alkali each time usually sufficed to give a product which, after one recrystallization from alcohol, melted at 107–108°.

The "crude" ester and the purified ester gave the same saponification equivalent 134, and both products contained essentially the same percentage of carbon, hydrogen, and nitrogen. This would indicate that the "crude" ester is a mixture of the diastereoisomerides previously postulated. The lachrymator 3-nitrobutene-2 was always present in the mother liquors from the recrystallization of the impure product but was not present in the liquor from the recrystallization of the pure product. Also the nitro-olefin was present in large quantities in the liquor resulting from the alkali treatment.

All of these facts seem to indicate that the 3-nitrobutanol-2 is a mixture of the two isomers and on esterification, the ester formed is "crude" because of the presence of both isomers. Also, one of the isomers is preferentially hydrolyzed and(or) is decomposed in the presence of alkali to 3-nitrobutene-2. Dilute solutions of ammonium hydroxide and sodium bicarbonate were also effective in this process. Several attempts were made to isolate the unstable isomer by fractional crystallization of the mother liquors but these were unsuccessful because of the thermal instability of the compound,[4,5] and only the decomposition products, *p*-nitrobenzoic acid and 3-nitrobutene-2, were isolated.

A study was made of the reduction and reduction products of 3-nitrobutyl-2 *p*-nitrobenzoate. Figure 1 illustrates the products formed under varying conditions of reduction with both Raney nickel and Adams platinum oxide catalysts. In all of the reductions employing Raney nickel the catalyst was promoted with platinic chloride

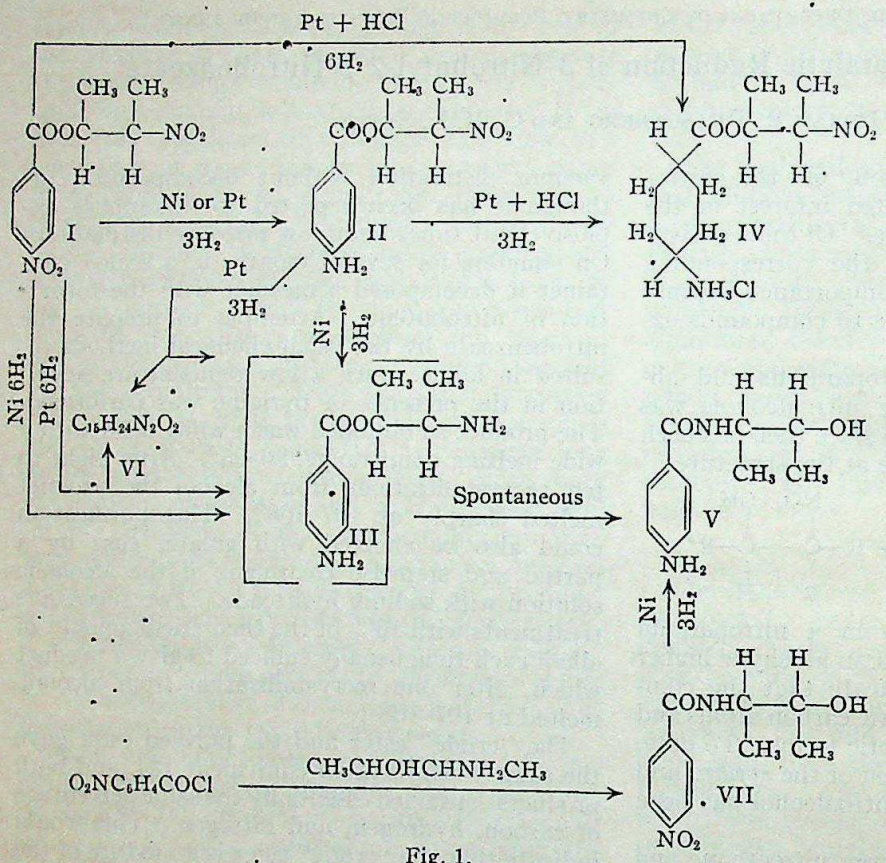

Fig. 1.

as previously described.[7] The qualitative and quantitative results did not vary when similar experiments were performed with the promoted and unpromoted nickel but the reduction proceeded at a much more rapid rate when the platinic chloride was added to the nickel. Also the results did not vary whether the hydrogenation was performed at atmospheric pressure or at 3–4 atmospheres. The apparatus has been described previously.[7]

3-Nitrobutyl-2 *p*-nitrobenzoate I, contains two nitro groups and the reduction could be effected either stepwise or completely by allowing either 3 or 6 moles of hydrogen to be absorbed. With either catalyst the only product formed when 3 moles of hydrogen was absorbed was the corresponding amino compound II. This compound was then reduced under varying conditions to give a number of products. The hydrochloride of II was quite acidic and Raney nickel could not be used to effect its reduction. With Adams catalyst however, the hydrogenation proceeded slowly but smoothly with the formation of the cyclohexane derivative 3-nitrobutyl-2 *p*-aminohexahydrobenzoate hydrochloride IV. The formation of this product is probably due to the fact that acid inhibits the reduction of an aliphatic nitro group by means of platinum and promotes the reduction of the benzene ring by means of platinum.[8] On acid hydrolysis, 3-nitrobutene-2 and *p*-aminohexahydrobenzoic acid, m. p. 285°,[9] were formed.

In neutral solution with Raney nickel, II is reduced slowly to give V, N-(*p*-amino benzoyl)-2,3-butanolamine. The formation of this amide alcohol presumably occurs through the rearrangement of compound III, 3-aminobutyl-2 *p*-aminobenzoate. This rearrangement of esters of β-primary amino alcohols to the corresponding β-hydroxy amide in neutral or alkaline solution has been described for a wide variety of compounds.[10,11,12,13] The structure of compound V was proved by its synthesis from N-(*p*-nitrobenzoyl)-2,3-butanolamine by catalytic reduction.

With Adams platinum oxide in neutral solution, 3-nitrobutyl-2 *p*-aminobenzoate II is reduced to give two products, V and VI. Compound VI is an oily base which is insoluble in water but is soluble in most organic solvents and in dilute acid. The numbing effect of a local anesthetic is produced when a drop of the oil is placed on the tongue and mucous membranes of the mouth. All attempts to produce a solid salt with the common inorganic and organic acids failed. On hydrolysis, *p*-aminobenzoic acid was isolated. A diacetyl derivative was formed which could be obtained in pure crystalline form. The empirical formula of the oil is tentatively set at $C_{15}H_{24}N_2O_2$ and that of the diacetyl derivative at $C_{19}H_{28}N_2O_4$. The picrate was also prepared and analyzed. Its formula is postulated as $C_{21}H_{27}N_5O_9$.

In addition to compounds V and VI there was also isolated from the reduction of II, *p*-amino benzoic acid and ammonia. The difference between the postulated formula of VI and the formula of III is C_4H_8, and this together with the fact that ammonia was one of the products of reduction would indicate that VI might be formed by the reaction of III with butanolamine with the elimination of ammonia and water.

The complete reduction of 3-nitrobutyl-2 *p*-nitrobenzoate I with the absorption of 6 moles of

hydrogen produces the same results and products as the sum of the two stepwise hydrogenations involved. Thus I with Pt and HCl forms IV; I with Pt in neutral solution gives V and VI; and I with Raney nickel forms V.

Experimental

3-Nitrobutanol-2.[14]—A solution of 40 g. of acetaldehyde (0.91 mole) and 71 g. of nitroethane (0.90 mole) dissolved in 60 ml. of 95% ethanol was treated with 0.8 g. sodium hydroxide dissolved in 2 ml. of water. The solution was allowed to stand for five days at room temperature at which time the color had deepened to yellow. The alkali was neutralized with concd. hydrochloric acid, the color changing to blue-green, and the precipitated sodium chloride was allowed to settle and was separated by decantation. The solvent was removed by distillation under diminished pressure and the residue was vacuum distilled. After a small fore-run of 3-nitrobutene-2 (strong lachrymator) the main fraction of 3-nitrobutanol-2 came over as a light yellow liquid with a slight acrid odor weighing 99 g. The product had the following characteristics: b. p. 90° (11 mm.), b. p. 99° (17 mm.), d^{20}_4 1.1260, $n^{22}D$ 1.4425, mol. ref. calcd. 28.0, found 28.0.[15]

2,3-Butanolamine.[16,17,18,19]—A solution of 47.6 g. of 3-nitrobutanol-2 dissolved in 120 ml. of ethanol was reduced at 3–4 atm. with 3–4 g. of Raney nickel. The reduction was complete in two hours. The catalyst was removed by filtration and the filtrate was distilled at atmospheric pressure. The aminoalcohol, 7.8 g., boiled at 159°; d^{20}_{20} 0.9414, d^{20}_4 0.9396, $n^{24}D$ 1.4520, mol. ref. calcd. 25.5, found 25.6. Primary oxalate $C_4H_{11}ON \cdot H_2C_2O_4$ from ethanol m. p. 164° dec., secondary oxalate $(C_4H_{11}ON)_2 \cdot H_2C_2O_4$ from ethanol m. p. 206° dec.[20]

3-Nitrobutyl-2 *p*-Nitrobenzoate (I).—Freshly distilled *p*-nitrobenzoyl chloride (53 g. 0.29 mole) was dissolved in 350 ml. of benzene and 34 g. of 3-nitrobutanol-2 (0.29 mole) was added. The beaker and contents were cooled with an ice-bath and, to the well-stirred, yellow solution, was slowly added 26 g. of pyridine (excess), the temperature being kept below 25°. During the addition the color changed to blue-green. The pyridine hydrochloride was removed by filtration and was washed with 50 ml. of benzene. The filtrates were combined and washed with cold dilute solution of sodium bicarbonate which changed the blue-green solution to yellow. The liquid was then washed with water, dried over anhyd. sodium sulfate, and evaporated under diminished pressure to a volume of 100 ml. The temperature was adjusted to 50° and the solution was diluted with 100 ml. of petroleum ether and a precipitate formed. When cold the solution was filtered and the product washed with a little petroleum ether and dried; 70 g. of crude ester m. p. 80–85° was obtained. This was recrystallized once from hot ethanol to give a product melting at 85–90°.

Anal. Calcd. for $C_{11}H_{12}N_2O_6$: C, 49.27; H, 4.51; N, 10.45; sap. eq., 134.1. Found: C, 49.76; H, 4.68; N, 10.17; sap. eq., 134.0.

Separation of Isomers.—The "crude" nitro nitro ester described just above was purified as follows: a hot solution of 450 g. of "crude" ester dissolved in 2500 ml. of ethanol and 500 ml. of water was treated with a solution of 8 g. of sodium hydroxide in 50 ml. of water. The solution darkened to an orange-yellow color and the strong odor of the lachrymous nitrobutene was evolved. The solution was allowed to cool and a white crystalline product started to form. When the temperature reached 40° another 8 g. of sodium hydroxide was added slowly with stirring over a period of one hour. The solution was allowed to stand overnight and the precipitate was then removed by filtration and washed with two 50-ml. portions of cold ethanol and gave on drying 190 g. of ester m. p. 100–104°. This was recrystallized from 2 liters of hot ethanol to give 166 g. of product m. p. 106–108°. One subsequent recrystallization raised the m. p. to 107–108°. The product was a white crystalline compound with a very slight yellowish cast.

Anal. Calcd. for $C_{11}H_{12}N_2O_6$: C, 49.27; H, 4.51; N, 10.45; sap. eq., 134.1. Found: C, 49.17; H, 4.55; N, 10.39; sap. eq., 134.5.

***p*-Nitrobenzoic Anhydride.**—The pyridonium chloride obtained in the acylation described above was dissolved in water and the insoluble fraction was filtered, washed with water and dried; 8 g. of product m. p. 180–185° was obtained. This was recrystallized from ethyl acetate and benzene; soft, slightly yellow, nacreous plates m. p. 191–192° were formed. This product is *p*-nitrobenzoic anhydride[21] and was also synthesized by the method of Holleman,[22] m. p. 191–192°, and a mixed m. p. gave the same value.

Anal. Calcd. for $C_{14}H_8N_2O_7$: N, 8.86; eq. wt., 158. Found: N, 8.98; eq. wt., 158.

3-Nitrobutyl-2 *p*-Aminobenzoate (II).—A solution of 26.8 g. of nitro ester (I) (0.10 mole) dissolved in 100 ml. of dioxane was treated with 4.5 g. of Raney nickel and 0.30 ml. of 10% platinum tetrachloride solution as promoter. The hydrogenation was performed at atmospheric pressure and the hydrogen was absorbed at the rate of 100 ml. per min. When 7200 ml. of hydrogen (0.3 mole) had been absorbed, the rate of hydrogenation diminished considerably and the reduction stopped. The reductate was separated from the catalyst by filtration and the yellow filtrate was treated with 16.7 ml. of 6 *N* hydrochloric acid dissolved in isopropanol (0.10 mole). The copious white precipitate which formed was filtered, washed twice with 30 ml. of dioxane and twice with 50 ml. of ether and dried; 21 g. of white product resulted. This was recrystallized from isopropanol and white platelets of 3-nitrobutyl-2 *p*-aminobenzoate hydrochloride (II HCl) m. p. (rapid heating) 182–183° (dec.) resulted. This compound could be diazotized and coupled with beta-naphthol and gave a red dye. Acid hydrolysis of the amino nitro ester hydrochloride yielded *p*-aminobenzoic acid and 3-nitrobutene-2.

Anal. Calcd. for $C_{11}H_{15}N_2O_4Cl$: C, 48.09; H, 5.50; N, 10.20; Cl, 12.91; sap. eq., 91.5. Found: C, 47.90; H, 5.62; N, 10.23; Cl, 12.99; sap. eq., 91.8.

The free base was prepared by dissolving 65 g. of (II HCl) in 600 ml. of hot ethanol and pouring the resulting solution with stirring into 1 liter of ice and water, containing an excess of ammonium hydroxide. The precipitate was allowed to stand for one hour and was filtered, washed with water and dried; 54 g. of product m. p. 100–102° was obtained. This was recrystallized from 350 ml. of isopropanol after treatment with Darco and 48 g. of white crystalline 3-nitrobutyl-2 *p*-aminobenzoate (II) resulted, m. p. 103°, acetyl derivative m. p. 110°, nitrate m. p. (fast heating) 167–169° (dec.).

Anal. Calcd. for $C_{11}H_{14}N_2O_4$: N, 11.76; sap. eq., 119.0. Found: N, 11.52; sap. eq., 119.0.

3-Nitrobutyl-2 *p*-Aminohexahydrobenzoate Hydrochloride (IV).—A solution of 9.15 g. of 3-nitrobutyl-2 *p*-aminobenzoate hydrochloride (II HCl) (0.033 mole) dissolved in 100 ml. of ethanol was treated with 0.40 g. of platinum oxide. The reduction was performed at atmospheric pressure and room temperature. The hydrogenation proceeded very slowly, 200 ml. of hydrogen being absorbed in seventy-five minutes. After about 800 ml. of hydrogen had been absorbed another 0.20 g. of platinum oxide was added until a total of 2670 ml. of hydrogen had been added and a total of 1.0 g. of platinum oxide had been used.

This corresponds to 3 equivalents of hydrogen plus that required for the reduction of the platinum oxide. The reductate was filtered and the filtrate was evaporated under diminished pressure until all of the solvent had been removed and 30 ml. of benzene and 50 ml. of *n*-butanol were added. A white precipitate formed which was filtered, washed with butanol and ether and dried; 2.50 g. of 3-nitrobutyl-2 *p*-aminohexahydrobenzoate hydrochloride (IV) was obtained. This was recrystallized from isopropanol and a fine white crystalline product resulted which decomposed at 177° with slow heating and at 184° with rapid heating. The compound formed a neutral aqueous solution which could not be diazotized and coupled with β-naphthol. Upon alkaline hydrolysis the lachrymous nitrobutene was evolved. The chloroplatinate was formed in water solution from which it crystallized as orange cubes with 2 moles of water of crystallization which could be removed by heating at 110° leaving a hygroscopic product.

Anal. Calcd. for $C_{11}H_{21}N_2O_4Cl$: C, 47.06; H, 7.54; Cl, 12.63. Found: C, 46.86; H, 7.70; Cl, 12.71. Calcd. for $(C_{11}H_{21}N_2O_4Cl)_2 \cdot PtCl_4 \cdot 2H_2O$: C, 28.27; H, 4.96; Pt, 20.89. Found: C, 28.47; H, 4.73; Pt, 20.78.

p-Aminohexahydrobenzoic Acid.—One hundred ml. of 10% sulfuric acid was added to 1.92 g. of IV and the solution was refluxed for twenty-four hours. 3-Nitrobutene-2 was evolved during the initial stages of the hydrolysis. The resulting clear colorless solution was treated with an excess of silver sulfate and the silver chloride removed by filtration. The solution was treated with hydrogen sulfide, the precipitate, silver sulfide, was separated by filtration, and the excess hydrogen sulfide was expelled by boiling. The solution was then treated with barium hydroxide until alkaline to phenolphthalein and the slight excess of barium hydroxide was carefully neutralized with 0.1 *N* sulfuric acid. The barium sulfate was removed and the clear colorless solution was evaporated to a volume of 20 ml. On dilution with isopropanol a precipitate formed which was separated by filtration, washed with alcohol and ether and dried; 0.6 g. of white product was obtained. This was recrystallized from aqueous acetone and *p*-aminohexahydrobenzoic acid, m. p. 285°,[9] resulted.

Anal. Calcd. for $C_7H_{13}NO_2$: C, 58.63; H, 9.14. Found: C, 58.45; H, 9.04.

N-(*p*-Aminobenzoyl)-2,3-butanolamine V.—A solution of 7.63 g. of II in 100 ml. of alcohol was treated with 4.5 g. of promoted Raney nickel and reduced at 3–4 atm. The equivalent of 3 moles of hydrogen was absorbed in two and one-half hours and on further shaking for two hours no more was absorbed. The solution was filtered and the filtrate was evaporated *in vacuo*. The oily residue was dissolved in 75 ml. of dioxane and saturated with hydrogen chloride. The insoluble oil which formed was separated from the dioxane and dissolved in 50 ml. of isopropanol, 35 ml. of benzene was added and the solution was evaporated to a volume of 35 ml. when, on cooling, a precipitate formed. This was filtered, washed with a few ml. of isopropanol and dried: 3.56 g. of N-(*p*-aminobenzoyl)-2,3-butanolamine hydrochloride was obtained.

The free base was prepared from the hydrochloride, which decomposes without melting, by dissolving it in water and making the solution ammoniacal. On standing this solution deposited crystals which were recrystallized from water to give V as white crystals which can be diazotized and coupled with β-naphthol, m. p. 145–146°. The acetyl derivative, formed from acetic anhydride and water solution of V, crystallized from water as white needles, m. p. 194–195.

Anal. Calcd. for $C_{13}H_{18}N_2O_3$: C, 32.38; H, 7.25; N, 11.19. Found: C, 62.31; H, 7.44; N, 11.40.

V was also synthesized directly. The corresponding *p*-nitrobenzamide was prepared by allowing 1 mole of *p*-nitrobenzoyl chloride to react with 2 moles of 2,3-butanolamine in chloroform solution. The resulting solid was recrystallized from water and gave N-(*p*-nitrobenzoyl)-2,3-butanolamine, VIII, m. p. 158°. This was reduced in alcohol with Raney nickel and 3 moles of hydrogen was absorbed. The reductate was filtered, evaporated, and a solid resulted which by recrystallization from water yielded V, m. p. 145–146° (mixed m. p. 145–146°); acetyl derivative, m. p. 194–195° (mixed m. p. 194–195°).

$C_{15}H_{24}N_2O_2$, VI.—A solution of 12.0 g. of amino nitro ester II, 0.7 g. of platinum oxide and 80 ml. of methanol was treated with hydrogen at atmospheric pressure. A total of 3750 ml. of hydrogen (3 mol.) was absorbed in six hours. The reductate was filtered free of catalyst and the filtrate was evaporated on the water-bath under vacuum after the addition of 20 ml. of benzene. The gummy residue was dissolved in dilute hydrochloric acid and treated with Darco. The filtrate was made neutral to litmus with sodium bicarbonate and the small amount of oil which had formed was removed by filtration. The clear solution was made ammoniacal and the oil which formed was extracted with ether. This was dried over anhydrous sodium sulfate and evaporated; 2.50 g. of oil was obtained which was anesthetic to the tongue.

The water solution which remained after the ether extraction was treated with an excess of acetic anhydride; 3.55 g. of *p*-acetaminobenzoic acid m. p. 255 was formed. The filtrate was made ammoniacal once again and on standing deposited 1.74 g. of N-(*p*-acetaminobenzoyl)-butanolamine m. p. 190–193° (acetyl derivative of V).

The anesthetic oil is a yellow viscous liquid insoluble in water but soluble in all the common organic solvents and dilute acids. Attempts to form a solid salt of this base with the common acids failed. On alkaline hydrolysis, *p*-aminobenzoic acid is formed. The acetyl derivative prepared from acetic anhydride and recrystallized from benzene-ligroin solution melts at 151°.

Anal. Calcd. for $C_{19}H_{28}N_2O_4$: C, 65.49; H, 8.10; N, 8.04. Found: C, 65.58; H, 8.35; N, 8.20.

The picrate, a bright yellow solid, was formed in benzene, m. p. 171.5–172.0°.

Anal. Calcd. for $C_{21}H_{27}N_5O_9$: C, 51.11; H, 5.51; N, 14.20. Found: C, 50.99; H, 5.51; N, 15.09.

Summary

1. The existence of diastereoisomers in 3-nitrobutanol-2 has been demonstrated. One of these had been isolated in the form of the *p*-nitrobenzoate.

2. The catalytic reduction of 3-nitrobutyl-2 *p*-aminobenzoate has been studied under a variety of conditions.

3. Reduction of 3-nitrobutyl-2 *p*-aminobenzoate with Raney nickel results in the formation of N-(*p*-aminobenzoyl)-2,3-butanolamine by rearrangement of the expected product O-(*p*-aminobenzoyl)-2,3-butanolamine.

4. Reduction of 3-nitrobutyl-2 *p*-aminobenzoate with platinum in acid solution causes the ring to be reduced without affecting the aliphatic nitro group.

5. Reduction in neutral solution with platinum results in the formation of an anesthetic oil whose structure has not been completely elucidated.

Carbanilates of α- and β-Methyl-*d*-glucosides

BY W. M. HEARON, GORDON D. HIATT AND CHARLES R. FORDYCE

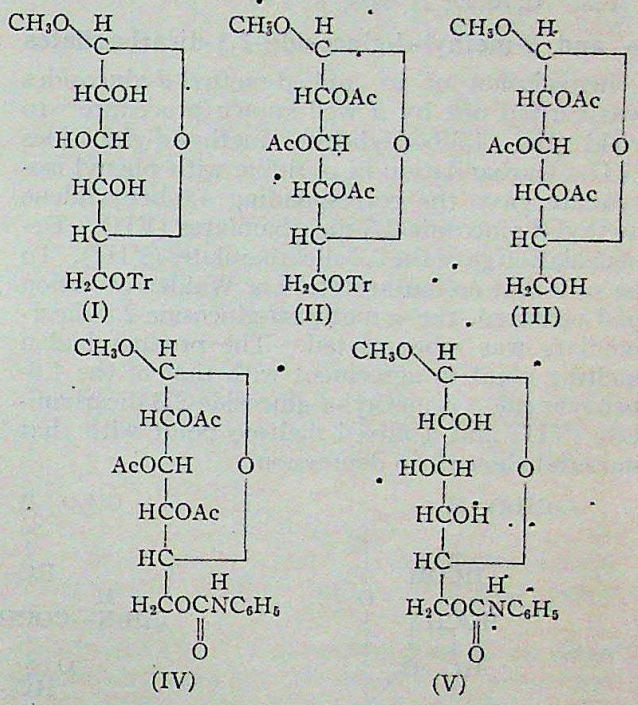
The carbanilate group imparts to its derivatives certain properties which are of considerable value for investigations in the sugar field. These include tendency toward high melting point, water insolubility, tendency to crystallize, ease of preparation under mild conditions, and stability toward mild acid and alkaline reagents.

Tessmer[1] in 1885 prepared carbanilate derivatives of certain sugar alcohols. In 1904, carbanilates of five common sugars were prepared.[2] Jolles and Botrini[3] in 1935 used the carbanilate group to prepare derivatives of four naturally occurring glucosides, and recently Wolfrom and Pletcher[4] have extended this reaction to include several of the simple methyl glucosides. The tendency for glucoside carbanilates to crystallize was utilized by Salmon and Powell.[5]

This report covers the preparation of representative mono, di, and tri carbanilates of α- and β-methyl-*d*-glucosides, and comparison of their physical properties.[5a]

α- and β-Methyl-*d*-glucoside-6-carbanilates. The tritylation[6] of α- or β-methyl-*d*-glucoside[7] gives the corresponding 6-monotrityl derivative (I). Acetylation of this gives 6-trityl methyl-*d*-glucoside 2,3,4-triacetate (II). However, both tritylation and acetylation may be carried out without isolating the intermediate.[8,9] Removal of the trityl group with complete retention of acetyl has been found by Helferich to proceed in acetic acid under the influence of dry hydrogen bromide.[10]

Methyl *d*-glucoside-2,3-4-triacetate (III) prepared by this procedure was carbanilated with phenyl isocyanate in pyridine to produce methyl *d*-glucoside-2,3,4-triacetate-6-carbanilate (IV), which upon deacetylation yielded methyl-*d*-glucoside-6-carbanilate (V). That neither mutarotation nor migration of groups had occurred during deacetylation was shown by reacetylation of the α-methyl-*d*-glucoside-6-carbanilate in good yields to a product whose melting point and



mixed melting point showed no depression with that of α-methyl-*d*-glucoside-2,3,4-triacetate-6-carbanilate.

α- and β-Methyl-*d*-glucoside-2,3,4-triacetate-6-carbanilates.—After drying at 90° for two hours, 50 g. of α-methyl-glucoside-2,3,4-triacetate was dissolved in 40 cc. of dry pyridine and treated with 24 g. (1.5 theory) of phenyl isocyanate. After the initial liberation of heat, the mixture was heated under reflux at 100° for one hour, cooled, diluted with 30 cc. of methanol to remove excess isocyanate, and heated another ten minutes. After cooling, the mixture was poured into cold water, stirred until semi-solid, and the water decanted. Recrystallized twice from hot methanol, 46 g. of α-methyl-*d*-glucoside-2,3,4-triacetate-6-carbanilate (84%) was obtained melting at 147–148°; $[\alpha]^{25}D$ +145°, ($CHCl_3$, $C = 1$).

Anal. C, 54.62; H, 5.80; N, 3.26. Calcd. for $C_{20}H_{25}O_{10}N$: C, 54.7; H, 5.68; N, 3.19.

The crude product from 10 g. of the β-isomer was isolated by warm ligroin, then recrystallized from hot methanol–water; yield, 12 g. (87.5%); m. p. 147–148°; $[\alpha]^{25}D$ +15, ($CHCl_3$, $C = 1$).

Anal. C, 54.95; H, 5.84; N, 3.29.

α- and β-Methyl-*d*-glucoside-6-carbanilates.—Five grams of α-methyl-*d*-glucoside-2,3,4-triacetate-6-carbanilate was refluxed for two hours at 100° with 100 cc. of 0.5% hydrogen chloride in methanol. After cooling, 5 g. of barium carbonate was added, the mixture shaken and filtered. The neutral solution was evaporated by means of an air stream to a sirup containing a white precipitate. The sirup was dissolved in warm ethyl acetate, and filtered from the barium chloride. The solution deposited a gelatinous precipitate which was filtered off, washed with ethyl acetate, and dried. Recrystallization from ethyl acetate yielded 2.5 g. (70%), m. p. 131–133°; $[\alpha]^{25}D$ +115° (pyridine, $C = 1$).

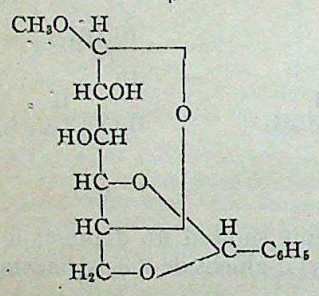
Prepared as the α-isomer, 5 g. of β-methyl-*d*-glucoside-2,3,4-triacetate-6-carbanilate with 100 cc. of 0.5% HCl in methanol gave after recrystallization from ethyl acetate, 2.7 g. (75%) melting at 144–145°. A mixed melting point with the triacetate precursor gave a 10° depression. $[\alpha]^{25}D$ −9°, (pyridine, $C = 1$).

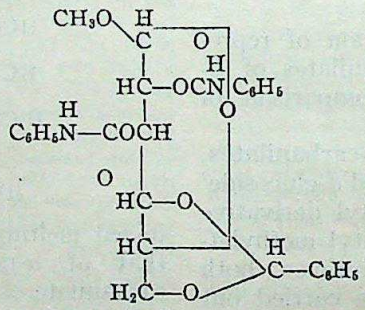
Anal. C, 53.29; H, 6.08; N, 4.44.

α- and β-methyl-*d*-glucoside-2,3-dicarbanilates

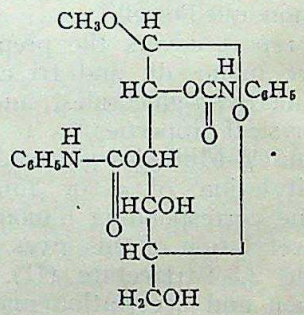
Benzalation of α- and β-methyl-*d*-glucosides was carried out by a well-known procedure[11] to yield the 4,6-benzylidene methyl-*d*-glucosides (VI). Carbanilation in pyridine with phenyl isocyanate gave the corresponding 4,6-benzylidene methyl-*d*-glucoside-2,3-dicarbanilates (VII). Debenzalation gave the 2,3-dicarbanilates (VIII). To be sure that no mutarotation or Walden inversion had occurred, the α-methyl-*d*-glucoside-2,3-dicarbanilate was rebenzalated. The product had a melting point in agreement with that of the 4,6-benzylidene α-methyl-*d*-glucoside-2,3-dicarbanilate (VII) and a mixed melting point with that material showed no depression.



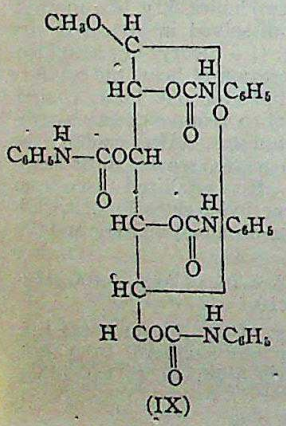
(VI)



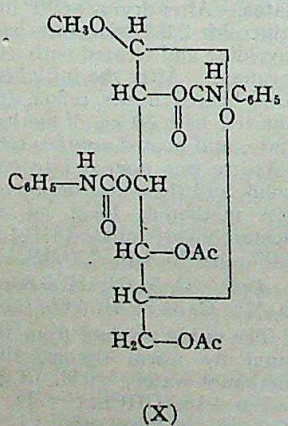
(VII)



(VIII)



(IX)



(X)

α-Methyl-*d*-glucoside-2,3-dicarbanilate (VIII) further reacted completely with phenyl isocyanate in pyridine to give the tetracarbanilate (IX) previously prepared.[4] Both α- and β-methyl-*d*-glucoside-2,3-dicarbanilates (VIII) were acetylated in pyridine with acetic anhydride to give the corresponding 4,6-diacetates (X). These materials have somewhat better crystallizing properties than their precursors, as might be expected.

4,6-Benzylidene α- and β-Methyl-*d*-glucoside-2,3-dicarbanilates.—To 20 g. of 4,6-benzylidene α-methyl-*d*-glucoside (dried at 100° for four hours) dissolved in 40 cc. of dry pyridine was added 25 g. of phenyl isocyanate (1.5 × theoretical). After the initial evolution of heat, the mixture was heated for one hour at 100° under reflux. To the cold solution was added 10 cc. of methanol to remove excess isocyanate. After ten minutes, 700 cc. of ligroin was added and the mixture stirred on a steam-bath. The oil changed to a white solid and was removed by filtration while hot. The filtrate containing methyl carbanilate was discarded. The precipitate when dried was ground to a powder, digested with hot methanol, cooled, and filtered; yield, 30 g. (92%); m. p. 216–217°; $[\alpha]^{25}D$ +40°, ($CHCl_3$, $C = 1$).

Anal. Calcd. for $C_{28}H_{28}O_8N_2$: C, 64.6; H, 5.43; N, 5.38; CH_3O, 5.96. Found: C, 64.64; H, 5.36; N, 5.39; CH_3O, 5.91.

Nine grams of 4,6-benzylidene β-methyl-*d*-glucoside in 30 cc. of dry pyridine treated with 11.4 g. of phenyl isocyanate gave 14 g. of product from hot alcohol (85%), m. p. 247–248°; $[\alpha]^{25}D$ −50°, ($CHCl_3$, $C = 1$).

Anal. C, 64.94; H, 5.40.

α- and β-Methyl-*d*-glucoside-2,3-dicarbanilates.—Thirty grams of 4,6-benzylidene-α-methyl-*d*-glucoside-2,3-dicarbanilate was refluxed for two hours with 300 cc. of 0.75% hydrogen chloride in methanol. The hydrogen chloride was removed with 36 g. of barium carbonate, the filtrate concentrated to a sirup, and after dilution with chloroform was filtered from barium chloride and concentrated to a small volume. Seeding the solution yielded a white precipitate, which was recrystallized from a mixture of ligroin and ethyl acetate (3:1); yield 23 g. (92%); m. p. 151–153°; $[\alpha]^{25}D$ +55°, (pyridine, $C = 1$).

Anal. Calcd. for $C_{21}H_{24}O_8N_2$: C, 58.3; H, 5.60; N, 6.48. Found: C, 58.51; H, 5.53; N, 6.49.

4,6-Benzylidene β-methyl-*d*-glucoside-2,3-dicarbanilate (13.5 g.) in 135 cc. of 0.75% hydrogen chloride in methanol gave 6 g. of product from hot methanol (53%); m. p. 219–220°; $[\alpha]^{25}D$ −103°, (pyridine, $C = 1$).

Anal. C, 58.2; H, 5.54; N, 6.35.

α- and β-Methyl-*d*-glucoside-2,3-dicarbanilate-4,6-diacetates.—Acetylation of α-methyl-*d*-glucoside-2,3-dicarbanilate (6.5 g.) in 50 cc. of pyridine by 30 cc. of acetic anhydride for three hours at 100° gave, after recrystallization from methanol, 5.2 g. (67%), m. p. 189–190°; $[\alpha]^{25}D$ +124° (pyridine, $C = 1$).

Anal. Calcd. for $C_{25}H_{28}O_{10}N_2$: C, 58.2; H, 5.47; N, 5.43. Found: C, 58.31; H, 5.44.

β-Methyl-*d*-glucoside-2,3-dicarbanilate (0.44 g.) in 3 cc. of pyridine, treated with 2 cc. of acetic anhydride gave 0.4 g. from hot methanol (64%), m. p. 217–218°; $[\alpha]^{25}D$ −22° (pyridine, $C = 1$).

Anal. C, 58.2; H, 5.28; N, 5.48.

α- and β-Methyl-*d*-glucoside-2,3,4-tricarbanilates

6-Trityl methyl-*d*-glucoside (I) treated with phenyl isocyanate in pyridine gave the tricarbanilate (XI) which on detritylation produced the desired 2,3,4-tricarbanilate (XII).

(XII)

6-Trityl α- and β-Methyl-*d*-glucoside-2,3,4-tricarbanilates.—To 10 g. of 6-trityl-α-methyl-*d*-glucoside, dried at 100°, in 25 cc. of dry pyridine was added 15.9 g. of phenyl isocyanate. After one hour at 100°, the mixture was washed with water, then with hot ligroin, after which it solidified. Recrystallization from benzene gave 12.8 g. (83%), m. p. 229–231°, $[\alpha]^{25}D$ +52° ($CHCl_3$, $C = 1$).

Anal. Calcd. for $C_{47}H_{43}O_9N_3$: C, 71.2; H, 5.42; N, 5.29; trityl, 30.6. Found: C, 70.89; H, 5.35; N, 5.53; trityl, 30.1.

Prepared as the α-isomer, 10 g. of 6-trityl-β-methyl-*d*-glucoside in 15 cc. of pyridine and 15 cc. of phenyl isocyanate gave from hot benzene 7.45 g. (82%), m. p. 232–234°; $[\alpha]^{25}D$ −5° ($CHCl_3$, $C = 1$).

Anal. C, 71.13; H, 5.45; N, 5.35.

α- and β-Methyl-*d*-glucoside-2,3,4-tricarbanilates.—6-Trityl α-methyl-*d*-glucoside-2,3,4-tricarbanilate (4 g.) was refluxed for two hours with 20 cc. of methanol containing 1% hydrogen chloride. After cooling, the solution was seeded with trityl methyl ether. The precipitate was filtered off and the filtrate evaporated on a steam-bath to a small volume then to dryness by means of air. The residue was dissolved in acetone diluted with benzene and the solution heated until most of the acetone had boiled off. On cooling, the product was precipitated and was filtered off. This purification was repeated twice, giving 1.5 g. (54%), m. p. 192–193°; $[\alpha]^{25}D$ +84° ($CHCl_3$, $C = 1$). The product, when dissolved in concentrated sulfuric acid, gave no yellow color and on dilution with water produced no precipitate.

Anal. Calcd. for $C_{23}H_{29}O_9N_3$: C, 60.96; H, 5.27; N, 7.62. Found: C, 60.71; H, 5.20; N, 7.56.

Following the procedure for the α-isomer, 5 g. of 6-trityl-β-methyl-*d*-glucoside-2,3,4-tricarbanilate was refluxed for three hours in 40 cc. of methanol containing 1% hydrogen chloride. During this period of heating β-methyl-*d*-glucoside-2,3,4-tricarbanilate precipitated. After cooling the precipitate was filtered, washed with methanol and dried; yield, 2.4 g. (68%), m. p. 230–232°. By repeated crystallization from ethyl acetate and acetone, the melting point could be raised to 234.5°; $[\alpha]^{25}D$ +6° (pyridine, $C = 1$).

Anal. C, 60.83; H, 5.18; N, 7.59.

Acknowledgment.—The authors wish to express their appreciation for the assistance of John T. Clarke in connection with the experimental part of this paper.

Summary

Certain mono-, di- and tricarbanilates of both α- and β-methyl-*d*-glucosides have been prepared and identified.

For preparation of glucoside derivatives these carbanilates have the advantages of being high melting, stable, readily prepared, and, in general, easily crystallized.

Unsaturated Synthetic Glycerides. VII. Preparation and Properties of Synthetic 1-Monoglycerides and Simple Triglycerides of Linoleic and Linolenic Acids[1]

BY B. F. DAUBERT AND A. R. BALDWIN[2]

During the investigation in this Laboratory on the preparation of synthetic glycerides containing unsaturated acids, it was determined experimentally that both linoleyl and linolenyl chlorides could be prepared, in good yields, from the respective debromination acids and oxalyl chloride.[3] The total diene conjugation in each acid chloride, when examined spectrophotometrically, was less than 1%. As a result of this work these acid chlorides were considered satisfactory for the synthesis of highly purified synthetic glycerides.

Since both 1-monolinolein and trilinolein have been reportedly prepared by other methods, a comparison of the properties of the compounds prepared by independent methods would serve to establish whether the glycerides synthesized, using acid chlorides as intermediates, exhibit any significant differences in properties.

The preparation of 1-monolinolein by heating dry potassium linoleate with 1-monochlorhydrin at 160° for one hour in an atmosphere of carbon dioxide was reported by Izar.[4] This same investigator also reported the synthesis of trilinolein from trichlorhydrin and potassium linoleate. In both instances, the compounds were reported as oily liquids but were not further characterized. More recently Black and Overley[5] reported the synthesis of 1-monolinolein and trilinolein by debromination of the respective 1-(9,10,12,13-tetrabromo)-stearin and tri-(9,10,12,13-tetrabromo)-stearin; the latter compounds were synthesized using tetrabromostearyl chloride. These investigators indicated that possible configurational changes could be avoided when de-

bromination of the glycerides was delayed until the final step of the synthesis. Later, Wheeler, Riemenschneider and Sando[6] reported the preparation of trilinolein by direct esterification of glycerol with linoleic acid. While iodine values and saponification equivalents of the latter two independently prepared trilinoleins agreed well with theoretical values, the melting points and refractive indices were significantly different. To clarify the obvious discrepancies in these two physical constants we have prepared trilinolein, by an accepted method of synthesis, using linoleyl chloride and glycerol. Analytical constants of the resulting product indicated a high degree of purity. The refractive index and capillary melting point were essentially the same as those reported by Wheeler, *et al.*[6] Thermometric measurements, by a method described previously,[7] verified the existence of the two polymorphic forms reported by the latter investigators.

Experimental

Preparation of Intermediates.—Linoleic and linolenic acids were prepared from tetrabromostearic acid (m. p. 115°) and hexabromostearic acid (m. p. 186°), respectively, by debromination in ether solution according to the method of Frankel and Brown.[8]

Linoleyl and linolenyl chlorides were prepared from the respective acids by the method described previously.[3] In each case, the resulting chlorides had the same constants as those reported.

Preparation of 1-Monolinolenin.—To a cooled solution of acetone-glycerol (36 g.) in quinoline (23 g.) and dry chloroform (40 ml.) there was added slowly linolenyl chloride (43 g.). The mixture was allowed to stand at room temperature for four hours. After the addition of dry peroxide-free ether, the solution was washed carefully and successively with cold 0.5 *N* sulfuric acid, 5% potassium carbonate solution and distilled water. The ether solution was then dried over anhydrous sodium sulfate and after filtration it was then reduced in volume to *ca.* 100 ml., *in vacuo*, at room temperature. The solution was transferred to a liter beaker and cooled to approximately 0° in an ice-bath. Hydrochloric acid (100 ml.) was poured into the solution slowly with constant stirring. After allowing the solution to stand for thirty minutes, ice water (500 ml.) was added, the separated product dissolved in peroxide-free ether, and the solution was washed with distilled water until free of mineral acid. The ether solution was dried over anhydrous sodium sulfate and after filtration it was reduced to a volume of *ca.* 75 ml. After the addition of an equal volume of petroleum ether, it was cooled to −20° for twenty-four hours. The 1-monolinolenin, which separated as a white crystalline mass, was recrystallized several times from the same mixture of solvents: melting point (capillary tube)[9] 16.0–17.0°; iodine value (Wijs) 214.8 (calcd. 216.2); molecular weight, 351.6 (calcd. 352.5); $n^{50.0}D$ 1.47589 (dn/dt = 0.00039).

1-Monolinolein was prepared in a similar manner and had the constants: m. p. (capillary tube) 14.0–15.0°; iodine value (Wijs) 142.7 (calcd. 143.3); $n^{20.0}D$ 1.47682 (dn/dt = 0.00038).

Preparation of Trilinolenin.—Glycerol (1 g.) was dissolved in a mixture of quinoline (6 g.) and dry chloroform (30 ml.) and to the solution there was added slowly linolenyl chloride (10 g.). The mixture was heated on a steam-bath for two hours, and after cooling it was dissolved in petroleum ether (300 ml.). The solution was then washed successively with cold 0.5 *N* sulfuric acid, 5% potassium carbonate solution, distilled water and dried over anhydrous sodium sulfate. The solvent was removed completely, *in vacuo*, at room temperature and the liquid residue was dissolved in 95% ethyl alcohol. Crystallization of the trilinolenin from the solution was induced at −60°. Several crystallizations from a mixture of 95% alcohol and ether (2:1) yielded a product of a high degree of purity. The trilinolenin was a colorless liquid at room temperature: melting point (capillary tube) −23.0 to −24.0°; iodine value (Wijs) 261.4 (calcd. 261.6); molecular weight, 866 (calcd. 873); $n^{40.0}D$ 1.48190 (dn/dt = 0.00040).

Trilinolein was prepared in a similar manner and had the constants: m. p. (capillary tube) −13.0°; iodine value (Wijs) 172.8 (calcd. 173.3); $n^{50.0}D$ 1.46815 (dn/dt = 0.00039).

Bromination of Monoglycerides and Triglycerides.—The bromination procedure, given in detail for trilinolenin, was essentially the same for 1-monolinolein, 1-monolinolenin and trilinolein.

Trilinolenin (2 g.) was dissolved in cold petroleum ether (50 ml.). Bromine was added dropwise to the solution, with constant stirring, until the liquid assumed a definite orange color. During the addition of the bromine a gummy mass separated. After decantation of the supernatant liquid, the gummy mass was washed repeatedly with cold petroleum ether. During this treatment practically all of the color was removed. The bromides were then dissolved in a small volume of warm dioxane and on the addition of an equal volume of petroleum ether, crystalline bromides separated. After repeated crystallizations from the same mixture of solvents, the product was dried in a vacuum desiccator; melting point 150–151°.

Anal. Calcd. for $C_{57}H_{92}O_6Br_{18}$; Br, 62.22. Found: Br, 62.18, 62.15.

Bromination of 1-monolinolenin produced a crystalline bromide melting at 172°.

Anal. Calcd. for $C_{21}H_{36}O_4Br_6$: Br, 57.63. Found: Br, 57.60, 57.55.

Melting points of the crystalline bromides obtained from 1-monolinolein and trilinolein were 101.5° and 81.0°, respectively, and were in agreement with those previously reported.[5,6]

Spectrophotometric Analyses.—Each synthetic glyceride was examined for total diene and triene conjugation using a Beckmann Quartz Spectrophotometer, Model DU. In each product, the total diene conjugation was less than 1% and the triene conjugation was negligible. The glyceride exhibiting the least conjugation, oddly enough, was trilinolenin. The absence of a greater amount of conjugation seems to indicate that the synthesis of glycerides containing linoleic and linolenic acids through the acid chlorides does not materially affect the position of the double bonds. It should be borne in mind, however, that the acids present in the synthetic glycerides, while not significantly different from the original debromination acids, may not be identical with the naturally occurring acids.[8]

Discussion

In the warming curves for trilinolein (Fig. 1) it may be observed that Form II melts at −45.6° and Form I at −12.9°. In the thermometric measurements[10] on a bulk sample (1.0 to 1.5 g.), cooling at −75° for twenty to thirty minutes was necessary for its solidification into Form II. Since the temperature of melting was so low, visual observation of the transition of Form II to Form I was possible during warming of the

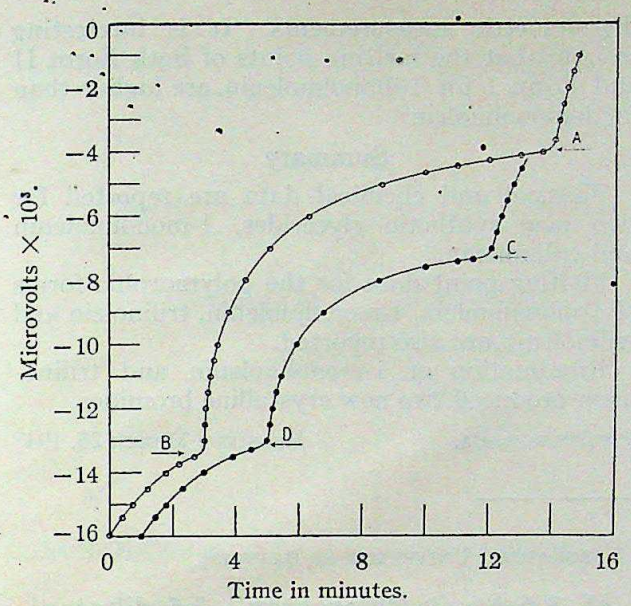

Fig. 1.—Warming curves for trilinolein and trilinolenin: trilinolein—A, 3950 microvolts = −12.9°; B, 13370 microvolts = −45.6°; trilinolenin—C, 7300 microvolts = −24.2°; D, 13100 microvolts = −44.6°.

sample at room temperature. The time required for complete melting of Form II and solidification into Form I depended on the rate of warming. To permit the change to occur sufficiently slowly for complete visual observation, the triglyceride in a small vial was cooled at −75° for thirty minutes in a dry-ice-bath; the temperature was measured with a calibrated thermel and potentiometer. At the end of thirty minutes the glyceride had completely solidified. After the vial was removed from the bath and transferred quickly to a small transparent Dewar flask cooled to −60° on the inside, it was allowed to warm spontaneously at room temperature. Complete transition of Form II into Form I, under these conditions, required approximately three minutes. In the photograph (Fig. 2) it may be seen that an actual melting of Form II occurred at the surface of the glyceride (heat leakage into the sample occurred faster through the thermel than through the sides of the vacuum flask). The progressive melting of Form II and the solidification of the liquid into Form I can be followed in the same photograph. In vials 2, 3, 4, 5 and 6, three phases are observable, solid Form II, melted Form II and solid Form I. While melting of Form II could be demonstrated in small capillary tubes on immersing them in baths of the required temperature, the evidence in Fig. 2 is much more convincing. It may be concluded, therefore, that the transition of Form II to Form I in a bulk sample of trilinolein is definitely accompanied by melting.

Transition Forms of Trilinolein

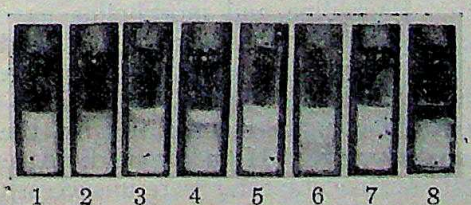

Fig. 2.—Progressive melting of the polymorphic forms of trilinolein: 1, Form II solidified at −75°; 2, Form II beginning to melt; 3, solidification of melted Form II to Form I; 4, 5, 6, progressive stages of transition; 7, completely solid Form I; 8, melting of Form I; m. p. Form II, −45.6°; m. p. Form I, −12.9°.

When the sample of trilinolein was cooled quickly to −60° in a dry-ice-bath no solidification occurred. But on removing the supercooled liquid from the bath and quickly transferring it to the small Dewar flask again cooled to −60° on the inside and allowing it to warm as before, the glyceride solidified at −45.6° in Form I which later melted normally at −12.9°.

Warming curves in Fig. 1 show that trilinolenin also may exist in at least two different forms. Cooling of a bulk sample in a similar manner to trilinolein causes solidification in Form II. Form II melts at −44.6° and Form I at −24.2°. While warming curves only are shown in Fig. 1, Form II was indicated also on cooling curves. The transition of Form II to Form I was not as sharply defined as for trilinolein and occurred much more rapidly.

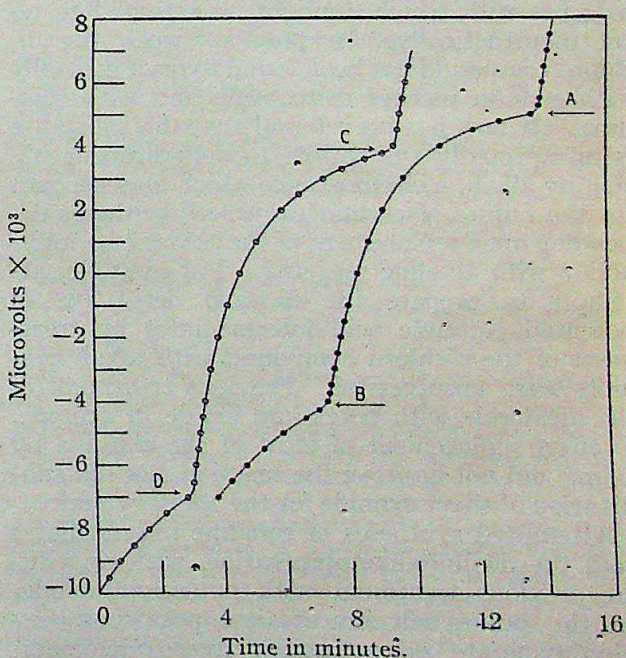

Fig. 3.—Warming curves for 1-monolinolein and 1-monolinolenin: monolinolenin—A, 5000 microvolts = 15.7°; B, 4125 microvolts = −13.5°; monolinolein—C, 3900 microvolts = 12.3°; D, 6875 microvolts = −22.8°.

Warming curves in Fig. 3 indicate the existence of two polymorphic forms for 1-monolinolenin, Form II melting at −13.5° and Form I at 15.7°. As in the case of the triglycerides, Form II was observed visually to melt in bulk sample and sub-

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

sequently to solidify as Form I at −13.5°. This unsaturated monoglyceride, previously prepared in this Laboratory by Dr. T. R. Wood and one of us (A. R. B.), when exposed for a short time to air at room temperature, quickly developed a film and a decrease in iodine value. The rates of oxidation of the glycerides reported in this paper are being studied and will be reported at a later date.

Two polymorphic forms (Fig. 3) were also found for 1-monolinolein, Form II melting at −22.8 and Form I at 12.3°. While other forms were anticipated for each 1-monolinolein and 1-monolinolenin on the basis of previous experience, evidence for these forms could not be found from thermometric measurements. It is interesting to note that the melting points of both Form II and Form I for 1-monolinolenin are higher than for 1-monolinolein.

Summary

Physical and chemical data are reported for two new synthetic glycerides, 1-monolinolenin and trilinolenin.

Melting point data for the polymorphic forms of 1-monolinolein, 1-monolinolenin, trilinolein and trilinolenin are also reported.

Bromination of 1-monolinolenin and trilinolenin produced two new crystalline bromides.

Synthetic Amino Acids. Some Reactions of 3,6-*bis*-(β-Chloroethyl)-2,5-diketopiperazine

BY H. R. SNYDER AND M. E. CHIDDIX[1]

In a continuation of a study[2] of the preparation of amino acids from the easily available 3,6-*bis*-(β - chloroethyl) - 2,5 - diketopiperazine[2b] (I), this substance has been treated with a number of reagents with which it might be expected to react metathetically. In previous work the dichloro compound has been found to react normally with sodium methyl mercaptide and with thiourea. It now has been found that the substance is unexpectedly susceptible to dehydrohalogenation by alkali, a circumstance which may account for the failure of certain projected syntheses depending upon replacement of the chlorine by interaction with alkaline reagents. For example, attempts to prepare the dicyano derivative (a potential glutamic acid intermediate) by treatment of the dichloro compound with alkali cyanides were unsuccessful. Previous treatment of the dichloride with potassium iodide in acetone, to effect replacement of most of the chlorine by iodine, did not improve the reaction, nor did substitution of silver cyanide for the alkali cyanide.

Attempted syntheses of canaline intermediates from the dichlorodiketopiperazine, with or without previous treatment with potassium iodide, and the sodium salt of acetoxime, potassium benzohydroxamate or potassium hydroxylaminedisulfonate likewise were unsuccessful, despite the fact that the closely related reaction of α-benzamido-γ-iodobutyric acid and potassium benzohydroxamate is reported to occur readily.[3]

The dichlorodiketopiperazine reacted readily with sodium hydroxide in refluxing ethanol to form the divinyldiketopiperazine (II). When the chloro compound was present in slight excess the reaction mixture became neutral within twenty to thirty minutes. Although some of the experiments referred to above were carried out after the properties of the divinyl compound were known, the substance was definitely isolated as a product only from the reactions with the sodium salt of acetoxime. However, some of the impure reaction products, from which no unchanged dichlorodiketopiperazine could be recovered, did yield the hydrochloride of α-amino-γ-butyrolactone when subjected to hydrolysis with hydrochloric acid. Both the *bis*-chloroethyl- and divinyldiketopiperazines are converted to the aminolactone by this treatment. In one of the attempted reactions between the dichloro compound and potassium silver cyanide the product isolated was 3,6-*bis*-(β-hydroxyethyl)-2,5-diketopiperazine. This substance also would yield the aminolactone hydrochloride on hydrolysis with hydrochloric acid.

Certain replacements of the halogen atoms in the dichlorodiketopiperazine were effected without difficulty. Piperidine and morpholine gave the corresponding *bis*-tertiary amines (IV and V). The sodium salt of benzylmercaptan reacted to give the *bis*-benzylthioldiketopiperazine (VI). Potassium thiocyanate reacted to give the *bis*-thiocyano derivative (VII) in low yield. Attempts to alkylate acetoacetic ester were unsuccessful.

Experimental

3,6-*bis*-(β-N-Morpholinoethyl)-2,5-diketopiperazine (IV).—A mixture of 5 g. of the dichloride (I) and 15 cc. of morpholine was heated on the steam-bath to 85°. A clear dark solution resulted and the temperature rose to 125°. The mixture was allowed to cool and the crystals were separated by dilution of the liquid portion with ether

and filtration. The solid was extracted with two 50-cc. portions of chloroform, and the residue from evaporation of this solvent was recrystallized from 95% ethanol. The yield of the product, m. p. 229–232° (cor.), was about 40%.

Anal. Calcd. for $C_{16}H_{28}N_4O_4$: N, 16.45. Found: N, 16.48.

3,6-*bis*-(β-N-Piperidinoethyl)-2,5-diketopiperazine (V) was prepared in much the same way from 2 g. of the dichloride and 5 g. of piperidine. Piperidine hydrochloride and piperidine were separated from the product by water extraction, and the substance was purified by recrystallization from 60% ethanol. It melted at 242–243° (cor.).

Anal. Calcd. for $C_{18}H_{32}N_4O_2$: C, 64.20; H, 9.59. Found: C, 64.26; H, 9.63.

3,6-*bis*-(β-Thiocyanoethyl)-2,5-diketopiperazine (VII).—A mixture of 10 g. of the dichloride (I), 10 g. of potassium thiocyanate and 100 cc. of acetone was shaken mechanically at room temperature for forty hours and then heated under reflux for twenty hours. The hot mixture was filtered and the residue from the evaporation of the filtrate was extracted with hot water and recrystallized from 33% acetic acid. The yield of product, m. p. 207–208° (cor.), was about 15%.

Anal. Calcd. for $C_{10}H_{12}N_4O_2S_2$: C, 42.24; H, 4.23. Found: C, 42.51; H, 4.45.

3,6-*bis*-(β-Benzylthiolethyl)-2,5-diketopiperazine (VI).—A mixture of 5 g. of the dichloride and 100 cc. of an absolute ethanol solution containing 3.25 g. of sodium ethoxide and 6 g. of benzyl mercaptan was heated under reflux for one hour. The hot solution was filtered and the filtrate was cooled. The crystals were separated and the mother liquor was used in a second hot extraction of the original residue. The process was repeated until no additional crop was obtained. The product so obtained melted at 173–174° (cor.) after recrystallization from ethanol (lit.,[4] 165°, 176°). The yield was about 50%.

Anal. Calcd. for $C_{22}H_{26}N_2O_2S_2$: C, 63.73; H, 6.33. Found: C, 63.65; H, 6.49.

3,6-Divinyl-2,5-diketopiperazine (II).—A mixture of 88 g. (0.37 mole) of the dichloride (I) and a cold solution of 26.8 g. (0.67 mole) of sodium hydroxide in 400 cc. of absolute ethanol was stirred mechanically and gradually heated to boiling over a period of about thirty minutes. After being heated under reflux for twenty minutes, the hot mixture was filtered and the filtrate was distilled to dryness under diminished pressure. The yellow crystalline residue was dissolved in 100 cc. of hot chloroform and the solution was filtered. Dilution with 100 cc. of hot carbon tetrachloride and cooling caused crystallization. The solid was collected and washed with a mixture of chloroform and carbon tetrachloride (volume ratio, 1:2), and then with a mixture of ethanol and ether (volume ratio, 1:3). Evaporation of the filtrate and washings gave an additional crop which was treated in the same way. For complete removal of the solvents it was necessary to dry the product under a pressure of 2 mm. or less. The yield of pure, colorless 3,6-divinyl-2,5-diketopiperazine was 38 g. (62%). In ordinary melting point determinations the material darkened slowly and decomposed at temperatures above 240°; however, it melted at 192.5° (cor.) to a clear liquid when the sample tube was immersed in a bath at this temperature. The yields were inferior when other ratios of reactants were used or when sodium ethoxide was substituted for the hydroxide.

Anal. Calcd. for $C_8H_{10}N_2O_2$: C, 57.81; H, 6.06. Found: C, 58.07; H, 6.24.

Hydrochloride of α-Amino-γ-butyrolactone (III).—A solution of 4 g. of the divinyldiketopiperazine in 30 cc. of a mixture of equal volumes of concentrated hydrochloric acid and water was heated on the steam cone for eight hours. The solution was concentrated under diminished pressure and the sirupy residue was dissolved in 50 cc. of water. The resulting solution was concentrated to a colorless crystalline residue. This was recrystallized from 95% ethanol. The lactone hydrochloride weighed 3.9 g. (59%) and melted at 199–200° (cor.) (lit.,[5] 198–200°).

Anal. Calcd. for $C_4H_8ClNO_2$: C, 34.92; H, 5.86. Found: C, 35.15; H, 6.08.

The same product was obtained when the dichlorodiketopiperazine was refluxed for two and one-half hours with 15 volumes of concentrated hydrochloric acid. The reaction mixture was diluted with water and worked up as above, to give a product of the same analysis and melting point.

Attempted Preparation of 3,6-*bis*-(β-Iodoethyl)-2,5-diketopiperazine.—Reaction occurred when the dichlorodiketopiperazine was refluxed with an acetone solution containing a slight excess of sodium iodide. The crude iodide decomposed at about 240°. A solvent for recrystallization was not found, and the pure substance was not isolated. A sample recrystallized from methylcellosolve (with apparent decomposition in the hot solvent) was free of inorganic materials and had a carbon content of 26.85% (calcd. for the diiodide, 22.75; for I, 40.0%).

Attempted Reactions of the Dichlorodiketopiperazine (I) with Inorganic Cyanides, with Derivatives of Hydroxylamine and with the Sodium Derivative of Acetoacetic Ester.—Numerous experiments with each reagent were carried out, usually with both the dichloride and the crude diiodide. The divinyldiketopiperazine (II) was definitely

isolated (identified by m. p. and mixed m. p.) from reactions of the dichloride and the sodium salt of acetoxime in absolute ethanol. The solid product isolated from a similar reaction with potassium benzohydroxamate appeared to be impure II; the oily products gave only III on hydrolysis with hydrochloric acid, as did similar oils obtained from reactions with potassium hydroxylaminedisulfonate. Most of I was recovered from attempted reactions with sodium cyanide in acetone or ethanol or potassium cyanide in acetone; dark solutions resulted when ethanol was used with potassium cyanide and no pure product could be isolated. Aqueous potassium silver cyanide and I gave 3,6-*bis*-(β-hydroxyethyl)-2,5-diketopiperazine (identified by m. p. and analysis). Treatment of the crude diiodide with ammoniacal silver cyanide, followed by hydrolysis with hydrochloric acid, gave only III. No pure substance was isolated from the reactions with sodio acetoacetic ester.

Summary

3,6-*bis*-(β-Chloroethyl)-2,5-diketopiperazine is dehydrohalogenated rapidly by treatment with ethanolic sodium hydroxide. The reaction provides a convenient preparation of 3,6-divinyl-2,5-diketopiperazine. The only reaction observed when the dichlorodiketopiperazine is treated with the sodium salt of acetoxime is dehydrohalogenation. The readiness with which this reaction occurs probably accounts for the failure of replacement reactions with other hydroxylamine derivatives, with alkali cyanides, and with sodio acetoacetic ester. Replacement of the chlorine atoms of the dichlorodiketopiperazine occurs readily when the substance is treated with sodium benzyl mercaptide, morpholine or piperidine, and less readily with potassium thiocyanate.

Non-Markownikoff Addition in Reactions of 3,6-Divinyl-2,5-diketopiperazine

BY H. R. SNYDER AND M. E. CHIDDIX[1]

The dehydrohalogenation of 3,6-*bis*-(β-chloroethyl)-2,5-diketopiperazine[1a] proceeds under such mild conditions as to suggest an analogy to reactions of β-halocarbonyl compounds. In this paper are recorded some reactions of the dehydrohalogenation product (3,6-divinyl-2,5-diketopiperazine, I) which show its properties to resemble those of α,β-unsaturated carbonyl compounds.

The divinyldiketopiperazine (I) was found to undergo the addition of hydrogen chloride readily. The product so obtained had physical properties identical with those of the 3,6-*bis*-(β-chloroethyl)-2,5-diketopiperazine (II) from which the divinyl compound was prepared. Since the yield of the addition product was good, and since the divinyl compound was halogen-free, it is not possible that the dichloro compound isolated was present as an impurity in the unsaturated substance (I). That the addition product is indeed 3,6-*bis*-(β-chloroethyl)-2,5-diketopiperazine was proved by converting it to the known methionine anhydride (III)[2] and the known 3,6-*bis*-(β-benzylthiolethyl)-2,5-diketopiperazine (IV).[3] The same derivatives were prepared from the original dichloro compound as well, and mixed melting point determinations were made. In addition, both samples of methionine anhydride were hydrolyzed and samples of benzoylmethionine (V) were prepared. All these derivatives had approximately the melting points ascribed to them in the literature, and in no instance was there a depression of melting point on mixing of the derivatives from the two sources. The racemic and *meso* forms of S-benzylhomocysteine anhydride (IV) have been characterized[3] as melting at 165 and 176°, respectively. The samples obtained in this work melted at about 175°, so it seems likely that the diketopiperazine II is the *meso* form, or that this form preponderates if both it and the racemic variety are present in the samples of II. The only discrepancy in melting points was encountered with *dl*-S-benzylhomocysteine (VI); the sample prepared by hydrolysis of IV melted with decomposition at about 230°, whereas the recorded[4] melting point is 190–191°. The sample of VI had the expected composition.

The divinyldiketopiperazine (I) underwent addition of hydrogen bromide to give the dibromo analog of II. The 3,6-*bis*-(β-bromoethyl)-2,5-diketopiperazine (VII) so formed was identified by conversion to methionine anhydride (III). The dibromodiketopiperazine decomposed readily. It dissolved slowly in hot alcohol or hot water to give strongly acid solutions. In an experiment in which a sample was heated with water the amount of acid generated was determined by titration; it corresponded to a neutral equivalent of 181, as compared to the theoretical value of 164 calculated on the assumption that one molecule of VII yields two molecules of hydrogen bromide. The formation of the acid may be due either to dehydrohalogenation or to hydrolysis.

Treatment of the divinyldiketopiperazine with hydrogen sulfide gave an addition product containing two atoms of sulfur. Attempts to direct the reaction by carrying it out in the dark, to favor Markownikoff addition, and under strong

ultraviolet irradiation, to favor non-Markownikoff addition,[5] were unsuccessful, the same product being obtained in all instances. The reaction product was hydrolyzed to homocysteine thiolactone hydrochloride (IX) in good yield, so evidently the addition of hydrogen sulfide occurred in the non-Markownikoff fashion. The addition product, although of analytical purity, melted with decomposition at a temperature much lower than the recorded[3] melting point of either the *meso* or racemic homocysteine anhydride. It is possible that the material is a mixture of the two forms.

The non-Markownikoff addition observed in these instances cannot be ascribed to an effect of peroxides, since reactions of hydrogen chloride and olefins are not susceptible to such influence. An explanation can be based on the assumption that the group —CH(NH)CO— of the diketopiperazine ring polarizes the double bond of the attached vinyl group by withdrawing electrons from it. The reactive form thus would be $\left[\overset{\delta+}{CH_2}=\overset{\delta-}{CH}-CH(NH)CO\right]_2$. The effect of the diketopiperazine ring on the double bond is similar to that of a *m*-directing group in producing the polarization.[6] On this basis the addition of halogen acid is to be regarded as strictly comparable to the non-Markownikoff addition of hydrogen bromide to divinylsulfone,[7] in which the addition to the double bond is directed by a *m*-orienting group which cannot participate in 1,4-addition. It is of interest to note that in the nitration of phenylglycine the side-chain is strongly *m*-directing.[8] During the occurrence of this reaction the side-chain must be in the form of the salt —CH(NH$_3^+$)CO$_2$H. It is not surprising that this group should be *m*-directing, inasmuch as the group —CH$_2$NH$_3^+$ is *m*-orienting[6] and incorporation of the carbonyl group would be expected to increase its effectiveness in this regard. The addition of halogen acids to the divinyldiketopiperazine (I) may involve preliminary salt formation. However, the non-Markownikoff addition of hydrogen sulfide in the absence of strong acids and in the absence of ultraviolet irradiation and the extraordinary ease[1a] of dehydrohalogenation of the dichlorodiketopiperazine (II) suggest that the free diketopiperazine ring has a strong polarizing effect on groups attached at the 3 and 6 positions.

Experimental

(1) **Addition of Hydrogen Chloride to 3,6-Divinyl-2,5-diketopiperazine.**—Dry hydrogen chloride was bubbled into a solution of 17.5 g. of 3,6-divinyl-2,5-diketopiperazine[1a] in 150 cc. of 100% acetic acid until the gain in weight was 9.0 g. The mixture was allowed to stand for one hour, after which period it was heated on the steam-bath until a clear solution resulted. The solution was allowed to cool and the crude 3,6-*bis*-(β-chloroethyl)-2,5-diketopiperazine (II) was collected and washed with water, alcohol, and ether. It weighed 14.9 g. (59%) and melted at 233–234° (cor., with decomp.; lit.,[2] 231–232°); the melting point was not lowered by admixture of authentic II. The divinyldiketopiperazine was regenerated by heating the hydrogen chloride addition product with alcoholic sodium hydroxide.[1a]

(2) **Preparation of Methionine Anhydride (III).**—The product from the preceding experiment was treated with sodium methyl mercaptide according to the procedure described previously.[2] Methionine anhydride melting at 230–231° (lit.,[2] 231–232°) was obtained and its melting point was not depressed by admixture of an authentic sample.

Anal. Calcd. for $C_{10}H_{18}N_2O_2S_2$: C, 45.77; H, 6.92. Found: C, 46.26; H, 7.13.

(3) ***dl*-Methionine and Benzoyl *dl*-Methionine.**—The methionine anhydride so obtained was hydrolyzed as described previously. The methionine was analyzed.

Anal. Calcd. for $C_5H_{11}NO_2S$: C, 40.25; H, 7.43. Found: C, 40.71; H, 7.51.

Digitized by Arya Samaj Foundation Chennai and eGangotri

Benzoyl *dl*-methionine was prepared by the procedure of Windus and Marvel.[9] It melted at 151–151.5° (cor., lit.,[9] 143–145°).

Anal. Calcd. for $C_{12}H_{15}NO_3S$: C, 56.90; H, 5.97. Found: C, 56.86; H, 6.20.

The derivative prepared from authentic methionine melted at 149–150.5° (cor.) and a mixture of the two samples also melted at this temperature.

(4) **Preparation of 3,6-*bis*-(β-Benzylthiolethyl)-2,5-diketopiperazine (IV).**—The previously described method[1a] was used with the hydrogen chloride addition product obtained in (1). The product melted at 177–178° (cor.) and this melting point was not depressed by admixture of IV prepared from authentic II.[1a]

Anal. Calcd. for $C_{22}H_{24}N_2O_2S_2$: C, 63.73; H, 6.33. Found: C, 64.27; H, 6.34.

(5) **Hydrolysis of 3,6-*bis*-(β-Benzylthiolethyl)-2,5-diketopiperazine.**—A mixture of 2 g. of the anhydride (IV) prepared in (4), 15 cc. of water and 45 cc. of concentrated hydrochloric acid was heated under reflux for seven hours, then filtered. The filtrate was diluted with 100 cc. of water and evaporated to dryness under diminished pressure. The white solid residue was dissolved in 20 cc. of hot absolute ethanol; the solution was clarified with charcoal and treated with 2 cc. of pyridine. The solid which separated was collected and recrystallized from water. It melted at 226–230° (cor., with dec.; lit.[4] 190–191°).

Anal. Calcd. for $C_{11}H_{15}NO_2S$: C, 58.64; H, 6.72. Found: C, 58.98; H, 6.75.

Exactly the same results were obtained in the hydrolysis of the anhydride[1a] prepared from authentic 3,6-*bis*-(β-chloroethyl)-2,5-diketopiperazine. The yield was about 75% in both instances.

(6) **3,6-*bis*-(β-Bromoethyl)-2,5-diketopiperazine (VII).**—A cold solution of 2.4 g. of dry hydrogen bromide in 6 cc. of glacial acetic acid was added slowly to a cold, stirred solution of 1.12 g. of the divinyldiketopiperazine (I) in 7 cc. of glacial acetic acid. The solution was allowed to stand without cooling for one hour, during which time crystallization occurred. The mixture was stirred in 80 cc. of cold water and the solid was collected and recrystallized from glacial acetic acid. The product (VII) melted at 221–222° (cor., with dec.) and was obtained in yields of about 50%.

Anal. Calcd. for $C_8H_{12}Br_2N_2O_2$: C, 29.27; H, 3.69. Found: C, 29.74; H, 3.69.

A sample of 0.20 g. of VII was dissolved in 20 cc. of water by heating on the steam-bath for five minutes. The clear solution was cooled and titrated with 0.0445 *N* sodium hydroxide and phenolphthalein. The end-point was fugitive. The partly neutralized solution was heated for a few minutes longer, then cooled and titrated to a permanent end-point (23.85 cc. of the standard solution required).

A mixture of 0.4 g. of the dibromo compound (VII) and a solution of 0.186 g. of sodium methyl mercaptide in 15 cc. of absolute ethanol was shaken mechanically for five hours, then allowed to stand three hours, and finally heated to boiling until a clear solution resulted. The crystals which separated when the solution was cooled were collected, washed with water, and recrystallized from 10 cc. of absolute ethanol. The yield of methionine anhydride (III), m. p. 231–232° (cor.), was about 30%; the melting point was not depressed by admixture of authentic (III).

Anal. Calcd. for $C_{10}H_{18}N_2O_2S_2$: C, 45.77; H, 6.92. Found: C, 46.09; H, 6.99.

(7) **Addition of Hydrogen Sulfide to 3,6-Divinyl-2,5-diketopiperazine.**—A solution of 10 g. of the divinyldiketopiperazine (I) and 2 cc. of glacial acetic acid in 250 cc. of absolute ethanol was saturated at 0° with hydrogen sulfide. The container was closed by a wired-on stopper and the mixture allowed to stand at room temperature overnight. A crystalline, light green solid was collected, washed with ethanol, and dried in the air (wt., 6.94 g.). The mother liquor was resaturated with hydrogen sulfide and allowed to stand as before to give a second crop of 1.0 g. of light blue crystals. The combined product was nearly colorless after recrystallization from ethanol; m. p. 185–186° (cor., with dec.).

Anal. Calcd. for $C_8H_{14}N_2O_2S_2$: C, 41.01; H, 5.98. Found: C, 41.14; H, 6.13.

The substance dissolved in 2.5% aqueous sodium hydroxide and could be regenerated by saturation of the solution with carbon dioxide. It gave a positive sulfhydryl test with sodium nitroprusside.

In similar experiments in which acetic acid was not added to the mixtures the reaction was very slow, requiring about four days to proceed to a 50% yield. No difference could be detected between runs carried out in quartz apparatus under an ultraviolet lamp and those carried out in the dark. The crude products from these runs were of darker green color than that described above, but the purified materials were nearly colorless.

(8) **Homocysteine Thiolactone Hydrochloride.**—A solution of 4 g. of the dithiol (VIII) in 60 cc. of concentrated hydrochloric acid was heated under reflux for two hours, then diluted with 100 cc. of water and evaporated to dryness under diminished pressure. The residue was dissolved in 150 cc. of water and after decolorization the solution was again evaporated under diminished pressure. The residue was washed well with absolute ethanol; the thiolactone salt (IX) weighed 3.2 g. and melted at 199–200° (lit.,[10] 200–201°).

Anal. Calcd. for C_4H_8ClNOS: C, 31.28; H, 5.25. Found: C, 31.82; H, 5.64.

Summary

3,6-Divinyl-2,5-diketopiperazine undergoes addition of hydrogen chloride, hydrogen bromide and hydrogen sulfide in the manner opposite to that predicted from Markownikoff's rule. In this regard the double bonds resemble that of an α,β-unsaturated carbonyl compound. The abnormal orientation may be attributed to polarization of the double bond by the attached —CH(NH)CO— group of the diketopiperazine ring.

Saponins and Sapogenins. XXIV. Norechinocystenol-A and Norechinocystenone-A

BY G. H. HARRIS AND C. R. NOLLER

It has been reported previously[1] that Clemmensen reduction of norechinocystenone-B[2] or of norechinocystendione gives a hydrocarbon identical with oleanene III, obtained by Winterstein and Stein[3] from oleanolic acid. This was the first direct indication that echinocystic acid and oleanolic acid have the same carbon skeleton. Since the preparations of oleanene III from echinocystic acid and from oleanolic acid involve a Clemmensen reduction, which Winterstein and Stein[3] have shown produces a molecular rearrangement, it was considered desirable to attempt to interrelate the two compounds by other methods.

In the monoacetyl derivative of methyl echinocystate prepared by direct esterification, the hydroxyl group acetylated is the one which is not "β" to the carboxyl group[4] and apparently occupies the same position in the carbon skeleton as the hydroxyl group in oleanolic acid, as evidenced by the fact that both echinocystic acid and oleanolic acid give hydroxyagathalene on selenium dehydrogenation.[5] Oxidation of this monoacetyl methyl echinocystate gives the monoacetyl monoketo ester.[4] If the carbonyl group of the keto ester could be replaced by a methylene group one should obtain a compound identical or isomeric with acetyl methyl oleanolate. Wolff–Kishner reduction seemed the most promising since it would avoid the isomerizations taking place on Clemmensen reduction. All attempts to prepare a semicarbazone failed so a direct reduction with hydrazine hydrate and sodium ethylate[6] was carried out. Analysis of the product and the formation and analysis of an acetyl derivative showed that not only had the carbonyl group been reduced to methylene but the carboxyl group was eliminated and the acetyl group alcoholyzed. To confirm this conclusion, acetylnorechinocystenolone[4] was subjected to the same treatment and an identical product obtained. This compound, which has been named "norechinocystenol-A," is isomeric with oleanol[7] but not identical with it.

It was conceivable that norechinocystenol-A is epimeric with oleanol. Accordingly the former compound was oxidized to the ketone and compared with oleanone but again the two compounds were found to be different. The new compound has been named "norechinocystenone-A." The difference in structures may arise from a difference in constitution or configuration of the carbon skeletons of oleanolic acid and echinocystic acid or to molecular rearrangements taking place during the Wolff–Kishner reductions or the decarboxylation reactions.

Attempts to carry out a Clemmensen reduction of norechinocystenolone resulted in the formation of a resin which could not be purified and from which no pure derivative could be obtained.

Experimental

Norechinocystenol-A.—A mixture of 0.93 g. of the acetyl keto methyl ester derived from echinocystic acid,[4] 5 cc. of hydrazine hydrate and 1 g. of metallic sodium dissolved in 35 cc. of absolute alcohol was heated in a sealed tube at 200° for eight hours.[6] The contents were poured into a large volume of water and the insoluble material extracted with ether. The ether solution was washed with barium hydroxide solution and water and dried over sodium sulfate. Evaporation of the ether gave a product which was recrystallized from methanol to a constant melting point of 188–191°. The product is only slightly soluble in ligroin, fairly soluble in toluene and very soluble in dioxane, acetone, chloroform and ether; $[\alpha]^{25}D$ + 15.1° in chloroform. *Anal.* Calcd. for $C_{29}H_{48}O$: C, 84.40; H, 11.71. Found: C, 83.91, 83.96; H, 11.91, 11.83.

Reduction of 0.23 g. of acetylnorechinocystenolone[4] by the above procedure gave a product which after two crystallizations from methanol melted at 187–189°. A mixture with the above product showed no depression in melting point. The reported melting point of oleanol is 216–220° and $[\alpha]^{20}D$ +59.1° in chloroform.[7]

Reaction of 0.30 g. of norechinocystenol-A with 1 cc. of acetic anhydride in 2 cc. of pyridine, precipitation in water and crystallization from methanol gave the acetate melting at 217–220°; $[\alpha]^{21}D$ +21.6° in chloroform. *Anal.* Calcd. for $C_{31}H_{50}O_2$: C, 81.88; H, 11.08. Found: C, 81.54; H, 10.87. The reported melting point for oleanol acetate is 209–210° and $[\alpha]^{21}D$ +44.7° in chloroform.[7]

Norechinocystenone-A.—A solution of 0.11 g. of norechinocystenol-A in glacial acetic acid was oxidized at 50° with a solution of 0.18 g. of chromium trioxide in glacial acetic acid. After standing one hour, 2 cc. of methanol was added to destroy the excess chromium trioxide and the product was precipitated by adding a large volume of water. The precipitate was collected in ether and the ether solution washed with alkali, dried and the solvent evaporated. The residue was crystallized twice from methanol and then from 95% ethanol to give a product melting at 159–162°; $[\alpha]^{21}D$ +30.8° in chloroform. *Anal.* Calcd. for $C_{29}H_{46}O$: C, 84.81; H, 11.30. Found: C, 84.98; H, 11.14. A mixture with an equal amount of oleanone,[8] m. p. 170–173°, melted at 157°. The melting point of oleanone has been reported to be 167–169°[8] and 168–172°[3] and $[\alpha]^{20}D$ + 95.8° in chloroform.[3]

Summary

Norechinocystenol-A has been prepared by removing the carboxyl group of echinocystic acid and the hydroxyl group "β" to the carboxyl group. It is not identical with oleanol prepared

(1) Todd, Harris and Noller, THIS JOURNAL, **62**, 1624 (1940).

(2) This compound previously has been called simply "norechinocysteneone." The carbonyl group is derived from the hydroxyl group in echinocystic acid which is "β" to the carboxyl group. The designation "B" has been added to distinguish it from norechinocystenone-A in which the carbonyl group is derived from the hydroxyl group in echinocystic acid which is not "β" to the carboxyl group.

Alkyl Sulfites—Cyclohexyl Sulfite

BY L. P. KYRIDES

In 1931 Voss and Blanke[1] reported the preparation of alkyl sulfites in high yields from primary and in fair yields from secondary alcohols. They also reported a yield of 54% of cyclohexyl sulfite—b. p. 182° (19 mm.), $n^{13.7}D$ 1.4865; S 13.16% (calcd. 13.02%). At about the same time Kitasato and Sone[2] reported that cyclohexyl sulfite made in the presence of pyridine boiled at 55° (12 mm.), which would appear to be too low for the boiling point of this ester.

Later, Carré and Libermann[3] cast doubt on the isolability of cyclohexyl sulfite, stating that cyclohexene was the only reaction product of cyclohexanol with thionyl chloride. The criticism of Carré and Libermann was countered by a subsequent report of Voss and Wachs[4] reasserting the isolation of cyclohexyl sulfite in a 42% yield, b. p. 173–173.5° at 14.5 mm.; $n^{17.3}D$ 1.48497; S, 12.85%. Finally, Carré and Libermann[5] made the categorical statement that "the new experiments have confirmed our previous results: the reaction of thionyl chloride with cyclohexanol gives mainly cyclohexene, with only a small quantity of cyclohexyl sulfite which we were unable to distil under vacuum without decomposition."

Having prepared cyclohexyl sulfite in these laboratories at three different times during the past twelve years and tested the products at intervals for stability, we concluded that, if properly prepared, the ester is stable over long periods of time. It distils within a very narrow range under a fairly good vacuum and always smells of sulfur dioxide and cyclohexene.

The procedure for the preparation of *n*-butyl sulfite given in "Organic Syntheses"[6] is not applicable to secondary alkyl sulfites. Following the reaction, distillation gives some olefin and the unchanged alcohol. Voss and Blanke obtained fair yields of secondary alkyl sulfites only by displacing the hydrogen chloride in the course of its liberation during the reaction with a stream of carbon dioxide. This elimination of hydrogen chloride appears to be of significance in driving the esterification to completion.

We have been able to improve the process, and consequently the yields, by carrying out the reaction under reduced pressure. Using the vacuum obtainable by an ordinary water pump, it was demonstrated that the halogen acid is removed quite successfully and excellent yields of both secondary and primary sulfites are obtained from the corresponding alcohols.

Since in the process for *n*-butyl sulfite referred to above 3–5% of butyl chloride is formed, we chose a lower reaction temperature in order to minimize chloride formation. At the recommended temperatures (10–20°), the reaction proceeds quite rapidly, giving the high yields desired.

The following experimental work relating to improvements in the technique of preparing sulfites in general is submitted in order to clarify the situation regarding cyclohexyl sulfite.

Experimental

The apparatus consisted of a four-necked flask carrying an efficient reflux condenser, a thermometer for following the reaction temperature, a dropping funnel and an agitator revolving in a lubricated rubber sleeve[7] for operation under vacuum.

Cyclohexyl Sulfite.—Two hundred grams of anhydrous cyclohexanol was charged into the reaction flask and cooled with agitation to incipient crystallization (25°). Vacuum was applied (24″) and 121 g. of freshly distilled thionyl chloride was slowly dropped in. As the addition progressed and the cyclohexanol liquefied, the reaction temperature was lowered gradually. When about one-half of the thionyl chloride had been added (time fifteen minutes) the temperature had fallen to 15°. At this point, further addition of thionyl chloride induced the evolution of hydrogen chloride which further lowered the temperature. External cooling was discontinued when the temperature had fallen to 5° and addition of the rest of the chloride was regulated to maintain this temperature and the pressure given. Total addition time was forty-five minutes. The vacuum was now increased to 30″ in order to expedite the more complete elimination of hydrogen chloride which in turn lowered still further the temperature (0°). After a short time the flask was immersed in a water-bath and the temperature raised slowly to 55°, taking a half-hour for this operation. After an additional reaction time of a half-hour at 55°, vacuum was broken off and the liquid was transferred into a distillation flask with an attached Vigreux column. After separating a small amount of low boiling liquid under partial vacuum, the main fraction was distilled using a high vacuum pump. The distillate weighed 217 g. and boiled constantly at 134–136° at 3 mm. The low boiling fraction upon refractionation gave 11 g. of unreacted cyclohexanol. The yield of cyclohexyl sulfite was therefore 93.5% on cyclohexanol consumed and 86% on thionyl chloride used. There was evidence of evolution of

traces of cyclohexene and sulfur dioxide in the exit gases during the reaction and distillation. The finished product also gave positive evidence of traces of these two products. The cyclohexyl sulfite was redistilled a year later and its boiling range and refractive index ($n^{25}D$ 1.4848) were found unchanged. After another two years the material boiled constantly at 165° under 14 mm. with no change in the refractive index. Upon analysis the product contained 13.10% sulfur against 13.02% expected. These results substantiate Voss and Blanke's statements regarding cyclohexyl sulfite.

It was observed that unless the reaction is carried out to completion, as indicated, cyclohexyl sulfite cannot be distilled successfully under vacuum because of the continuous decomposition of the product to sulfur dioxide and cyclohexene. This fact would explain the inability of the French workers to isolate the product. Repeated distillation after long standing has not given evidence of deterioration, excepting for the smell of sulfur dioxide and cyclohexene. It was also observed that cyclohexyl sulfite containing very small amounts of sulfuric acid can be distilled under vacuum without decomposition.

Following the procedure given, no difficulty was experienced in the preparation of other esters such as:

Sulfite	Yield, %	Boiling range, °C.
Dimethyl	84	124–127
Diethyl	Quantitative using slight excess of anhydrous ethanol.	154–157
Isopropyl	(Refractionated) 84% on isopropanol	73–74° at 25 mm.
n-Butyl	Yield (refractionated) 92.5% on butanol	124–126° at 29 mm.
Methylhexylcarbinyl	85 (reaction temp. 20–25°)	147–149° at 5–6 mm.

It should be noted that with methanol, ethanol and isopropanol, the reaction should be carried under a lower vacuum because of their low boiling points. It is advantageous to regulate the vacuum so that the alcohol barely refluxes during the addition and later to increase the vacuum.

Summary

Sulfites are obtained in excellent yields from the reaction of primary and secondary alcohols with thionyl chloride using low pressures during the operation.

Cyclohexyl sulfite made by the above procedure is a relatively stable product and can be redistilled repeatedly without change in composition.

On the Thermodynamics of Azeotropic Solutions. I. Shift of Equilibrium in Binary Systems[1]

BY O. REDLICH AND P. W. SCHUTZ

Among the numerous authors who have contributed to the vast amount of experimental data on azeotropic solutions in early and recent times, several have felt the advantages which are to be expected from a thermodynamic discussion.[1a] Obviously thermodynamic predictions are apt to enhance the value of available data and the efficiency of new experimental research, especially in the field of industrial applications.

Apart from the well-known fundamental properties of azeotropic solutions, theoretical discussions either referred to the properties of solutions in general and arrived only at qualitative conclusions regarding the azeotropic properties,[2] or started from special relationships[3] between vapor pressure and composition which are necessarily of restricted validity.

Actually the problem of the shift of azeotropic equilibrium can be easily formulated in a general way and solved by straightforward thermodynamic methods.

The azeotropic equilibrium of a solution of two miscible liquids is characterized by three intensive variables: the composition, which is equal for the liquid and the vapor, the temperature and the pressure. Under the condition, that the azeotropic equilibrium should be maintained, only one of these variables is independent. The shift of equilibrium is therefore exhaustively described by two relations between the variables.

In the development it is assumed only that the vapor is a perfect gas mixture. This restriction can be removed without any essential difficulty but the practical gain would be small and by no means sufficient to justify the complication of the formulas.

In the following, the standard notation of Lewis and Randall is used, the pure components being chosen as reference states. The heats of vaporization of the two components from the solution are denoted by $\Delta H_1 = \Delta H_1^0 - \bar{L}_1$ and $\Delta H_2 = \Delta H_2^0 - \bar{L}_2$, where ΔH_1^0 and ΔH_2^0 are the heats of vaporization of the pure components, and $\bar{L}_1$ and $\bar{L}_2$ the relative partial molal heat contents.

The relationship between azeotropic pressure and temperature is represented by

$$\left(\frac{dP}{dT}\right)_{az} = \left(\frac{\partial P}{\partial T}\right)_{N_1} + \left(\frac{\partial P}{\partial N_2}\right)_T \left(\frac{dN_2}{dT}\right)_{az} \quad (1)$$

The last term is equal to zero since $(\partial P/\partial N_2)_T = 0$ constitutes one of the fundamental properties of the azeotropic equilibrium.

Thus we obtain

$$\left(\frac{\mathrm{d}\ln P}{\mathrm{d}T}\right)_{az} = \frac{p_1}{P}\left(\frac{\partial \ln p_1}{\partial T}\right)_{N_2} + \frac{p_2}{P}\left(\frac{\partial \ln p_2}{\partial T}\right)_{N_2} \quad (2)$$

$$\left(\frac{\mathrm{d}\ln P}{\mathrm{d}\,1/T}\right)_{az} = -\frac{N_1\Delta H_1 + N_2\Delta H_2}{R} = -\frac{\Delta H}{R} \quad (3)$$

where ΔH represents the heat of vaporization of one mole of the solution.

The dependence of the azeotropic composition on the temperature is to be derived in a slightly less direct way. With the abbreviation $Q = p_1N_2/p_2N_1$ the maintenance of the azeotropic equilibrium can be represented by

$$\left(\frac{\mathrm{d}Q}{\mathrm{d}T}\right)_{az} = \left(\frac{\partial Q}{\partial T}\right)_{P,N_2} + \left(\frac{\partial Q}{\partial P}\right)_{T,N_2}\left(\frac{\mathrm{d}P}{\mathrm{d}T}\right)_{az} + \left(\frac{\partial Q}{\partial N_2}\right)_{T,P}\left(\frac{\mathrm{d}N_2}{\mathrm{d}T}\right)_{az} = 0 \quad (4)$$

since $Q = 1$ as long as azeotropic equilibrium exists.

The first of the partial differential coefficients is determined by $\Delta H_2 - \Delta H_1$. For the second we derive

$$\left(\frac{\partial \ln Q}{\partial P}\right)_{T,N_2} = \frac{\bar{v}_1' - \bar{v}_1 - \bar{v}_2' + \bar{v}_2}{RT} = \frac{-\bar{v}_1 + \bar{v}_2}{RT} = \frac{v}{P} \quad (5)$$

where the prime indicates the vapor phase and v the ratio of the difference of the partial molal volumes in the liquid to the molal volume of a perfect gas under the given conditions.

In (5) we made use of the relation

$$\bar{v}_1' - \bar{v}_2' = 0 \quad (6)$$

which results from the assumption of a perfect gas phase. The term (5) is in general entirely negligible.

The third partial differential coefficient in (4) is simplified by means of the Duhem–Margules relation

$$N_1\,\mathrm{d}\ln\frac{a_1}{N_1} + N_2\,\mathrm{d}\ln\frac{a_2}{N_2} = 0 \quad (7)$$

which yields

$$\left(\frac{\partial \ln Q}{\partial N_2}\right)_{T,P} = \frac{\partial}{\partial N_2}\left(\ln\frac{a_1}{N_1}\right) - \frac{\partial}{\partial N_2}\left(\ln\frac{a_2}{N_2}\right) = -\frac{1}{N_1}\frac{\partial}{\partial N_2}\left(\ln\frac{a_2}{N_2}\right) \quad (8)$$

Combination of (3), (4), (5) and (8) leads to[3a]

$$\left(\frac{\mathrm{d}\frac{1}{T}}{\mathrm{d}N_2}\right)_{az} = \frac{R}{\Delta H_2 - \Delta H_1 - v\Delta H}\cdot\frac{1}{N_1}\left(\frac{\partial \ln\frac{a_2}{N_2}}{\partial N_2}\right)_{T,P} \quad (9)$$

The third relationship between the three azeotropic variables is immediately derived from (3) and (9)

$$\left(\frac{\mathrm{d}\ln P}{\mathrm{d}N_2}\right)_{az} = -\frac{\Delta H}{\Delta H_2 - \Delta H_1 - v\Delta H}\cdot\frac{1}{N_1}\left(\frac{\partial \ln\frac{a_2}{N_2}}{\partial N_2}\right)_{T,P} \quad (10)$$

(3a) N_2 is chosen as the independent variable since (9) and (10) will commonly be used in this form.

Thermodynamic relations like these need no test in the proper meaning of the word. However, we wish to illustrate the practical application in an example. A complete and accurate set of the data required in equations (9) and (10) is available for hydrochloric acid.[4]

The following procedure was adopted: the data given for $\bar{L}_1$ and $\bar{L}_2$ in the range from 0 to 60° were inter- and extrapolated on $1/T$ graphs. The values (25°) of $\log(a_2/N_2)$ were interpolated for $N_2 = 0.05, 0.1, 0.2$. The corresponding values for five temperatures up to 123° were computed and represented as parabolic functions of $\log N_2$. The heats of vaporization ΔH_1 and ΔH_2 were calculated from ΔH_1^0, ΔH_2^0, $\bar{L}_1$ and $\bar{L}_2$. The term $v\Delta H$ was neglected.

The differential coefficients for five points were computed according to (3) and (9). They are listed in Table I. Three of the values of N_2, $1/T$, and $\log P$, as observed by Bonner and his collaborators, were used to calculate two parabolic functions; the values of these functions for the two other points and the differential coefficients derived from them are denoted "par." in Table I.

Considering the various inter- and extrapolations, and differentiations, the agreement between the observed ("parabolic") values and calculated ones, which were derived from entirely independent data, is very satisfactory and indicates the high accuracy of the data.

Discussion.—Equation (3) has the form of the Clausius–Clapeyron equation because the system under condition of azeotropic equilibrium acts just like a one-component system.

All conclusions which will be drawn from equation (9) can be derived in the same way from equation (10), and are therefore immediately applicable also to the pressure–composition relationship.

We discuss equation (9) in order to find the characteristic differences in the azeotropic behavior of certain types of solutions. It is convenient to consider first the factor

$$\frac{1}{N_1}\left(\frac{\partial \ln\frac{a_2}{N_2}}{\partial N_2}\right)_{T,P} = \frac{1}{N_2}\left(\frac{\partial \ln\frac{a_1}{N_1}}{\partial N_1}\right)_{T,P} \quad (11)$$

and later the denominator, $\Delta H_2 - \Delta H_1 - v\,\Delta H$.

Term (11) is zero for a perfect solution, negative if $p_1 > N_1p_1^0$, *i. e.*, especially for the maximum vapor pressure type, positive in the opposite case.

TABLE I

AZEOTROPIC FUNCTIONS OF HYDROCHLORIC ACID

N_2		0.10603	0.11088	0.11557	0.12157	0.13090
$10^3/T$	obs.	2.5247	2.6103	2.6977	2.8224	3.1073
	par.	...	2.598	...	2.826	...
$\log P$	obs.	3.0864	2.9031	2.6990	2.3979	1.6990
	par.	...	2.897	...	2.407	...
$d(1/T)/dN_2$	par.	0.0149	0.0182	0.0214	0.0255	0.0318

Term (11) is therefore positive. This explains why azeotropic electrolytes always belong to the minimum vapor pressure or maximum boiling point type.

The equations (9) and (12) demonstrate that *dissociating* azeotropic *systems* always have an *infinite* azeotropic *temperature range.* In dilute solution, the temperature increases with decreasing concentration of the dissociating substance if its heat of vaporization is larger than that of the solvent. For dilute hydrochloric acid ΔH_2 is greater than ΔH_1 so that $\lim dT/dN_2 = -\infty$. In a diagram of the data of Table I one realizes immediately that the T–N_2 curve must have an inflection point at some concentration below the range of the table.

If neither component dissociates, term (11) is always finite.[5] One verifies easily that the left-hand side is finite for $N_2 = 0$, corresponding to a dilute solution of the second component in the first, the right-hand side for $N_2 = 1$.

The integration of (9) from $N_2 = 0$ to $N_2 = 1$ leads, therefore to a finite interval of the azeotropic temperature at least if the denominator $\Delta H_2 - \Delta H_1 - v\Delta H$ is different from zero in the whole interval. This is a matter of some practical interest as distillation at temperatures and pressures outside the azeotropic interval would lead to complete separation. At first, one is inclined to assume that the denominator will vanish or even assume a small value only in rare exceptional cases since heats of vaporization run over a fairly wide range and the denominator contains the difference of two of these quantities. It will be seen later, however, that an assumption of this kind is erroneous and that a small denominator, *i. e.*, a large azeotropic interval, may occur quite frequently and under well defined conditions.

The Isobaric Temperature.—If the vapor pressure–temperature curves of the two pure liquid components cross each other, the temperature at which $p_1^0 = p_2^0$ is of considerable interest.[6] It will be called the "isobaric temperature."

Complete miscibility presupposed, the total vapor pressure–composition curve can assume any of three forms: it may be a straight line, concave or convex. In the first case the system forms a perfect solution, in the latter cases the total vapor pressure has a maximum or minimum as the end-points of the curve are fixed at the same ordinate value. The perfect solution at the isobaric temperature is to be considered as the limiting case of a system azeotropic at any composition.

The result as required in the following discussion can be expressed by either of the statements: "Any system is azeotropic at the isobaric temperature" or: "The azeotropic temperature range always includes the isobaric temperature."

Some information on the shift of azeotropic equilibrium is derived from this fact in connection with Trouton's rule, according to which the ratio of heat of vaporization to absolute temperature is approximately equal for non-associating liquids at those temperatures where their vapor pressures are equal. Trouton's ratio is larger, usually by not more than fifty per cent., for associating substances like alcohols, water, etc.

Trouton's rule defines a family of vapor-pressure–temperature curves with the following properties: At a given temperature the heat of vaporization is greater for the less volatile liquid; with increasing temperature the vapor pressures approach one another asymptotically.

Thus a pair of ideal Trouton liquids is always below the isobaric temperature. Actually vapor pressure curves even of non-associating or "normal" liquids frequently cross in the limited interval between the melting points and critical points, the approximate validity of Trouton's rule being indicated by the small angle between the curves.

If the Trouton ratios of the two components do not deviate considerably from each other, the difference between the heats of vaporization and therefore the denominator in equation (9) $\Delta H_2 - \Delta H_1 - v\Delta H = \Delta H_2^0 - \Delta H_1^0 - \bar{L}_2 + \bar{L}_1 - v\Delta H$ is small, inasmuch as the other terms are small in any case. Thus in the neighborhood of the isobaric temperature, a small value of the denominator or a steep slope of the azeotropic temperature–composition curve is to be expected, if Trouton's rule is satisfied by both components or if only both Trouton coefficients are equal.

Small values of the denominator are also to be expected at high temperatures as the heats of vaporization vanish at the critical point. As vapor pressures increase rapidly with increasing temperatures, the formulas derived under the condition of a perfect gas phase cease to be valid at high temperatures, but this fact will hardly impair a qualitative conclusion.

Classification of Non-dissociating Azeotropic Systems.—A convenient classification starts from a "Trouton type" and describes characteristic deviations from this case.

(A) The azeotropic temperature–composition curve of a system of two non-associating liquids starts at $N_2 = 0$ or $N_2 = 1$ at a finite slope. The slope increases with increasing temperature and the curve extends to the critical temperature. The only known case of a system of this "Trouton type," benzene–cyclohexane (Fig. 1), shows a small part of this curve. It may be expected

(5) This is not a strictly thermodynamic statement. It results from the fact that the behavior of non-dissociating solutes at low concentrations can always be described by $\ln(a_2/N_2) = kN_2^s$ with $s \geqq 1$. Only for ions is $s = 1/2$, due to the long range of interionic forces. Next to these, the forces between zwitterions have the longest range. Already for this case the relation $s = 1$ holds (G. Scatchard and J. Kirkwood, *Physik. Z.*, **33**, 297 (1932)), the more for other types of solutes. However, an appreciably ionized amphoteric electrolyte would constitute an exception inasmuch as, due to the presence of ions, s were equal to 1/2 although no dissociation in the strict sense occurs.

(6) This has been realized already by W. D. Bancroft ("The Phase Rule," Ithaca, New York, 1897), and by S. Young ("Distillation Principles and Processes," London, 1922).

that frequently crystallization will occur before the lower end of the curve is reached.

(B) A similar curve results from two associating liquids if the Trouton coefficients are approximately equal and the isobaric temperature is high (water–ethanol, Fig. 1).

(C) If the Trouton coefficients differ appreciably, *i. e.*, especially in systems composed of an associating and a non-associating component, the slope in general is finite. A steep slope is not strictly excluded as the heats of vaporization still may happen to be equal at some temperature. This temperature, however, must be remote from the isobaric temperature and, therefore, has no particular chance of being included in the azeotropic range. Thus a steep slope will be a rare exception as long as the gas phase is nearly perfect.

Considering the previous discussion of term (11), one is justified in extrapolating some of the experimental curves (Fig. 1) of this type to the lower end (ethyl acetate–carbon tetrachloride and ethanol–chloroform) and to the upper end (toluene–ethanol). The extrapolation is less certain in the latter case as approach to critical conditions may result in a considerable change of the slope.

Wrewsky[2] already has stated that in a system with maximum (minimum) vapor pressure the azeotropic concentration of the component with the larger heat of vaporization increases (decreases) with increasing temperature. Considering equation (9) and the previously discussed significance of the isobaric temperature, the direction of the temperature–composition curve is conveniently described also by the following statement: The azeotropic curve of a maximum (minimum) vapor pressure system ends, if at all, on the side of the more (less) volatile component. This is true both of lower and upper ends.

Frequently, though not always, the azeotropic behavior of non-dissociating systems is sufficiently described with the aid of the relationship

$$RT \ln a_2/N_2 = w N_1^2 \qquad (13)$$

where w characterizes the interaction between the two components. This has been shown by Herzfeld and Heitler[7] and recently in more detail by Kirejew.[8]

From a practical viewpoint, a thermodynamic examination of ternary systems is perhaps more interesting inasmuch as the experimental investigation requires so much more labor. The thermodynamic discussion, of course, is more complicated, too. Equations for ternary solutions similar to (13), derived by Porter[9] and by Scatchard,[10] greatly simplify the discussion which will be presented in a following paper of this series.

Acknowledgment.—The authors are indebted to Professor George Scatchard, the reviewer of this paper, for important critical advice.

Summary

1. The two thermodynamic relationships connecting the three azeotropic variables (composition, temperature, pressure) of a binary system are expressed in terms of common quantities with the only restriction that the vapor is a perfect gas mixture (equations 3, 9, 10).

2. The azeotropic temperature–composition curves depend in a characteristic way on whether one or both components are normal, dissociating or associating.

3. Dilute azeotropic solutions of a dissociating substance belong necessarily to the minimum vapor pressure type. The slope of the azeotropic

temperature–composition curve decreases or increases without limit with decreasing concentration in dilute solutions of a dissociating component, and only of a dissociating component.

4. The term "isobaric temperature" is proposed for the temperature at which the vapor pressures of the pure components are equal. The slope of the azeotropic temperature–composition curve is steep at the isobaric temperature if the deviations from Trouton's rule are small for both components.

5. If the azeotropic temperature–composition curve of a maximum (minimum) vapor pressure system extends to a pure component, this component is the more (less) volatile one. The rule holds both for upper and lower limits of the azeotropic temperature range. In connection with the fact that this range includes the isobaric temperature, the rule conveniently indicates the direction of the curve.

The Ternary System Barium Bromate–Barium Chlorate–Water at 25°

BY J. E. RICCI AND S. H. SMILEY

Introduction.—During various attempts to determine bromate in the presence of chlorate by precipitation with excess of barium chloride, it became apparent that the precipitated barium bromate was repeatedly and almost reproducibly contaminated with barium chlorate, despite all precautions for its proper formation in the pure state. The weight of the solid obtained, after the usual drying, was always too high, and its oxidizing equivalent, determined by iodometry, was also too high, indicating the presence of some chlorate. It was consequently suspected that the two salts, barium bromate and barium chlorate, isomorphous and both mono-hydrated, were forming solid solutions from their aqueous solutions. This was verified by a phase rule study of the ternary system involved. Since the resulting solid solution turned out to be a continuous one, the data were therefore used in testing the applicability of a semi-empirical relationship previously reported as describing the distribution of such isomorphous salts in solubility equilibrium between liquid and solid phases.[1]

Experimental Procedure.—The barium bromate used was a C. P. grade of the monohydrate, the purity of which was checked, with the following results: by iodometry, 95.73% $Ba(BrO_3)_2$, and by dehydration to constant weight at 110°, 95.53%. The theoretical value is 95.60%. A C. P. grade of $Ba(ClO_3)_2 \cdot H_2O$ also was used, found to contain 5.69% of water (by drying at 110°) as compared with the theoretical 5.60%. A qualitative test for bromate or other strong oxidizing agents proved negative (<0.001% as $Ba(BrO_3)_2$).

The experimental procedure for the solubility determinations has been described in similar publications. The temperature of the determinations was 24.95 ± 0.02°. Equilibrium was approached from two directions, in about half of the experiments from undersaturation, *i. e.*, lower temperature, and in the others from higher temperature. In most cases equilibrium was proved by the constancy of the composition of the liquid on repeated analysis. In other cases, although such direct proof was not possible since the solution was all consumed in repeated analyses before actual constancy was established, it is felt that the systems must have been very close to if not at true equilibrium, because care was taken to keep the relative amount of solid phase in the complexes very low, and because of the long period of stirring generally used (one to six, averaging three and one-half, months).

The liquid solution was analyzed after sampling by means of calibrated pipets fitted with filtering tips. The wet residues were either pressed between coarse filter paper or centrifuged briefly, before weighing and analysis.

Water was determined by drying at 110° and bromate was determined iodometrically (in the presence of chlorate) by a procedure already described[2] for a similar investigation on the system sodium bromate–sodium chlorate–water. The correction there reported for the effect of relatively high concentrations of chlorate was verified and applied in the present case. These two determinations allowed the calculation of the percentage of each salt in the various solutions and residues.

A slight complication arose from the fact that final traces of water were not easily driven off at 110°, but required a brief treatment at about 300°. Since this temperature would also cause a slight decomposition of the two salts, especially of the barium bromate, experiments were made to determine the rate of loss of weight of each salt at 300°. The results indicated that after the initial expulsion of traces of water, barium chlorate suffered no measurable loss of weight in one or two hours, while barium bromate lost almost 4 mg. per gram per hour at this temperature, a correction which was then applied in the actual analyses.

Results.—The results are tabulated in Table I, which lists all compositions in weight per cent. The density of the saturated liquid solution was not always measured. Some of the values listed were read from a plot of the density, d, against c, the total percentage of salt in the saturated solution; the dependence was in fact found to be roughly linear, with an average error of about 0.002, according to the expression

$$d = 0.993 + 0.00935c \qquad (1)$$

The solubility of barium chlorate here found is the same as the accepted value in the literature.[3] The solubility of barium bromate here reported, 0.791%, also agrees well with the important literature values: 0.788%, by Trautz and Anschütz,[3a] and 0.796%, by Harkins.[4]

[a] Densities in parentheses are interpolated. [b] Average of two extrapolations, where wet residue analysis is reported; otherwise extrapolation through liquid solution and original complex.

The composition of the solid solution in equilibrium with the saturated liquid solution was calculated by the algebraic extrapolation,[5] to the line joining the compositions of the two separate monohydrates, of appropriate tie-lines through the liquid composition and the original complex, and also through the liquid composition and that of the wet residue whenever the latter was analyzed.

Figure 1 is the usual graphical representation of the isothermal relations of the ternary system, showing principally the disposition of the tie-lines for the distribution of the two isomorphous salts between the two continuous conjugate solutions. The shape of the solubility curve itself cannot be shown on such a scale. It is therefore presented separately on Fig. 2, which brings out an inverted S-shape similar to that of the 25° isotherm of the corresponding system sodium bromate–sodium chlorate–water.[2] The dip in the curve near the chlorate end, accompanied with divergence of the tie-lines in the direction of the solid solution, indicates, as in the sodium salt system, a tendency toward discontinuity of the solid solution and the formation of an isothermally invariant liquid. This is borne out by the mathematical analysis of the distribution of the salts between liquid and solid phases, in which it is inferred that the solid solution involves positive deviations from Raoult's law.

Distribution between the Aqueous and the Solid Solutions.—According to a relation already shown to hold with at least approximate correctness in a number of cases of pairs of isomorphous salts, the distribution of the salts of the present investigation, at equilibrium between their solid solutions, is given by the expression

$$\log R_l = \log K + m \log R_s \qquad (2)$$

in which R_l is the mole ratio of chlorate to bromate in the liquid solution, R_s is the same ratio in the solid solution, K represents the square root of the ratio of the thermodynamic solubility product of barium chlorate to that of barium bromate, and m is an empirical constant characteristic of the particular pair of salts and representing some measure of the degree of non-ideality of the solid

solution formed by them. With ideal relations, $m = 1$. The equation has been found to apply to a number of systems both of alums and of picromerites.[1]

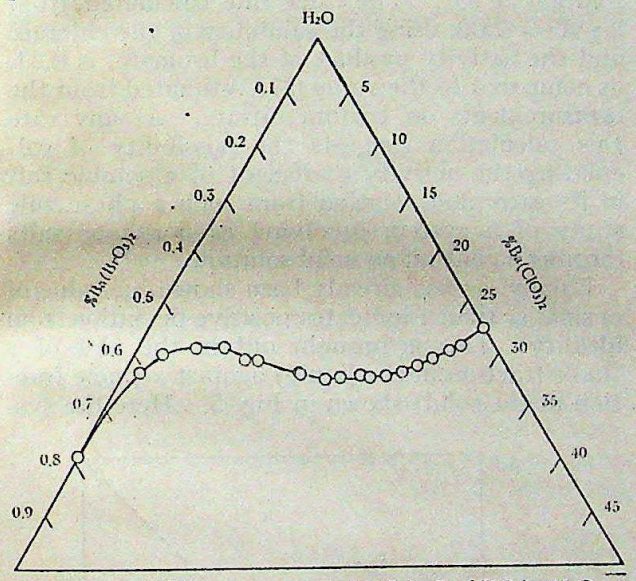

Fig. 2.—Solubility curve: $Ba(BrO_3)_2$–$Ba(ClO_3)_2$–H_2O at 25°.

The quantities required for testing this distribution equation in the present system are listed in Table II. Here R_l and R_s are the ratios already explained, and x and y are the mole fractions of barium chlorate in the solid and in the liquid phases, respectively, excluding water.

These quantities were first plotted to see whether the solid solution of these salts constituted a "regular" solution in the Hildebrand sense.[6] This would require a linear relation between log (R_l/R_s) and x, the mole fraction of one of the salts in the solid. Figure 3 shows

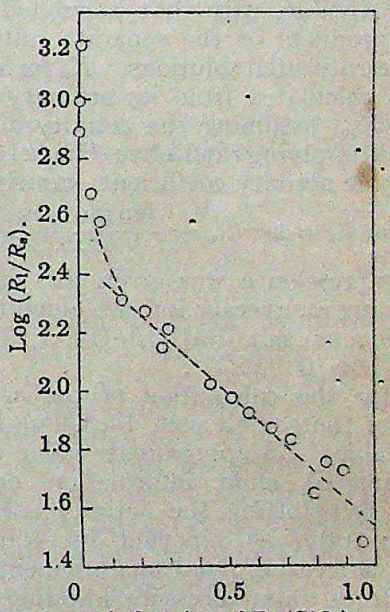
that while the relation is linear for values of x above 0.2, it is distinctly non-linear at lower mole fractions of the chlorate.



x = the mole fraction of $Ba(ClO_3)_2$.

Fig. 3.—Test of "regularity" of the solid solution.

Figure 4 shows the data plotted to test equation (2). The over-all linearity of the relation between log R_l and log R_s is evident, especially with respect to intermediate values of the ratios. The scattering from linearity toward the extreme values is not necessarily significant, since the ratios at either end are more sensitive to experimental errors in the analytical determinations. Since the percentage of $Ba(ClO_3)_2$ is calculated by difference the error in the determination of R_s is relatively high when the solid phase approaches

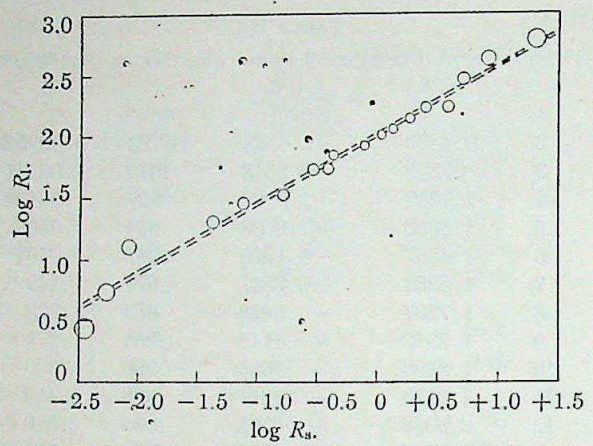

Fig. 4.—Distribution curve according to equation [4].

pure $Ba(BrO_3)_2 \cdot H_2O$. At the other extreme R_1 becomes uncertain because of the decreasing precision of the determination of the small solubility of the bromate. Fortunately the important region of the plot of Fig. 4 is that near $\log R_s = 0$, and here the precision of the measurement of the ratios is high and the linearity is definite, giving a value of $m = 0.58$. At $\log R_s = 0$, $\log R_1 = \log K = 2.0_0$.

This "observed" value of $\log K$ is to be compared, if possible, with that calculated from the activity products of the separate salts in their respective saturated solutions. K_a for $Ba(BrO_3)_2 \cdot H_2O$ was calculated from its ordinary solubility product, K_m, assuming the activity of water to be one, and applying the Debye–Hückel expression for the ionic activity coefficient, namely

$$\log K_a = \log K_m - \frac{6(0.510)(\mu)^{1/2}}{1 + 0.329a(\mu)^{1/2}} \qquad (3)$$

In this expression a was given the value of 2.5 Å., assuming an average ion size equal to that for the analogous salt $Ba(IO_3)_2 \cdot H_2O$.[7] This gives $K_a = 7.74 \times 10^{-6}$ at 25°.

Data for the calculation of the activity coefficient of the soluble salt, $Ba(ClO_3)_2 \cdot H_2O$, were not available. An approximate value was therefore estimated from information on barium nitrate. By plotting the activity coefficient of barium nitrate, as reported by Randall and Scott[8] from freezing point measurements, and by Ratner[9] from vapor pressure lowerings, at 70°, of solutions up to 1 M in concentration, against the square root of the ionic strength, and extrapolating to the solubility of the chlorate, (1.13 M), a value of $f_\pm = 0.18$ was obtained. The applicability of the estimate is subject to uncertainty both because the two salts differ in respect to hydration and because an extrapolation was involved to a concentration somewhat beyond the range of Ratner's measurements. At any rate, using this value for the ionic activity coefficient, K_a for $Ba(ClO_3)_2 \cdot H_2O$ is calculated as

$$K_a = K_m a_{H_2O} (f_\pm)^3 \qquad (4)$$

For this calculation the activity of water in the saturated aqueous solution of barium chlorate was estimated as 0.95 from published data on the vapor pressures of barium chlorate solutions at 100°.[10] K_a thus equals 3.2×10^{-2}, whence $\log K$ for the distribution equation should equal $(3.2 \times 10^{-2}/7.7 \times 10^{-6})^{1/2} = 1.8_1$, whereas the "observed" value, as read from Fig. 4, is $\log K = 2.0_0$.

This may be considered as fair agreement, but it is not as good as that generally found for the alum and picromerite systems studied.[1] In view of the good linearity seen in Fig. 4, in conformity with the equation, and of the approximate agreement between the observed and calculated values of $\log K$, it is felt that the discrepancy is probably caused principally by the uncertainty in the value of the activity coefficient of the soluble salt, $Ba(ClO_3)_2 \cdot H_2O$, which had to be estimated by analogy only. Since the equation probably does describe the actual relations, it may be suggested that the observed value of $\log K$ can be used to estimate the unknown activity coefficient of $Ba(ClO_3)_2 \cdot H_2O$ in its pure saturated aqueous solution at 25°. The value thus calculated, from $\log K = 2.00$, using the solubility of the chlorate and the activity product of the bromate, is 0.24, as compared to the value 0.18 estimated from the measurements on barium nitrate. At any rate this calculation suggests the possibility of calculating the activity coefficient of a soluble salt in its saturated solution from such a phase rule study of a system involving isomorphous salts forming a continuous solid solution.

Finally, as has already been shown,[1] a value of m smaller than 1 indicates positive deviation from ideality. This is brought out in the plot of y (mole fraction in the liquid) against x (mole fraction in the solid) shown in Fig. 5. Here the sys-

tem is seen to belong to Type II of the Roozeboom classification of such distributions between liquid and solid solutions. Although the experimental points do not actually cross the diagonal as x and y approach 1, as is demanded by Roozeboom's Type II, it may be calculated that with $m = 0.6$ and $K = 100$ in the equation

$$\frac{y}{1-y} = K\left(\frac{x}{1-x}\right)^m \qquad (5)$$

which is derivable from equation (2), the curve of Fig. 5, plotting y against x, will cross the diagonal at $x = 0.99999$, a value beyond experimental handling.

Summary

1. The solubility equilibrium relations in the system $Ba(BrO_3)_2$–$Ba(ClO_3)_2$–H_2O were studied at 25°.

2. The formation of a continuous solid solution of the monohydrates of the two salts at this temperature explains the difficulties in the attempted analytical determination of bromate in the presence of chlorate by precipitation with excess of some barium salt such as barium chloride.

3. The system is found to belong to Type II of Roozeboom's classification of solid solutions, involving positive deviations from ideality.

4. The distribution constant for the two isomorphous salts between their aqueous solutions and the saturating solid solution was determined from a plot of the data. Log K so found = 2.0_0, in fair agreement with the value calculated from the separate aqueous solubilities of the two salts, namely, log $K = 1.8_1$.

5. The disagreement between calculated and observed distribution constants is attributed chiefly to the uncertainty of the value of the activity coefficient for $Ba(ClO_3)_2 \cdot H_2O$, and it is suggested that the distribution constant derived from this type of equilibrium study may be used for the calculation of such an activity coefficient.

NEW YORK, N. Y. RECEIVED MARCH 1, 1944

The Systems $NaClO_3$–NaBr–H_2O, $NaClO_3$–NaI–H_2O and $NaClO_3$–$NaNO_3$–H_2O, at 25°C.

BY J. E. RICCI

The solubility measurements here reported[1] have been made as additions to the systematic study of the equilibrium relations in aqueous systems involving sodium halates, particularly sodium chlorate.[2]

The experimental procedure was that already described for similar investigations. The salts were all C. P. or "reagent" materials, used without further purification. Equilibrium was established in representative instances by constancy of composition upon repeated analysis. Complexes were stirred for at least two days in every case, at a temperature of 25 ± 0.05°.

In the first two systems (I, $NaClO_3$–NaBr–H_2O; II, $NaClO_3$–NaI–H_2O) the analysis of the saturated aqueous solution involved argentometric titration of the halide salt, with eosin as adsorption indicator, determination of water in a separate sample by evaporation, and calculation of the sodium chlorate by difference. A few of the halide determinations for the isothermally invariant points were verified by the Volhard method. In the third system (III, $NaClO_3$–$NaNO_3$–H_2O) the chlorate was determined independently by treatment with standard arsenite solution and, after heating with hydrochloric acid, titration of the excess of arsenite by means of standard potassium bromate solution, using indigosulfonic acid as indicator; the sodium nitrate was then calculated by difference, after determination of water by evaporation. The solubilities of the individual salts (with the exception of sodium nitrate) were determined both volumetrically and by evaporation, with very close agreement between the two methods throughout.

The solid phases were in each case the pure separate salts or their respective hydrates stable at 25°, and were easily identified by means of tie-lines, on the ternary diagrams, drawn through the compositions of the original complex and of the corresponding saturated solution. The algebraic extrapolation of these tie-lines shows deviations from the points representing the pure salts or their hydrates, averaging 0.20, 0.21 and 0.34% in the three systems, respectively. This indicates, on the average, a relatively much smaller error in the total experimental procedure involving preparation of complexes, establishment of equilibrium and sampling and analysis of saturated solutions.

The numerical results are listed in Tables I, II and III, in terms of weight per cent. Densities were determined for the whole range of concentration only for the sodium nitrate system. These densities were obtained by using calibrated

pipets in the sampling of the saturated liquids for analysis; they are relatively less precise and dependable than the analytical results themselves.

The data are not shown graphically since the relations involve no unusual features: The values, however, all lie on smooth curves; and the systems are seen to be of the simplest type, each with two branches for the solubility curve, one for each of the separate component salts, and with no indication of the formation of either solid solutions or double salts. The isothermally invariant solutions saturated with two salts have the compositions

	% $NaClO_3$	% 2nd salt	Density
I	13.89	40.28 (NaBr)	1.583
II	4.32	61.68 (NaI)	1.911
III	34.28	25.94 ($NaNO_3$)	1.553

A few determinations were also made on the equilibrium relations of the first system, $NaClO_3$–NaBr–H_2O, at 50°, enough to show that the principal isothermally invariant point, at this temperature, containing 43.0% sodium chlorate and 16.2% sodium bromide, involves as solid phases sodium chlorate and anhydrous sodium bromide, instead of the dihydrate of the latter salt, which in the binary aqueous system is stable up to ~ 51.0°.

The absence of complexity in the sodium nitrate system is in some contrast with the relations in the system $KClO_3$–KNO_3–H_2O at the same temperature. These salts form a limited series of solid solutions consisting of potassium chlorate containing (at 25°) up to 14.37 *M* % of potassium nitrate, while no potassium chlorate is found to dissolve in the potassium nitrate phase.[3] This behavior seems to be related to the dimorphism of potassium nitrate. While the stable rhombic form of potassium nitrate changes to a monoclinic variety only at 129°, the solid solution seems to involve the unstable monoclinic form since potassium chlorate is itself monoclinic at room temperature. On the other hand, the stable rhombic potassium nitrate, which is the actual potassium nitrate phase of the ternary aqueous system, does not take up any of the monoclinic chlorate. For the sodium salts, however, the nitrate is simply rhombohedral, and while the chlorate appears to be at least dimorphous, its usual form is cubic, and no solid solution at all is observed in the system as studied at 25°.

Summary

Solubility measurements are given for the systems I, $NaClO_3$–NaBr–H_2O, II, $NaClO_3$–NaI–H_2O and III, $NaClO_3$–$NaNO_3$–H_2O, at 25°. These salt pairs form neither double salts nor solid solutions at this temperature.

The Viscosity of Aqueous Solutions of Electrolytes as a Function of the Concentration. VIII. Potassium Ferricyanide

BY GRINNELL JONES AND SCHUYLER M. CHRISTIAN

This paper is an extension of the work on the viscosity of solutions of electrolytes which has been reported in a series of earlier papers.[1]

Potassium ferricyanide was selected because it gives a good example of a salt of the 1–3 valence type. Measurements of the viscosity of solutions of this salt have been carried out by Wagner,[2] by Abegg,[3] and by Rankin and Taylor,[4] but the available data do not cover as wide a range of concentration or have as great precision as is desired for our purposes. It is of interest that Rankin and Taylor found that although at 25° the solutions of this salt are more viscous than water, yet at 1.6° the solutions are less viscous than water with a minimum in the viscosity–concentration curve.

The best grade of salt available by purchase was further purified by crystallization and carefully dried. The viscometer, thermostats, timing apparatus and experimental procedure were the same as those used by Jones and Stauffer. Two minor changes were made in the calculation of the corrections to the experimental data. In the previous papers of this series the kinetic energy correction has been calculated by the method recommended by Bingham, using the value $m = 1.12$ for the coefficient of the correction term. The value for this coefficient has recently been determined experimentally for this particular instrument by T. W. Dakin[5] and found to be $m = 0.98$, and this new value was used in the computation of the correction. For a nearly saturated solution (3.5 N) at 25° the kinetic energy correction computed by the old value of m is +0.00297, which is reduced to +0.00266 by the use of the new value of m, or a change of less than 0.03% of the viscosity. However, the correction decreases rapidly with dilution. Thus for the 1 N solution at 25° the correction is only +0.00011 with the old value of m and +0.00010 with the new value. At 0° the kinetic energy correction itself is much smaller than at 25° owing to the fact that the efflux time is approximately doubled and furthermore the viscosity of the solutions is much closer to that of water, so that for relative measurements the effect is substantially reduced. The kinetic energy correction for the strongest solution studied at 0° (2 N) was only −0.00025 and the difference in the correction caused by the change in the value of m is only 0.004%. We have not yet recomputed the correction for the data on other salts which have been determined in this Laboratory by the use of this instrument but these examples indicate that the error in this correction due to the use of $m = 1.12$ will not be significant except perhaps in a few of the most concentrated solutions studied. The situation is even more favorable in the cases of the measurements made with another viscometer designated as the T Instrument because (1) the kinetic energy correction is smaller because of a greater efflux time; and (2) Dakin's determination of the value of m for this instrument gave a value of 1.16 which is nearer to the assumed value of 1.12 used in the computation of the published data obtained with this instrument.

A surface tension correction is applied to the data by the use of a correcting factor computed by the formula $f = 1 + 0.0076\left(1 - \frac{\sigma_c \rho_0}{\sigma_0 \rho_c}\right)$ given by Jones and Fornwalt.[1] The surface tension data for 25° are taken from the paper by Jones and Ray.[6] Jones and Ray did not make any measurements at 0° but some approximate measurements made at 0° with a DuNouy tensiometer gave results for the relative surface tension which agree well with those at 25°. In contrast to the kinetic energy correction this surface tension correction is nearly independent of the temperature and is approximately linear with respect to the concentration. It amounts to +0.027% for a 1 N solution.

In a few cases a correction not exceeding 0.003% has been applied to the viscosity data and density data to bring the results to a round concentration. In all cases where the correction exceeded 0.003% the data as obtained are published and the estimated values at a round concentration are given in parentheses.

Interpretation of the Results

The experimental data on the density of potassium ferricyanide solutions may be expressed by equations having the form suggested by Root[7] with an average deviation of only 0.0023%.

$$d^{25}_4 = 0.99707_4 + 0.181448c - 0.0204195c^{3/2}$$

$$d^{0}_4 = 0.99987_0 + 0.193367c - 0.0204495c^{3/2}$$

The viscosity and fluidity of these solutions can be expressed by equations of the form suggested by Jones and Dole, as is shown in Table III. It is interesting that the viscosity–concentration curve at 0° has both a maximum (at $c = 0.0034$; $N =$

are needed. For 25° we shall use the values 73.52 for the potassium ion and 101.0 for the ferricyanide ion given by MacInnes,[9] based on measurements of the conductance of potassium ferricyanide solutions by Hartley and Donaldson.[10] These measurements were evidently well done and cover a very low range of concentration; N = 0.00004 to 0.0002. The results are supported by the measurement of Hölzl[11] which cover the range from N = 0.001 N to 0.03 N but when plotted appear to be consistent with those of Hartley and Donaldson. On the other hand, the earlier measurements of Harry C. Jones and C. Watkins[12] are inconsistent with the others by nearly 7%, and deserve no further consideration.

Unfortunately, the available information as to the mobility of the ferricyanide at 0° is far less satisfactory. The only measurements of the conductance of a ferricyanide solution at 0° which we have found in the literature are those of Harry Jones and Watkins which, as explained above, are grossly in error at 25°. There is a strong presumption that an error of this magnitude is due to a wrong choice of the reference standard used in the determination of their cell constants. This is supported by the values for potassium chloride given by Harry C. Jones[13] which are also substantially below the correct values at both 25 and 0°. It is necessary to multiply his values for potassium chloride by a factor 1.067 to obtain the correct values. We have, therefore, applied this factor to his data on potassium ferricyanide and plotted the results against $\sqrt{c}$. Extrapolation gives a value of 94.4 for the limiting conductance at infinite dilution. The values thus obtained are consistent with the values given in the "International Critical Tables" which are stated to be based on Jones and Watkins and, therefore, the process of adjustment described above must have been used in preparing the "International Critical Tables." Subtracting the mobility of the potassium ion at 0°, 40.4, gives 54 for the ferricyanide ion.

TABLE IV

	25°C.	0°C.
T	298.18	278.18
D	78.8	88.0
η	0.008949	0.01792
$l_1(K^+)$	73.52	40.4
$l_2(Fe(CN)_6^{---})$	101.0	54
A computed	0.0222	0.020
A experimental	.0244	.0211

The other parameters used in the calculation and in the results are shown in Table IV. The agreement between the computed and experimental results is about as close as usual[14] and shows that the formula of Falkenhagen and Vernon correctly evaluates the influence of valence type and of the temperature.

Summary

1. Data are given for the density and viscosity of potassium ferricyanide solutions at 25 and 0° covering the range up to saturation.

2. Equations expressing the density, viscosity and fluidity as functions of the concentration are given.

3. The predictions of the Falkenhagen and Vernon equation are verified for this case.

The Characterization of Capillaries Used for Dropping Mercury Electrodes in Polarographic Studies

BY OTTO H. MÜLLER

The best identifying characteristics of a capillary are its length and internal diameter, provided that it has a truly uniform bore. While some factory made capillaries fulfill this condition, all laboratory made capillaries do not, because they are drawn from wider stock and are consequently more or less tapered. Even if capillaries of uniform bore were used exclusively, the means for measuring with sufficient accuracy diameters varying from 10–50 μ, or for determining the uniformity of the bore are not available to most chemists. The present study was therefore undertaken to find certain characteristics which would (a) be peculiar to *all* kinds of capillaries, (b) be determinable without special apparatus, (c) permit comparison of straight and tapered capillaries and a prediction of their performance, and (d) give enough information for the duplication of any given capillary. It was found that the capillary constant, κ, and the radius of the capillary orifice, ρ, are two factors which meet all of these requirements. Some simple techniques for their precise determination and some incidental observations made during this study will be discussed in this

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

paper. The value of incorporating these factors in the Ilkovič equation will be described in another communication.

The capillary constant,[1] κ, represents the pressure of mercury necessary to force 1 mg. of mercury through the capillary per second. It is defined by means of the following equation

$$\kappa = \frac{p}{m} = \frac{8\eta l}{d\pi r_c^4} \qquad (1)$$

where p is the pressure (in dynes cm.$^{-2}$) producing a flow per second of m mg. of mercury of viscosity η and density d, through a capillary of length l and with uniform radius r_c. When this pressure is expressed in cm. of mercury and other known values (for 25°) are substituted in this equation, it reduces to

$$\kappa = 2.1567 \times 10^{-10}\, l/r_c^4 \qquad (2)$$

where κ is expressed in cm. sec. mg.$^{-1}$, and l and r_c in cm.

The effect of temperature on this constant is negligible, as may be seen by differentiation of equation (1) with respect to temperature. Using known temperature coefficients of the viscosity and density of mercury, one finds the temperature coefficient of the capillary constant equal to -0.0034 deg.$^{-1}$.

If the radius of the orifice, ρ, is substituted for r_c, the above equations also become applicable to capillaries without uniform bore; l then represents the length of an equivalent hypothetical capillary with a uniform bore of radius ρ. In other words, by means of equation (2) it is possible to calculate the dimensions of a capillary of uniform bore needed to replace a given laboratory made capillary.

Determination of κ.—The value of κ is easily obtained as the ratio of P/m, where P is the pressure (in cm. of mercury) producing a flow of m mg. of mercury per second through the capillary. Even fairly rough measurements of these quantities give practically constant values for κ under a variety of conditions.[1] As will be shown presently, a slight drift in the κ values with changing pressures can be eliminated in more accurate measurements by making appropriate corrections for the applied pressure.

In Tables I and II are given the results of two typical experiments in which the capillary was dropping in air and in a solution of 0.1 N potassium nitrate. The apparent or applied pressure ($P_{app.}$) was measured accurately to 0.1 cm. from the tip of the capillary to the level in the mercury reservoir. The capillary used was 6.32 cm. long and had an essentially uniform diameter of 54.0 μ. W, t and m were determined as before.[1] Although the drops in air are abnormally large and not as reproducible as drops falling in an electrolyte, the flow of mercury, m, at a given pressure, is constant. Yet, in both experiments, the values for the capillary constant, $\kappa_{app.}$, calculated from m and the apparent pressure, $P_{app.}$, show a small drift with changing pressure. This and the small but definite difference between corresponding m values of Tables I and II are caused by the back pressure of the mercury drops.

[a] P_{back} includes a correction of 0.1 cm. for loss in hydrostatic pressure, because the capillary was immersed into the solution to a depth of 1.3 cm.

It should be remembered that not all of the pressure measured is effective in forcing mercury through the capillary. A small fraction of it has to be expended in overcoming the back pressure caused by the surface tension of the expanding drop of mercury. The back pressure is greatest before the drop forms and may amount to tens of centimeters, depending on the capillary bore (see, *e. g.*, the critical pressure values given in Table III). Unless the total pressure exceeds this maximum value of the back pressure, the capillary stops dropping. As soon as a drop is formed, the back pressure diminishes; it becomes minimal as the drop reaches its maximum size before falling off.

According to Kučera,[2] the back pressure is equal to $2\sigma/r_d$, where σ is the surface tension of mercury and r_d is the radius of the mercury drop. Kolthoff and Lingane[3] have evaluated this equation in terms of m and t (the drop time) for the *average* size of the drop and for a surface tension of 400 dynes cm.$^{-1}$ and found

$$\text{Average } P_{back} = 3.1/m^{1/3}t^{1/3} \qquad (3)$$

Assuming, as a first approximation, the same surface tension, the data of Tables I and II were

(2) G. Kučera, *Ann. Physik*, 11, 529 (1903).

corrected. In column 6 is given $W^{1/3}$ (equal to $m^{1/3}t^{1/3}$), and in column 8, P, the pressure corrected for back pressure and any loss in hydrostatic pressure. The new value of κ (Column 9) is now constant within the experimental error and identical for the two media.

To test the validity of the corrected κ value, a further experiment was performed which involved no back pressure. For a carefully measured length of time the capillary was immersed into a pool of mercury contained in a small beaker which was weighed before and after the experiment. The increase in weight represented the quantity of mercury flowing through the capillary in the elapsed time under a pressure equal to the difference between the mercury levels in the reservoir and the beaker. In two experiments the following results were obtained

Pressure, cm.	Weight, g.	Time, sec.	Rate of flow, mg./sec.	κ, cm. sec./mg.
38.6	1.0432	720	1.45	26.6
67.1	2.4261	960	2.53	26.5

Upon substitution of the corrected κ and the known l values in equation (2), r_c was found to be 26.7 μ in good agreement with the direct measurement.

The Attachment of Mercury to Glass.—If the pressure is expressed in cm. of mercury, Kučera's equation becomes

$$P_{back} = 2\sigma/gdr_d \quad (4)$$

where d is the density of mercury and g the acceleration of gravity. For the present study it was desirable to evaluate this equation in terms of ρ. By combining the two well-known equations relating W, the drop weight, to r_d, the radius of the drop, and to ρ, the radius of the capillary orifice

$$W = 4/3\pi r_d^3 d \quad (5)$$

and

$$W = 2\sigma\pi\rho/g \quad (6)$$

one gets r_d expressed in terms of ρ

$$r_d = \sqrt[3]{3\sigma\rho/2dg} \quad (7)$$

Substituting this in equation (4), which is multiplied by 4/3 to represent the *average* back pressure[3] in cm. of mercury, we get

$$\text{Average } P_{back} = 4.1576 \times 10^{-3}\sigma^{2/3}\rho^{-1/3} \text{ cm.} \quad (8)$$

The average back pressure calculated by means of this equation for the capillary used in the above experiments is 1.6 cm. Since this agrees with the data of Table II only, the value of ρ must undergo some change when the capillary is dropping in air, because the surface tension of mercury cannot differ much from 400 dynes cm.$^{-1}$. Substituting in equation (8) the value of P_{back} from Table I, one finds that ρ must be about 320 μ instead of the known 27.0 μ.

This difference became understandable upon microscopic examination of the drops. As long as the mercury was dropping in a solution of 0.1 N potassium nitrate, it was suspended only from the thin column of mercury in the capillary bore. However, mercury dropping in air was attached mainly to the glass of the capillary. These observations are represented schematically in Fig. 1. It could be estimated that the attachment to the glass was over an area with a diameter about ten times that of the capillary orifice.

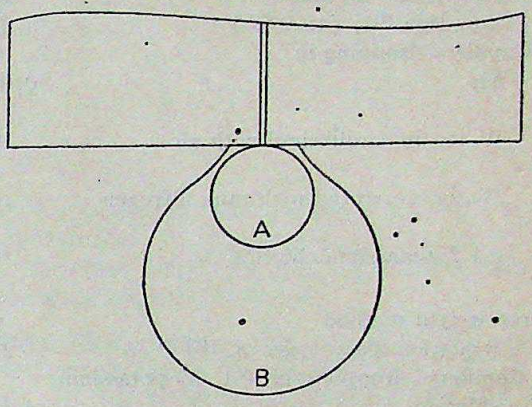

Fig. 1.—Schematic representation of mercury drops formed at a capillary whose orifice is 54 μ in diameter: A, in 0.1 N potassium nitrate—the drop is suspended from the mercury column only; B, in air—the drop is attached to the glass of the capillary.

Kolthoff and Kahan[4] have observed a similar attachment of mercury to the capillary glass when electrically disconnected mercury was dropping in oxygen-containing water. This they explained on the basis of interaction between the negatively charged glass/water double layer and the water/mercury double layer which is charged positively by the adsorption of oxygen from the water. They believe that an aqueous film exists between the attached mercury and the glass. This is probably not the case when the electrode is dropping in air, because the abnormalities are much greater than when it is dropping in water. Hence, a gaseous layer between mercury and glass must be assumed.

Since mercury does not wet glass, it is probable that neutralization of the electrostatic forces acting between mercury and glass cannot take place by direct transfer of the charges but must be effected by means of a conductor, such as an electrolyte. Only partial neutralization of these charges is possible in the presence of the poor conductor, water. Thus we have the paradox: under suitable conditions mercury is attracted to glass because it does not wet glass. Not much can be said without further study about the cause for the opposite charges. Experiments in this Laboratory have shown that the abnormalities persist when the mercury is dropping in an atmosphere of hydrogen gas instead of air; on the other hand, no abnormalities were found in benzene or in absolute ethyl alcohol, although the latter is known to contain much dissolved oxygen and is a poor conductor.

[a] Values in italics were obtained by lowering the mercury reservoir, the other values by raising it.

Determination of ρ.—In equation (2), the capillary radius—or the radius of the capillary orifice—appears raised to the fourth power. It is therefore essential that this radius be determined as accurately as possible. Besides direct measurement under the microscope, there are available two indirect methods involving well-known equations relating to surface tension.

The *critical pressure method* is based on the equation

$$\rho = 2\sigma/gdP_c \qquad (9)$$

in which σ is the surface tension and P_c is that critical pressure (in cm. of mercury), which is necessary to stop the flow of mercury and which leaves the meniscus of the mercury just at the capillary orifice.

The *drop weight method* is based on equation (6), rewritten as follows

$$\rho = Wg/2\pi\sigma \qquad (6a)$$

Both of these methods have been tried with different capillaries and in different media. Because of the attachment of mercury to glass, irregularities were found unless the medium was a satisfactory electrolyte such as 0.1 *N* potassium chloride.[4] Some typical examples are presented in Table III and compared with the directly determined radius (accurate to $\pm 0.5\ \mu$). Capillary no. 1 was factory made, while the other two were drawn in this Laboratory from 0.5 mm. capillary tubing. Nos. 1 and 2 represent capillaries suitable for general polarographic work, while capillary no. 3 should be used for special studies only because its orifice is too narrow and the bore is too tapered. In the calculations, the following values were assumed for the surface tension, σ: in water,[5] in equilibrium with air, 374 dynes cm.$^{-1}$; in water,[6] free from air, 427 dynes cm.$^{-1}$; in air,[7] 461 dynes cm.$^{-1}$; in 0.1 *N* potassium chloride,[8] 380 dynes cm.$^{-1}$.

In view of the sensitivity of these measurements to slight vibrations and the uncertainty of some of the surface tension values, the results show a satisfactory agreement as long as the critical pressure is attained by gradually *raising* the mercury reservoir. When the critical pressure was determined by *lowering* the reservoir, erroneous results were often obtained because, in this case, the drops did not "break clean" from the mercury column, but left some residual mercury outside the capillary orifice attached to the glass (see also Kučera[2]). When the pressure was lowered sufficiently that the dropping finally did stop, it was found that the mercury column receded into the capillary for a considerable distance. Gradual increase in the mercury pressure forced the mercury column nearer the capillary orifice until the critical pressure was exceeded and the capillary began to drop. In the potassium chloride solution, such complications were minimal.

Position of the Capillary.—That the capillary should be vertical and the cut surface perfectly horizontal is a foregone assumption in all polarographic work. Yet no clear-cut test has heretofore been described to safeguard against errors from this source. Actually, photographs of capillaries with hanging mercury drops, published by several investigators,[4,9] indicate that this prerequisite was not fully appreciated.

If the capillary is cut off at an angle or tilted, the drops cannot fall freely and become deformed. Under such conditions equation (6a) no longer

holds and should give a value for ρ different from that obtained by means of equation (9). However, if the capillary is so adjusted that the plane of the cut surface is horizontal, the value for ρ obtained by both equations should be identical. This phenomenon has been actually observed and is represented diagrammatically in Fig. 2.

The capillary used here had been cut off improperly so that the cut surface formed an angle of 70° instead of 90° with the longitudinal axis of the capillary. The capillary radius was found equal to 13.4 μ by direct measurement of the smallest diameter of the oval orifice. In all subsequent calculations, this orifice was considered round and with a radius equal to the one measured. The critical pressure in water and the drop weight in a 0.1 N potassium chloride solution were then determined, first, when the capillary was vertical and the plane of the cut surface slanted, and, second, when the capillary was slanted to bring the orifice on a horizontal plane. The results and the calculated values were

Position of capillary	P_c, cm.	ρ, μ	W, mg.	ρ, μ
Straight	42.0	13.6	2.37	9.7
Slanted	39.5	14.5	3.32	13.7

From this, one must conclude that the ρ values obtained by the drop weight and critical pressure methods should certainly agree within 1μ to insure proper functioning of the capillary. It should be mentioned here that even this type of capillary can be used for some special polarographic work and will give good results as long as its position is rigidly fixed. Because of its extreme sensitivity to slight changes in position, it cannot be recommended for general use.

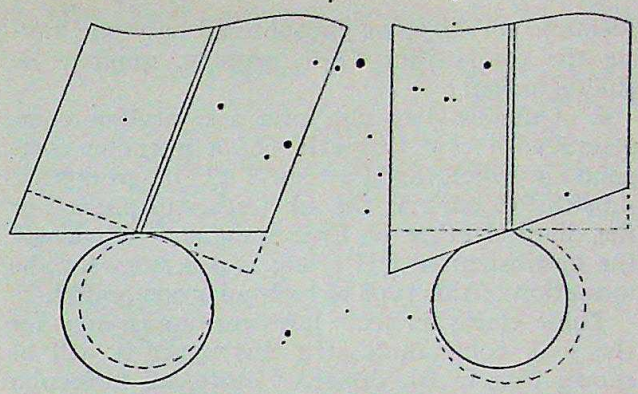

Fig. 2.—Graphical demonstration of the effect of position and improper cutting of the capillary on the drop size. Note that normal drops are obtained whenever the cut surface is perfectly horizontal.

Acknowledgment.—The author wishes to thank Mr. Howard Phipps and Dr. John Staige Davis, Jr., for financial support of this investigation.

Summary

Two factors have been proposed to serve as simple means for the complete characterization of all kinds of capillaries used for dropping mercury electrodes. These are the radius of the capillary orifice, ρ, and the capillary constant, κ, which is the pressure of mercury (in cm.) necessary to force 1 mg. of mercury through the capillary per second.

Various methods for their determination have been described which serve as checks for the proper behavior of the capillary.

Some abnormalities in the behavior of capillaries have been discussed.

Molecular Compounds of the Quinhydrone Type in Solution

BY LEONOR MICHAELIS AND S. GRANICK

The intensely colored molecular compounds of the quinhydrone type are best known in the crystalline state.[1] In solution all of them dissociate to a very high degree, although not completely. Such compounds usually consist of two components of which one is on a higher oxidation level than the other. One component may be a quinone, or an aromatic nitro compound; the other a phenol, an amine, or even a hydrocarbon such as hexamethylbenzene. Most of the studies here reported were carried out with compounds of a quinone with some phenolic compound. Crystalline compounds of this kind have the following characteristics:

1. When quinone combines with hydroquinone, the stoichiometrical composition of the compound is Q_1B_1, where Q stands for the quinoid and B for the benzenoid component.

2. When quinone combines with a phenolic compound having only one unsubstituted OH group, the molecular compound is Q_1B_2. Examples are the quinone compound of phenol and of *p*-methoxyphenol.

3. Some quinhydrone-like compounds of "anomalous composition" have been described.[2] Their compositions were inferred, not from a straight-forward analysis of the solid, but by indirect methods involving dubious interpretations. Among all such compounds which can be prepared in the crystalline state, and which are of

adequate stability, we encountered only one having the composition Q_2B_1, namely, quinone + phloroglucinol.

4. Quinone does not form a crystalline compound with any derivative of a phenolic compound in which the H atoms of all OH groups are substituted, such as the alkyl ether of phenol, or the di-alkyl ether of hydroquinone. Obviously the unsubstituted OH group is necessary for the formation of this type of molecular compound.

These characteristics, however, apply only for the solid compounds. In this paper it will be shown that in the dissolved state, all molecular compounds of the quinhydrone type are always of the composition Q_1B_1, regardless of their composition in the solid state, and even in such cases where no molecular compound exists at all in the solid state. As far as a comparison of various compounds in the same solvent can be carried out, one arrives at the conclusion that in the dissolved state the affinity of quinone is nearly the same for hydroquinone, its monomethyl ether, its dimethyl ether and its diethyl ether. It follows that problems concerning the composition and steric configuration of such compounds in the dissolved state cannot be dealt with on an equal footing with those holding for the solid state. The latter has been the subject of many experimental and theoretical studies[3] without a full understanding of the problem having been reached either with respect to the nature of the chemical bond, or to an explanation of the intense color, or to the general principle underlying the crystalline structure. Neither do the writers claim to have solved the problem, yet they have arrived at some definite experimental facts concerning the dissolved state which should have a bearing on any future general theory pertaining to the nature of such compounds.

It will be shown that all of the compounds of the quinhydrone type are highly dissociated in solution, and that the equilibrium within the limits of error can be expressed always as follows

$$qb/m = k \qquad (1)$$

where q and b are the total molar concentrations of the quinonoid and benzenoid components and m is the concentration of the molecular compound, instead of according to the more exact equation

$$(q - m)(b - m)/m = k \qquad (2)$$

In all cases, under all experimental conditions that can reasonably be applied, m is small, usually negligibly small, as compared with q and b. No method is available for the determination of the absolute value of m; only relative values can be obtained. This fact precludes any accurate determination of the association constant, k, for any one of these compounds. In solutions no evidence has yet been found for the existence of any compound other than Q_1B_1, both with respect to stoichiometrical composition and molecular size. The fact that, in the dissolved state, the substitution of the H in the OH group by the much more spacious CH_3 or C_2H_5 group, has no noticeable influence upon the formation of a molecular compound with a quinone, shows that, at least in the dissolved state, a hydrogen bond is not essential, as demonstrated by the formation of compounds such as quinone + hydroquinone-diethyl ether. The lack of any conspicuous steric hindrance caused by the alkyl group is compatible only with the assumption that in the dissolved state the molecular compound is always formed by superimposing the two rings upon each other, and not by a coplanar arrangement of the two rings.

The study of these molecular compounds in solution, where they exist only in extremely low concentration in equilibrium with their free components, depends on the relative intensity of their color. The free components absorb usually in the ultraviolet, and even where there is an additional absorption band in the visible spectrum as for quinone (with peak at 420 to 435 mμ, and with varying degree of fine structure (Fig. 5), according to the solvent) the molar absorption coefficient of this band at its maximum is very low. It is, for quinone, 17 to 19.8 depending on the particular solvent (whereas, for example, for regular dyestuffs of equivalent resonance structure it is of the order 10^4 to 10^5 at the peak of absorption). The quinhydrones also have a very high absorption coefficient at the peak of absorption, in or near the visible spectrum. Since the concentration of the molecular compound cannot be determined, its molar absorption coefficient cannot be determined either. However, it is always so large that even at those low concentrations at which they exist in equilibrium with the components, the optical density of the solution in or near the visible usually is due almost completely to the molecular compound alone, except for a small, sometimes negligible correction for the absorption due to the free components. This correction, then, consists in subtracting from the total optical density of the solution, that of its free components. Since always only a very small fraction (say 5% *in maximo* and usually very much less) of the components is used for the formation of the compound and the whole correction is usually small, no appreciable error is involved in subtracting the optical density due to the total concentration of the two components instead of subtracting the concentration of the uncombined part of the components. This correction is carried out by measuring the absorption against the pure solvent as a blank and subtracting the absorption due to the free components by calculation. Often a solution of one of the components in a proper concentration was used as a blank, and the correction for the other component was made by calculation. The

(3) In addition to references quoted,[1] special attention should be given to some brief remarks on the subject in a paper by L. Pauling.[4] The authors are indebted to Professor Pauling also for further discussion and advice with respect to the problems involved.

(4) L. Pauling, *Proc. Natl. Acad. Sci.*, **25**, 577 (1939).

Digitized by Arya Samaj Foundation Chennai and eGangotri

absorption was measured with the Beckman[5] photoelectric spectrophotometer which allows rapid and very precise readings of the transmission reproducible to within a fraction of 1%, from 215 to 1275 mμ.

The optical density, δ, of any solution is

$$\delta = \frac{I}{d} \log \frac{I_0}{I}$$

where I_0 is the intensity of light transmitted across the blank; I, that across the solution; and d, the thickness of the absorption cell in cm. The molar absorption coefficient of any single molecular species is $\epsilon_{mol} = \delta/c$ where c is the concentration of the substance in moles per liter.

The claim that all such molecular compounds in the dissolved state have the composition Q_1B_1, is based on the fact that the optical density due to the molecular compound is in all cases proportional to the concentration both of the Q component and of the B component, so that within the limits of error

$$\delta/qb = C$$

where the constant, C, depends on the particular compound and on the particular solvent used. This constant will, in what follows, be designated as ϵ_{st}, the "absorption coefficient of the molecular compound under standard conditions," in the particular solvent. Its significance will be discussed later.

Experimental Part

All substances were freshly purified either by sublimation, distillation, steam distillation, or recrystallization, and only quite fresh solutions were used, which is especially important for quinone.

In the diagrams, the corrected optical density of the solution, δ, is plotted against wave length in mμ. A few absorption spectra, in terms of the molar absorption coefficient, ϵ_m, for the single components are added.

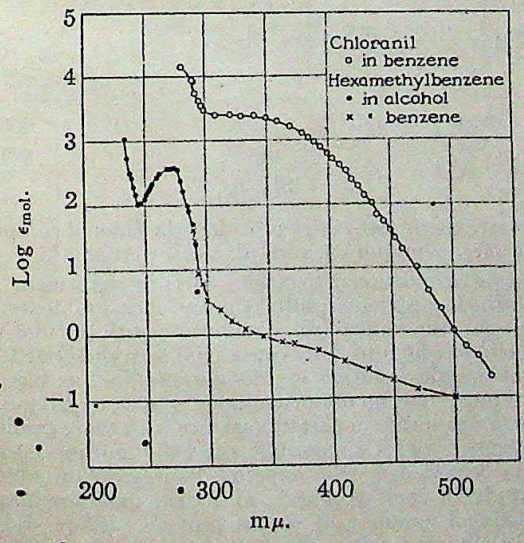

Fig. 1.

1. Examples of Compounds Having, in the Solid State, the Composition Q_1B_1

(a) **Tetrachloroquinone + Hexamethylbenzene.**—In Fig. 1, the molar absorption coefficient for either component separately is plotted logarithmically against wave length. The maximum absorption of the molecular compound (Figs. 2 and 3) is at 510 mμ. Here the contribution, to the density, of the free components is negligible and no correction is required. For all wave lengths > 450 mμ, the optical density of the mixture (Figs. 2 and 3) is solely due to the molecular compound. This optical density is shown in Fig. 2 to be proportional to the concentration of tetrachloroquinone, and, in Fig. 3, to be proportional to the product of the two concentrations if both are varied.

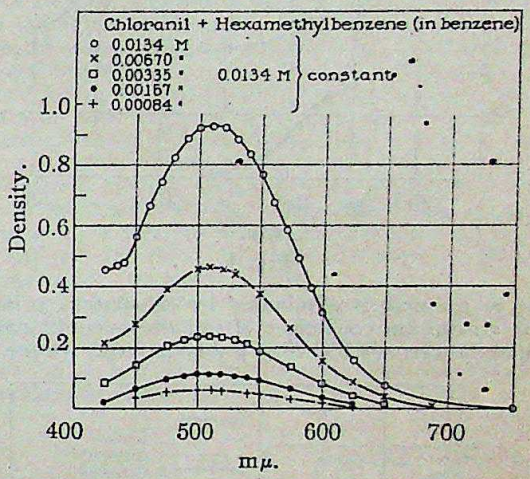

Fig. 2.

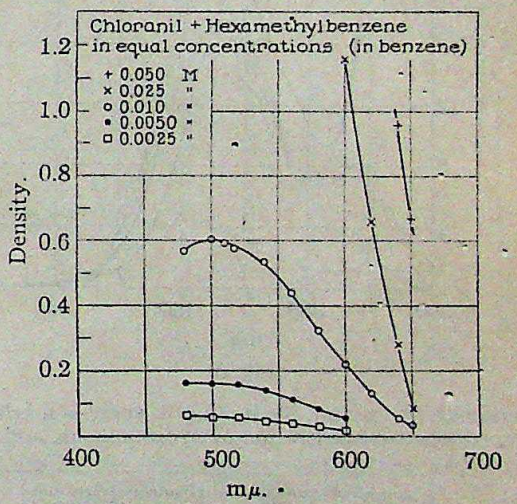

Fig. 3.

(b) **Quinone + Hydroquinone.**—The molar absorption coefficients are plotted, logarithmically, in Fig. 4, for the components singly. That part which is most important for this problem, in the violet region of the visible spectrum, is shown on a larger scale for quinone (not logarithmically) in Fig. 5. The molar absorption coefficient of quinone at its maximum around 430 mμ is 17 to 19.8 according to the solvent. Since the peak of absorption for quinone and for quinhydrone lie almost at the same wave length, the correction for the effect of quinone is always necessary. Although this correction is small in general, subtraction of the density due to the total quinone, instead of the uncombined quinone only, may cause a slight error. The effect of quinone is eliminated in Figs. 7 and 8, by taking as a blank a quinone solution of the same concentration but without hydroquinone. On the other hand, in Fig. 6, the

effect of quinone is eliminated by calculation, using the molar absorption coefficient of quinone according to the original data from which Fig. 5 was derived. In the three

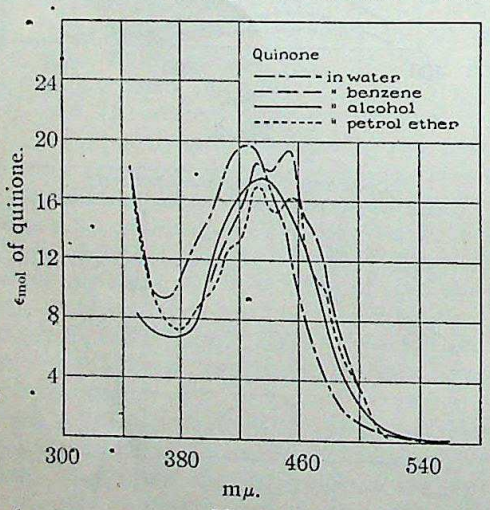

Fig. 5.

experiments ⊙, x and +, in Fig. 6, there is a relatively large, constant concentration of hydroquinone, and a low,

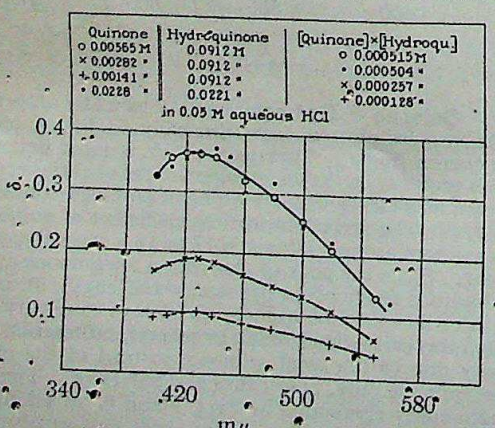

Fig. 6.

varied concentration of quinone. Here the optical density is proportional to the quinone concentration. In experiment ●, an equimolar concentration of both components is used. Considering the fact that for the latter experiment the quinone correction is unusually great, involving a larger uncertainty, it can be stated that in all four experiments of Fig. 6 the density is proportional to the product of the concentrations of the two components, within the limits of error. The fact that this is true whether hydroquinone is nearly at the same concentration as quinone, or in excess, is important with reference to an observation made by other authors which will be discussed presently.

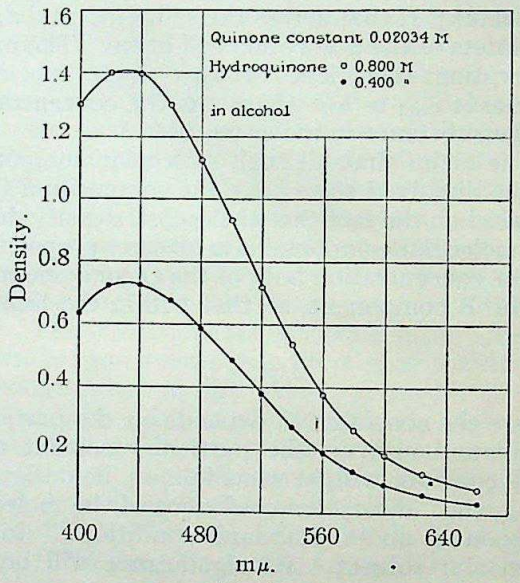

Fig. 7.

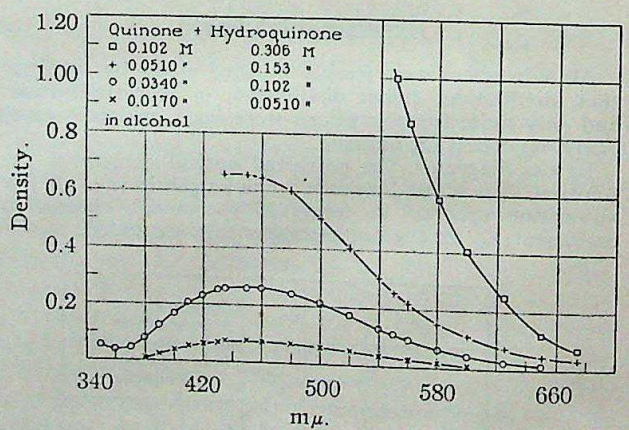

Fig. 8.

These experiments show also that the colored compound is not a free semiquinone radical. If it were so, the density would be proportional to $\sqrt{qb}$. It is in agreement with the authors' previous results[6] that no measurable amount of semiquinone radical is in equilibrium with the molecular compound (which may be considered as a dimerized radical) unless the solution is strongly alkaline, as has been shown for a solution of duroquinone + durohydroquinone.

These results are in part at variance with those published by Wagner and Grünewald,[7] the only authors, to the writers' knowledge, who have used spectrophotometry in the study of such problems, and then only for aqueous solutions of quinone + hydroquinone. They did not establish a continuous absorption curve nor locate the

maximum absorption but measured the optical density of aqueous solutions only at the wave length of three mercury lines. In equimolar mixtures of the components, the optical density was approximately proportional to the product of the two concentrations. On the ground of the small deviations from proportionality they calculated the dissociation constant of quinhydrone, which, however, they could not corroborate with measurements on mixtures with excess of hydroquinone. They refrain from making a decision as to whether this was due to some unknown optical effect or to the establishment of a compound different from Q_1B_1, say Q_1B_2. They agree with the writers that there is no measurable amount of semiquinone radical in equilibrium with the molecular compound. It can be seen that the present results do not coincide with those of the earlier authors' in several respects.

(c) **Duroquinone + Durohydroquinone.**—In one of the previous papers in this series (5) it was claimed that duroquinone + durohydroquinone do not combine to form any quinhydrone-like compound. This statement must be revised. To be sure, a mixture of the two substances in 20% pyridine or alcohol + 80% water, does not produce any precipitate, yet a very slight intensification of the color, compared with that of duroquinone alone, takes place. The steric hindrance for the formation of a quinhydrone due to the methylation at the ring is very conspicuous indeed, but it is not quite complete. Under proper conditions even a solid crystalline quinhydrone can be prepared. On dissolving equivalent amounts of either component at a high concentration in acetone, mixing both, and adding water slowly, a brownish precipitate arises, consisting of long, rod-shaped crystals, dichroitic blue and yellow. The dissociation of this quinhydrone in solution is extremely great. Judging from the appearance of color in a test-tube experiment, when a mixture of quinone + hydroquinone is compared with that of duroquinone + durohydroquinone at the same conditions, the dissociation of the latter is very much greater indeed. However, accurate spectrophotometric measurements cannot be carried out because durohydroquinone is so highly autoxidizable that the readings of the optical density rapidly change during the period of time necessary for an experiment.

Previous magnetic measurements[6,8] did not reveal any polymerization of the semiquinone radical of duroquinone as it arises in strongly alkaline solution. However, the crystalline, solid duroquinhydrone obtained as just described, from a non-alkaline solution, is diamagnetic. The susceptibility was measured with the method previously described[9] and found to be $= -140 \times 10^{-6}$ c.g.s.u., per equivalent (or half a mole). It is expected to be -124×10^{-6} according to Pascal's rules, on the assumption that the susceptibility of durohydroquinone is suitable for comparison. Considering the fact that this is just one single measurement and that the finely ground duroquinhydrone is a remarkably fluffy powder which can be packed homogeneously into the cylindrical vessel only with difficulty, the agreement is satisfactory. There is decidedly no paramagnetic semiquinone radical component in the crystals. The crystalline state, just as for the aromatic diamines,[9] is entirely in one of the two possible magnetic states, either fully diamagnetic or fully paramagnetic. This compound is fully diamagnetic. The previous magnetic measurements with the free radical in the dissolved state did not reveal any dimerization of the paramagnetic radical because they were carried out at *p*H 12, where the radical has the composition, $[OC_6(CH_3)_4O]^-$, but in the present investigations the solutions were neutral and so the radical has the composition $HOC_6(CH_3)_4O$, which is utterly unstable due to lack of equivalent resonance and which exists only, if at all, as the dimeric, diamagnetic quinhydrone with the H atom acting as a hydrogen bond involving dimeric resonance.[9] It may be added that in the meantime also the free radical, as a sodium salt, has been prepared in the solid state. In agreement with expectation, it is paramagnetic, however not to the full extent expected due to the fact that the solid preparation was not pure nor homogeneous.

(d) **Quinone + Resorcinol.**—The compound quinone + resorcinol is listed in Pfeiffer's book[1] among the compounds of composition Q_2B_1, according to indirect evidence presented by Kremann and associates.[2] These authors did not succeed in preparing the solid compound. It is however easy to prepare the intensely red, crystalline compound by mixing solutions of the components in acetone. One sample was prepared by mixing 1 g. of quinone (in 4 cc. acetone) with 1 g. of resorcinol (in 2 cc. of acetone), whereby the crystalline compound is obtained directly in pure form. Another preparation was obtained by mixing 0.4 g. of resorcinol (in 0.5 cc. of acetone) and a large excess of quinone, 1 g. (in 4 cc. of acetone). After slight evaporation of acetone, crystals of the free quinone are obtained. After addition of benzene the quinone dissolves and gradually brown crystals appear. Both samples of the quinhydrone were of the accurate composition, Q_1B_1. The analysis for quinone was made by dissolving the crystals in a little alcohol, diluting with water and titrating with titanous chloride. The stock solution of the latter diluted with a suitable volume of 6 *N* hydrochloric acid was standardized against quinone with methylene blue as internal indicator. It was ascertained that addition of resorcinol to a solution of quinone does not disturb the titration of quinone. So, the crystalline compound always has the composition Q_1B_1.

The spectrophotometric analysis of the solution containing quinone and resorcinol shows (Fig. 9 and Table I) that the optical density is proportional to the quinone concentration and also to the resorcinol concentration. The maximum absorption is at 370 mμ.

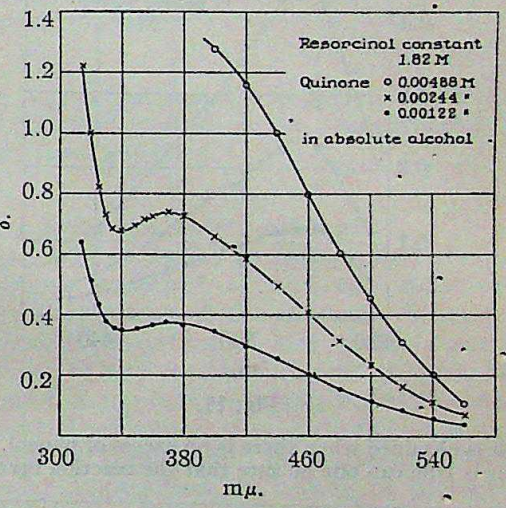

Fig. 9.

2. Examples of Compounds Having the Composition Q_1B_2 in the Solid State

(a) **Quinone + Phenol.**—First of all it was ascertained that solid "phenoquinone" has always the composition Q_1B_2 even when prepared from a solution, in petrolic ether, with a large excess of quinone. The analysis for quinone was made in the same manner as just described. The color of "phenoquinone" in solution is yellow, and the peak of absorption is not in the visible spectrum, but at 320 mμ. In Fig. 10 (disregarding for the time being the experiment marked △), it is shown that in alcoholic solution the optical density is proportional to the quinone concentration if the phenol concentration is kept constant. The same is true in petrol ether solution (Fig. 11). In Fig. 12 it is shown that on varying only the phenol concentration the density is proportional to the latter. So, in Fig. 12 the densities, corrected for the effect of both free components, for instance at 450 mμ, in the four experiments plotted, are in the ratio, 5.88:4.02:2.00:1.00, while the ratios of the phenol concentrations are, 6.1:4.0:2.00:1.00.

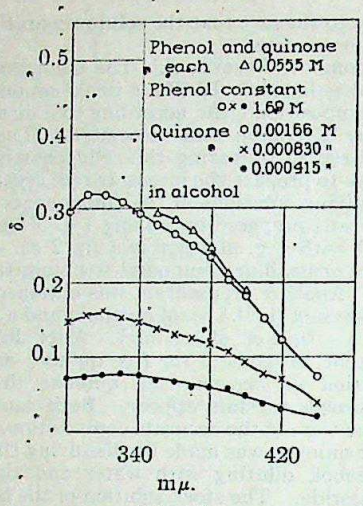

Fig. 10.

In these experiments although the concentrations have been varied, there is always an excess of phenol with respect to quinone. It is important to show that the same

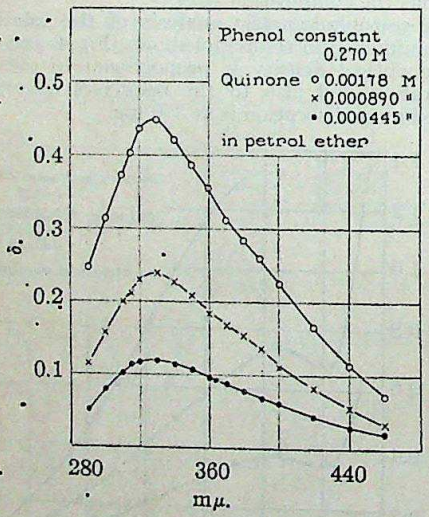

Fig. 11.

result is obtained when there is no excess of phenol. Only if this is true can one be sure that the reaction involved is always $Q + B \rightleftharpoons QB_1$ and that another reaction, $QB_1 + B \rightleftharpoons QB_2$, does not occur. Such an experiment is shown in Fig. 10, marked Δ, where the concentration ratio is 1:1.

The absorption due to free quinone is so strong here that the optical density due to the molecular compound can be measured only at wave lengths > 350 mμ, but not at the maximum of absorption at 320 mμ. On looking at the results, *e. g.*, at 360 mμ, the corrected density was found to be 0.284. This, divided by the product of the two concentrations, yields $\epsilon_{st} = 92$. For the same wave length, the other experiments gave values ranging from 92 to 96, a satisfactory agreement.

(b) **Quinone + Hydroquinone Monomethyl Ether.**—The composition of the crystalline compound, a long time ago,[10] was found to be Q_1B_2. This can be easily confirmed by the method of analysis just described. For the dissolved state, however, it is shown (Table I) that the optical density of the mixture is proportional, at constant concentration of the hydroquinone ether, to the concentration of quinone. The maximum of absorption is at 420 mμ, very close to that of quinone + hydroquinone, and very far from that of phenol + quinone which is at 320 mμ. In Table I the density is shown to be proportional also to the concentration of hydroquinone monomethyl ether. So, the composition in solution is Q_1B_1.

3. Example for a Case Where the Solid Compound is Q_2B_1

Among the tri-hydroxybenzenes only phloroglucinol combines with quinone to form a crystalline compound stable enough to allow an analysis both in the solid and in the dissolved states. The solid compound is perfectly stable, the solution at least stable enough to permit of spectrophotometry with freshly prepared solutions. The crystalline compound has always the composition Q_2B_1, a composition which has heretofore not been known, nor even expected. One sample was prepared by mixing 1 g. of quinone (in 4 cc. of acetone) with 1.1 g. of phloroglucinol (in 2 cc. of acetone). Crystallization proceeds slowly but copiously. Another sample was prepared with an excess of quinone, by mixing 1.5 g. of quinone (in 6 cc. of acetone) with 0.5 g. of phloroglucinol (in 1 cc. of acetone). This mixture yields directly only quinone crystals. After adding an equal volume of benzene and slight evaporation at room temperature the red-brown quinhydrone crystals appear. Both samples of the solid quinhydrone, when titrated with titanous chloride, were found to have accurately the composition Q_2B_1.

A mixture of the two components in alcohol shows the formation of a brownish compound with maximum absorption at 420 mμ, close to that of quinone + hydroquinone, and very different from quinone + resorcinol (360 mμ). Freshly prepared alcoholic solutions gave the results presented in Table I. In another experiment, in which only the quinone concentration was varied, the optical density was proportional to that concentration, within the limits of error. So, the optical density due to the molecular compound is proportional to the product of the concentrations of the two components, hence its composition in the dissolved state is Q_1B_1.

4. Examples of Molecular Compounds Which do not Exist in the Solid State

(a) **Quinone + Hydroquinone Dimethyl Ether.**—No molecular compound of phenol + hydroquinone dimethyl ether has been obtained. However, a remarkable phenomenon can be observed in this case, which throws much light on the difference in behavior in the solid and in the liquid state. When a mixture of solid phenol and dimethylhydroquinone is melted, an intensely red liquid is obtained which remains so, even after supercooling. As crystallization sets in, all the red color disappears. The solid material is yellow and consists of two kinds of crystals, the light yellow ones of quinone and the colorless ones of hydroquinone dimethyl ether. This process is reversible. In alcoholic solution a mixture of quinone + dimethylhydroquinone shows an orange color, very much more intense than that of quinone alone, and here again the absorption due to this strongly colored substance is proportional both to the concentration of quinone and, as shown in Table I, to that of dimethylhydroquinone, so, the composition of the colored compound is Q_1B_1, but this compound exists only in solution.

The absorption maximum of this molecular compound in alcohol solution is, at 410 mμ, close to but not quite equal to that of quinhydrone.

(b) **Quinone + Hydroquinone Diethyl Ether.**—This case is quite analogous in every respect to that of the dimethyl ether. The larger volume of the ethyl group, as compared with the volume of the methyl group, does not influence the properties of the molecular compound. Table I shows the values both for alcohol and for benzene solutions.

(c) **Quinone + Anisole.**—No crystalline molecular compound of quinone and anisole can be prepared. In solution, however, such a compound does exist to a slight extent. When a solution of quinone, in alcohol or in petrol ether is mixed with anisole, the color is intensified. The maximum absorption of the compound in alcohol is at 320 mμ (Table I), just as for phenoquinone, and at 350 mμ in petrol ether. Here again the absorption due to the molecular compound is very much stronger than that of quinone alone, and the optical density is rather accurately proportional to the concentration of anisole. So, the molecular compound again is Q_1B_1.

(d) **Quinone + Phenetol.**—The result is similar to that obtained in the preceding case.

Significance of the ϵ_{st}, the Standard Absorption Coefficient

Since the optical density due to the molecular compound must be

$$\delta = \epsilon_{mol} \times m$$

where ϵ_{mol} is the molar absorption coefficient of the compound and m is its concentration, one obtains from equation 1

$$\epsilon_{st} = \epsilon_{mol} \times k$$

where k is the association constant.

There is good reason to assume that the molar absorption coefficient of any one substance is nearly independent of the solvent. Whenever a considerable variation of the molar absorption coefficient of any dye in different solvents is encountered, it can be always attributed to a change in chemical structure, say, a change of a quinonoid–lactoid equilibrium, or a different state of molecular aggregation, according to the solvent. There is no reason to assume that the molar absorption coefficients of molecular compounds of composition Q_1B_1 should vary appreciably according to the solvent. Consequently, the values of ϵ_{st} for any one compound in different solvents may be considered approximately as relative values of the association constant of that compound in various solvents. For instance, Table I shows that the association constant of quinone + hydroquinone is about eight times greater in water than in alcohol, probably due to the fact that in the competition among the affinities of the components for the solvent and for each other, the association is more inhibited by alcohol than by water.

On the other hand, on comparing the various values of ϵ_{st} for a series of molecular compounds in the same solvent, it is not possible, in general,

(10) H. Wichelhaus, *Ber.*, **12**, 1501 (1879): for the correction of his result, see O. Hesse, *Ann.*, **200**, 254 (1880).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

to decide whether the variation is due to a change of ϵ_{mol}, or of k, or of both. However, on comparing a homologous series, such as the compounds of quinone and, on the other hand, either hydroquinone or its ethers, in the same solvent, the values of ϵ_{st} are found to vary but little within this homologous series. It does not seem probable that the variation of ϵ_{mol} should be always just inversely proportional to the variation of k. It may rather be inferred from this fact, with high probability, that both ϵ_{mol} and k are approximately constant within the homologous series. For instance, both the molar absorption coefficients and hence the association constants are found to be almost alike for the compounds formed by quinone either with hydroquinone, its monoether, or its di-ethers, in alcohol. The substitution in the OH group is no steric hindrance to the formation of the molecular compound in solution.

In benzene the situation is slightly different. Quinone + hydroquinone cannot be compared with the other compounds of quinone because in benzene even at extremely low concentration precipitation of crystalline quinhydrone occurs. However, the compounds of quinone with the various ethers of hydroquinone can be mixed at proper concentration without any precipitation occurring. It can be seen that ϵ_{st} for the monomethyl ether compound is about twice that for a di-alkyl ether compound. In all probability this is due, not to any appreciable change of ϵ_{mol}, but to a slight change in the association constant, k, which in its turn is probably due to competition between the mutual affinity of the components and the affinity between components and solvent.

Summary

Highly colored molecular compounds of the quinhydrone type exist, not only in the crystalline state, but, to a slight extent, also in solution, in equilibrium with their free components. Because of their intense color such compounds lend themselves to a study by spectrophotometric methods. The compounds studied here consist usually of a quinone (Q) and another component of benzenoid structure (B), usually a phenolic compound. In the crystalline state the stoichiometric composition of the compound may vary, according to the particular phenolic compound used. It may be Q_1B_1, Q_1B_2, or Q_2B_1. No solid compound is formed when the OH group of phenol, or all OH groups in a poly-phenol, are alkylated. In the dissolved state, however, all of these compounds have the composition Q_1B_1, and molecular compounds exist just as well with unsubstituted as with alkylated phenols. This conclusion is based on the fact that the absorption of light due to the molecular compound is always proportional to the concentration of either component. It is furthermore shown that the affinity of quinone for a phenolic compound in solution is not essentially altered by alkylation of the phenolic OH groups. It is inferred from this that in the dissolved state the rings of the two components are superimposed upon each other and are not coplanar, and that no hydrogen bond plays any essential role in the establishment of these compounds. The crystalline compounds may differ from the dissolved ones, both in their stoichiometrical composition and in their spatial structure.

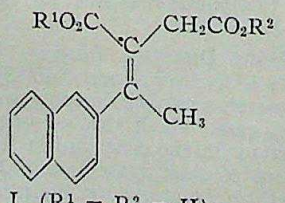
The Condensation of 2-Acetylnaphthalene with Diethyl Succinate[1]

BY WILLIAM S. JOHNSON AND ARTHUR GOLDMAN

In the course of certain synthetic work being carried out in this laboratory the occasion arose to investigate the condensation of 2-acetylnaphthalene with diethyl succinate. Through the efforts of Stobbe and his collaborators it has been well established that the alkoxide-catalyzed reaction of succinic ester with a ketone proceeds not by the acetoacetic ester type but mainly by an aldol type of condensation between the carbonyl group of the ketone and a methylene group of the ester. Stobbe and Lenzner[2] have reported that this condensation with 2-acetylnaphthalene gave a crystalline half-ester, m. p. 103–104° (yield unspecified). Saponification yielded a dicarboxylic acid, m. p. 165° (dec.), which they presumed to be an itaconic acid (formula I or II) by analogy with the products formed in similar condensations.[3]



I ($R^1 = R^2 = H$)
Ia ($R^1 = C_2H_5$, $R^2 = H$)
Ib ($R^1 = H$, $R^2 = C_2H_5$)
Ic ($R^1 = R^2 = C_2H_5$)

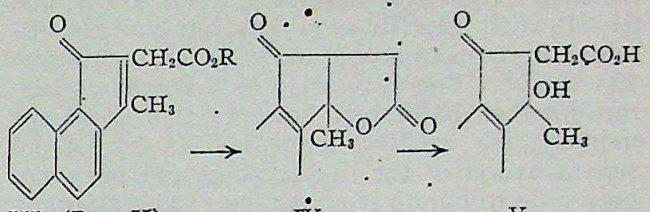
procedure,[2] an acidic mixture was produced from which a crystalline half-ester could be separated in 18% yield. This substance in contrast to that of Stobbe and Lenzner melted at 119–119.6° (pure). No other crystalline products could be isolated at this stage. The reaction proceeded similarly when carried out in ethanol with approximately one equivalent instead of excess sodium ethoxide. The latter procedure was easier and gave the 119° half-ester in 21% yield. Saponification yielded a dibasic acid, m. p. 179.5–180.5° (dec.), which gave an anhydride, m. p. 155.5–156°.

The oily mixture remaining after removal of the 119° half-ester was saponified with barium hydroxide, and the acidic material was treated with acetyl chloride. Fractional crystallization of the neutral material first gave a fraction which appeared to contain some of the previously mentioned 156° anhydride, followed by a more soluble fraction which consisted largely of a new isomer, m. p. 116°. This separation was inefficient, but did serve as a source of pure materials. From a study of the reactions, however, an indirect method was evolved for estimating the relative amounts of materials in the original mixture. This is described later.

Hydrolysis of the 116° anhydride gave a dibasic acid, m. p. 167–168° (dec.). The position of the ethylenic bond in this and in the 180° acid was shown by ozonolysis of derivatives which gave 2-acetylnaphthalene in each case. This proves that these are the geometrically isomeric γ-methyl-γ-(2-naphthyl)-itaconic acids. Stobbe[3b] determined the configurations of the two corresponding γ-methyl-γ-phenylitaconic acids from their behavior with sulfuric acid. One of the acids was converted to its anhydride, while the other was cyclized to give 3-methyl-1-indone-2-acetic acid (and the corresponding lactone), indicating that it had the *allo*-cinnamic acid configuration. The method of Stobbe was not successful when applied to the present case, probably because the higher polycyclic nuclei are more susceptible to sulfonation by the reagent.[4] When hydrogen fluoride[5] was used instead of sulfuric acid satisfactory yields of cyclized products were obtained. The 180° acid gave a mixture of 3-methyl-6,7-benz-1-indone-2-acetic acid (III) and the corresponding lactone IV. It is therefore assigned the configuration shown in formula I. The 168° acid was converted to 4-hydroxy-1-methylphenanthrene-2-carboxylic acid (VI), and is therefore represented by formula II. The cyclization of II to form the phenanthrol instead of the anhydride (as with the phenylitaconic acid analog[3b]) may be explained by the greater reactivity of the naphthalene nucleus or/and a cyclizing action of hydrogen fluoride which is different from that of sulfuric acid. The proof of structure of the cyclization products III and VI is considered later.



III (R = H) IIIa (R = C_2H_5) IV V

VId ($R^1 = CH_3$, $R^2 = C_2H_5$)

VII

When the anhydride of I was treated with ethanol containing a drop of sulfuric acid it was converted into a new half-ester, m. p. 118°, which was different from the 119° isomer as shown by the melting point depression of the mixture. The 118° half-ester could be prepared also in good yield by mild esterification of the dibasic acid (I). Exhaustive esterification of the 118° half-ester gave the di-ester (Ic) which on partial saponification with one equivalent of barium hydroxide yielded the 119° half-ester, thus completing the cycle (see Fig. 1). The mode of formation of the two half-esters suggests that the 119° substance has the structure Ia and that the 118° isomer is Ib. These structures were substantiated by cyclization experiments. When heated with acetic anhydride and sodium acetate the 118° half-ester was converted into the red indoneacetic ester IIIa. Upon the same treatment the 119° isomer, in contrast, was recovered largely unchanged. The small neutral fraction contained the anhydride of I and none of the indone derivative. The above transformations are indicated in the accompanying chart (Fig. 1):

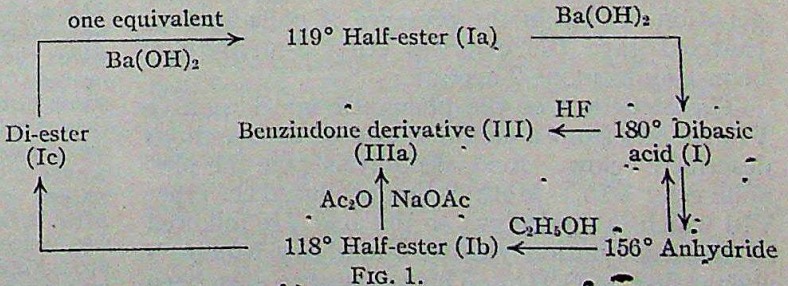

FIG. 1.

A sequence of transformations analogous to those described above for the dibasic acid I was developed from the stereoisomeric acid II (see

Fig. 2). Although the half-ester IIb obtained by alcoholysis of the 116° anhydride melted at 102–102.5°, its mode of formation makes improbable its identity with the material of Stobbe and Lenzner. This same argument seems to rule out the 118° half-ester Ib, even though it has been obtained in a polymorphic modification melting at 105–105.5°. This leaves IIa as a possible structure for their half-ester; however, this also seems unlikely, for we have prepared IIa by partial saponification of the di-ester IIc, and have not been able to obtain it crystalline. The alternate possibility still remains that their substance actually was a lower-melting modification of Ia,

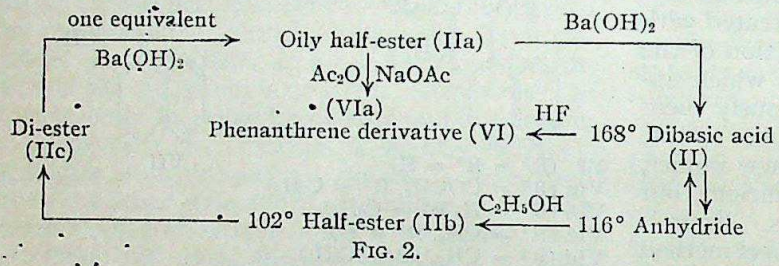

Fig. 2.

and that coincidentally their dibasic acid was similar to a low-melting (163–165°) fraction of I isolated in the present work.

The structures of the half-esters IIa and IIb were assigned on the basis of their behavior toward acetic anhydride and sodium acetate. The former was cyclized to ethyl 4-acetoxy-1-methylphenanthrene-2-carboxylate (VIa), while the isomeric half-ester IIb was converted largely to the anhydride.

The structure of the red indoneacetic ester IIIa was assigned on the basis of the following transformations. Oxidation with nitric acid gave benzene-1,2,3,4-tetracarboxylic acid which proved that ring closure took place into the 1-position of the naphthalene nucleus. On acid hydrolysis of IIIa the color (which is characteristic of an indone) was dispelled and the colorless lactone IV was produced. This was identical with the material obtained by the cyclization of the itaconic acid I. Alkaline cleavage gave the hydroxy acid V which reverted easily to the lactone on heating. Hydrogenation of IIIa in the presence of palladium on charcoal gave the colorless ethyl 3-methyl-6,7-benz-1-hydrindone-2-acetate.

The structure of the phenanthrene derivative VIa follows from a consideration of the reactions described below. Acid alcoholysis gave the phenolic ester VIb. Methylation produced the ether VId which on hydrolysis to the acid VIc followed by decarboxylation yielded 4-methoxy-1-methylphenanthrene (VII). This substance has been prepared previously[6] by the Pschorr synthesis, and the reported melting points of VII and of the picrate are in agreement with those found in the current work. Alkaline hydrolysis of VIa produced 4-hydroxy-1-methylphenanthrene-2-carboxylic acid (VI) which was the product of cyclization of the itaconic acid II.

A rough estimation of the amounts of the itaconic half-esters present in the original reaction mixture was made by treating the crude oily fraction which remained after the separation of the half-ester Ia (in 21% yield), with acetic anhydride and sodium acetate. The half-ester IIa thus was cyclized to the phenanthrol acetate VIa which crystallized in 30%[7] yield from the neutral fraction. On working up the acidic residues additional half-ester Ia was accounted for, raising the amount of this isomer in the original mixture to 29% of the theoretical. The total amount of itaconic half-esters thus accounted for is 59% of the theoretical based upon 2-acetylnaphthalene. This is in fair agreement with the yield (65%) of the mixture of itaconic di-esters obtained from the crude reaction mixture by esterification and fractional distillation. Partial saponification of this product gave a mixture which was rich in respect to the itaconic half-esters as shown by analysis according to the procedure described above for the crude mixture. About 47% of Ia and 38% of IIa were accounted for in this way.

Experimental Part[8]

The Condensation of Diethyl Succinate with 2-Acetylnaphthalene

(*a*) *By the Procedure of Stobbe and Lenzner.*[2]—The reported procedure has been repeated several times, and the results of a typical run are given herewith. When 19.5 g. (0.112 mole) of diethyl succinate, 19.1 g. (0.112 mole) of 2-acetylnaphthalene and 0.20 mole of alcohol-free sodium ethoxide (from 4.6 g. of sodium) were used, all but about 10% of the product was alkali-soluble. The oily acidic fraction was dissolved in ether, petroleum ether[9] was added to the point of incipient cloudiness and crystallization was induced. The crude product was filtered and then recrystallized from ether–petroleum ether.[9] The first and second crops of colorless crystals both had the same m. p., 118–119°, and amounted to 6.0 g., a yield of 18%.

(*b*) *With Alcoholic Sodium Ethoxide.*—To a solution of 6.4 g. (0.28 mole) of sodium in 120 cc. of absolute alcohol were added 43.5 g. (0.25 mole) of diethyl succinate and 42.5 g. (0.25 mole) of 2-acetylnaphthalene. The mixture was refluxed on the steam-bath for fifteen hours during which the solution turned brown and a heavy precipitate formed. Water was added, and the alcohol removed by steam-distillation. Ether extraction of the alkaline solution gave 5.9 g. of dark neutral oil which was not further investigated. The aqueous layer was acidified, and the orange oil which separated was taken up in ether and washed with water followed by saturated salt solution. After drying over anhydrous sodium sulfate the solution was concentrated and treated with petroleum ether[9] to precipitate the crude half-ester Ia. By recrystallization from ether–petroleum ether[9] a total of 15.3 g. (21% yield) of colorless plates, m. p. 117.5–118.5°, was obtained. The nature of the residues is considered later.

(6) Higginbottom, Hill and Short, *J. Chem. Soc.*, 263 (1937).

(7) The amount of IIa in the original mixture is probably more than indicated by this yield, since the cyclization of relatively pure IIa to VIa was not quantitative. See experimental part.

(8) Unless otherwise stated, all melting points are corrected.

(9) Boiling range 60–68°.

3-Carbethoxy-4-(2-naphthyl)-*cis*-3-pentenoic Acid (Ia).—Material obtained in the preceding experiment was recrystallized to constant m. p. from ether–petroleum ether.[9] It formed colorless plates, m. p. 119–119.5°.

Anal. Calcd. for $C_{18}H_{18}O_4$: C, 72.47; H, 6.08. Found: C, 72.60; H, 5.82.

3-Carboxy-4-(2-naphthyl)-*cis*-3-pentenoic Acid (γ-Methyl-γ-(2-naphthyl)-isoitaconic Acid) (I).—A mixture of 9.10 g. of the above half-ester (m. p. 117–118°), 13 g. of barium hydroxide, 75 cc. of alcohol and 100 cc. of water was heated under reflux on the steam-bath for six hours. The colorless barium salt was filtered from the cooled solution, washed with water, then with alcohol. Treatment with dilute hydrochloric acid gave 8.10 g. of crude dibasic acid, m. p. 169–171° (dec.). The first crop obtained by recrystallization from dilute alcohol amounted to 5.40 g. of colorless crystals, m. p. 176.5–178.5° (dec.). Repeated recrystallization from acetone–petroleum ether[9] gave material of constant m. p., 179.5–180.5° (dec.).

Anal. Calcd. for $C_{16}H_{14}O_4$: C, 71.10; H, 5.22. Found: C, 71.40; H, 5.26.

The mother liquor from the dilute alcohol crystallization yielded an additional 2.50 g. of acid, m. p. 163–165° (dec.), which could not be purified readily. The m. p. of a mixture with the analytical sample was not depressed (165–167°). When mixed with the stereoisomeric acid II (m. p. 167–168°) the m. p. was depressed (150–155°). This second crop of the dibasic acid I corresponds in m. p. to the acid of Stobbe and Lenzner.[2] This suggests that their half-ester possibly could have been a lower-melting polymorphic modification of the 119° half-ester.

The anhydride of I was prepared by Stobbe's general procedure[3a] with acetyl chloride at room temperature. From 0.670 g. of I (m. p. 179–180°) was obtained 0.552 g. of bicarbonate-insoluble material, m. p. 153–154°. The pure anhydride was obtained as colorless blades, m. p. 155.5–156°, from chloroform–petroleum ether.[9]

Anal. Calcd. for $C_{16}H_{12}O_3$: C, 76.18; H, 4.80. Found: C, 76.30; H, 4.94.

Ethyl 3-Carboxy-4-(2-naphthyl)-*cis*-3-pentenoate (Ib). (*a*) *From the Anhydride of I.*—A mixture of 1.04 g. of the anhydride described in the preceding experiment and 20 cc. of ethanol containing one drop of concentrated sulfuric acid was warmed on the steam-bath until solution was nearly complete. After standing overnight the solution was evaporated in a stream of air, and the solid residue was taken up in ether. The solution was washed with water, and then extracted with portions of 5% sodium bicarbonate solution. Acidification of these extracts gave 1.17 g. (95% yield) of colorless half-ester, m. p. 117–118°.

(*b*) *From the Dibasic Acid I.*—A mixture of 4.90 g. of the itaconic acid I (m. p. 177–179°), 40 cc. of alcohol and 60 cc. of benzene containing three drops of sulfuric acid was allowed to reflux through a system which included a constant water separator of the type described by Cope, Hofmann, Wyckoff and Hardenbergh.[10] After nineteen hours water had ceased to separate. The solvent was removed, and the product worked up as in (*a*) above. The crude half-ester was colorless and amounted to 5.03 g. (93% yield), m. p. 116–117.5°. The pure substance, m. p. 118.5–119°, formed fine colorless needles from ether–petroleum ether.[9] When mixed with the half-ester Ia, it melted at 98–105°.

Anal. Calcd. for $C_{18}H_{18}O_4$: C, 72.47; H, 6.08. Found: C, 72.45; H, 6.03.

On slow crystallization from dilute solution the half-ester Ib sometimes formed prisms, m. p. 105–105.5°. The polymorphic nature of this product was established by adding to the clear melt at 110° a seed of the higher-melting modification. Solidification occurred immediately, and the material then melted at 116.5–117.5°.

In order to show that no structural or configurational change had occurred in the acid portion of the molecule during the above alcoholysis reactions, the half-ester Ib was saponified with barium hydroxide, and the dibasic acid (I) was reconverted to the original anhydride, m. p. 154.5–155°.

Ethyl 3-Carbethoxy-4-(2-naphthyl)-*cis*-3-pentenoate (Ic).—The diethyl ester Ic can be prepared from either half-ester Ia or Ib. From structural considerations it was expected that the former would be easier to esterify. This was borne out by the fact that Ia could be esterified under conditions to which Ib already has been shown to be stable.

(*a*) *From Half-ester Ia.*—To esterify 7.51 g. of Ia (m. p. 117–118°) the procedure described in the preceding experiment, part (*b*), was followed. The quantities of solvents and catalyst were the same as before. The di-ester Ic was obtained from the neutral fraction; yield 6.95 g. of material boiling at 184–186° (0.05–1 mm.), $n^{22}D$ 1.5667. Partial saponification with one equivalent of barium hydroxide according to the procedure described below part (*b*), regenerated the half-ester Ia.

Anal. Calcd. for $C_{20}H_{22}O_4$: C, 73.60; H, 6.80. Found: C, 73.87; H, 6.82.

(*b*) *From Half-ester Ib.*—A solution of 0.650 g. of the half-ester Ib in 15 cc. of ethanol was saturated with hydrogen chloride and heated under reflux for twenty-four hours. Only a trace of acidic material remained, and the crude diester amounted to 0.639 g. This was characterized by partial saponification (of the di-ester Ic) to the half-ester Ia with 0.32 g. of barium hydroxide octahydrate in 9 cc. of alcohol and 6 cc. of water. After refluxing for six hours the insoluble barium salt of the dibasic acid was filtered. Decomposition with hydrochloric acid gave 0.113 g. of crude I characterized by conversion to the anhydride, m. p. 152–153°. The alcoholic filtrate containing the half-ester was evaporated, and the residue was treated with dilute hydrochloric acid, taken up in ether, washed with water and finally extracted with 5% sodium bicarbonate solution. The colorless half-ester obtained on acidification amounted to 0.295 g., m. p. 117–118°, not depressed on mixing with authentic Ia. Unchanged diester amounting to 0.120 g. was recovered from the ether solution.

3-Carboxy-4-(2-naphthyl)-*trans*-3-pentenoic Acid (γ-Methyl-γ-(2-naphthyl)-itaconic Acid) (II).—A condensation of 2-acetylnaphthalene (68.0 g.) and diethyl succinate (69.6 g.) was carried out according to procedure (*b*) described above. The crude half-ester remaining after crystallization of about 16 g. of Ia was hydrolyzed for five hours with 135 g. of barium hydroxide in 800 cc. of alcohol and 700 cc. of water. The mixture of acids obtained by decomposing the barium salt with hydrochloric acid was dried and treated with excess acetyl chloride at room temperature. The bicarbonate-insoluble mixture of anhydrides amounted to 62.0 g. (59%) of dark-brown solid material. Eleven grams of this material was distilled rapidly in a two-bulb flask under reduced pressure. The red, viscous distillate (9.6 g.) was crystallized from chloroform–petroleum ether[9] to yield the following fractions: (a) 2.6 g. (m. p. 85–108°); (b) 1.1 g. (m. p. 90–113°); (c) 2.1 g. (113–115°). Only crude anhydride of I (m. p. 141–148°) could be isolated from fractions (a) and (b) by recrystallization. Fraction (c), however, consisted largely of the anhydride of II, which after several recrystallizations had the constant m. p. 116–116.5°; colorless prisms from chloroform–petroleum ether.[9]

Anal. Calcd. for $C_{16}H_{12}O_3$: C, 76.18; H, 4.80. Found: C, 76.05; H, 4.89.

Hydrolysis of the above anhydride (0.105 g.) with 5 cc. of 2% sodium hydroxide solution yielded on acidification 0.091 g. of the dibasic acid II, m. p. 165–167° (dec.). The pure substance forms colorless microscopic crystals from dilute alcohol and melts at 167–168° (dec.).

Anal. Calcd. for $C_{16}H_{14}O_4$: C, 71.10; H, 5.22. Found: C, 71.29; H, 5.03.

With acetyl chloride this acid could be reconverted to the anhydride in practically quantitative yield.

Ethyl 3-Carboxy-4-(2-naphthyl)-*trans*-3-pentenoate (IIb).—Alcoholysis of 3.88 g. of the anhydride of II (m. p.

(10) Cope, Hofmann, Wyckoff and Hardenbergh, THIS JOURNAL, 63, 3452 (1941).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

115–116°) described in the preceding experiment was effected with 100 cc. of ethanol containing 4 drops of sulfuric acid. The procedure already described for the stereoisomer was followed, and 4.06 g. of colorless half-ester, m. p. 100–101.5° was obtained. Pure IIb crystallized from ether–petroleum ether[9] in colorless prisms, m. p. 102–102.5°.

Anal. Calcd. for $C_{18}H_{18}O_4$: C, 72.47; H, 6.08. Found: C, 72.54; H, 6.25.

This half-ester was reconverted to the anhydride, m. p. 115–116° (not depressed on mixing with anhydride of II prepared as above) in 77% yield by the usual saponification with barium hydroxide followed by dehydration of the dibasic acid with acetyl chloride.

Ethyl 3-Carbethoxy-4-(2-naphthyl)-*trans*-3-pentenoate (IIc).—Esterification of 3.09 g. of the above half-ester (IIb) was effected according to the procedure already described for the stereoisomer Ib. Thirty cubic centimeters of ethanol saturated with hydrogen chloride was used, and the yield of liquid di-ester IIc was 2.72 g. (81%) after a rough distillation in a two-bulb flask under reduced pressure; $n^{22}D$ 1.5670.

Anal. Calcd. for $C_{20}H_{22}O_4$: C, 73.60; H, 6.80. Found: C, 73.81; H, 6.77.

This ester gave a pale yellow color with concentrated sulfuric acid. In contrast the isomeric *cis* di-ester Ic gave a dark-red brown color. These observations are compatible with those of Stobbe[3o] regarding the color reactions and configurations of the methylphenylitaconic esters.

Partial saponification of IIc (1.52 g.) was effected with 0.76 g. of barium hydroxide octahydrate, 25 cc. of alcohol and 15 cc. of water. The procedure described above for the stereoisomer Ic was followed. Thus was obtained 0.30 g. of the dibasic acid II, m. p. 165–167°, which was converted to the anhydride, m. p. 113–115°, no depression on mixing with original anhydride of II. The neutral fraction amounted to 0.41 g. of unchanged di-ester, and the yield of oily **3-carbethoxy-4-(2-naphthyl)-*trans*-3-pentenoic acid (IIa)** was 0.64 g. All attempts thus far to crystallize this material have failed. It is easily characterized by conversion to ethyl 4-acetoxy-1-methylphenanthrene-2-carboxylate (VIa) which is described below, or by preparation of the crystalline **anilide**, m. p. 153–154°, which forms fine colorless needles from acetone–petroleum ether.[9]

Anal. Calcd. for $C_{24}H_{23}O_3N$: N, 3.75. Found: N, 4.06.

Ozonolysis. (*a*) *Of 3-Carbethoxy-4-(2-naphthyl)-cis-3-pentenoic Acid (Ia).*—A slight excess of ozone (detected by starch–iodide test), was introduced into a cold (ice-bath) solution of 1.00 g. of the pure half-ester Ia in 25 cc. of ethyl acetate. The ozonide was decomposed[11] by stirring with 1–2 g. of Raney nickel for two hours at room temperature, then at refluxing temperature for three hours. The filtered solution was extracted thoroughly with 5% sodium bicarbonate solution and dried over anhydrous potassium carbonate. The neutral oil obtained on evaporation was dissolved in 10 cc. of methanol and treated with 0.5 g. of semicarbazide hydrochloride and 0.42 cc. of pyridine by refluxing for twenty minutes. The semicarbazone was obtained as tan needles, m. p. 229–230° (dec.); yield 0.294 g. (39%). The mixed m. p. with authentic 2-acetylnaphthalene semicarbazone (m. p. 234–235° (dec.)) was not depressed. The above semicarbazone was cleaved by warming with 20% hydrochloric acid to give 0.201 g. of yellow ketone, m. p. 48.5–50°. Recrystallization from petroleum ether[9] containing a little benzene gave material having the m. p. 52–53° which was not depressed on mixing with authentic 2-acetylnaphthalene (m. p. 53–54°).

(*b*) *Of Ethyl 3-Carboxy-4-(2-naphthyl)-cis-3-pentenoate (Ib).*—One gram of the half-ester Ib was ozonized according to the preceding procedure. The semicarbazone amounted to 0.321 g., m. p. 228–230° (dec.). This and the ketone obtained by hydrolysis showed no depression of m. p. on mixing with authentic specimens.

(11) Cook and Whitmore, THIS JOURNAL, 63, 3540 (1941).

(*c*) *Of Ethyl 3-Carboxy-4-(2-naphthyl)-trans-3-pentenoate (IIb).*—The results of ozonolysis of IIb were practically identical with those described in the preceding experiment. The yield of 2-acetylnaphthalene semicarbazone was 0.320 g. or 42%.

Cyclization of Ethyl 3-Carboxy-4-(2-naphthyl)-*cis*-3-pentenoate (Ib).—A solution of 0.800 g. of the half-ester and 0.2 g. of sodium acetate in 7 cc. each of acetic anhydride and acetic acid was boiled under reflux for three hours. The deep-red solution was evaporated in a current of air, and the residue (which was insoluble in cold bicarbonate) was boiled for thirty minutes with 25 cc. of 5% sodium bicarbonate solution to decompose the anhydride of I. The undissolved portion was filtered, dried, and crystallized from petroleum ether.[9] Thus was obtained 0.111 g. of **ethyl 3-methyl-6,7-benz-1-indone-2-acetate (IIIa)** m. p. 95.5–97°. An additional 0.023 g., m. p. 93–95° was obtained from the filtrate. A purified sample crystallized from dilute alcohol as orange needles, m. p. 96.5–97°.

Anal. Calcd. for $C_{18}H_{16}O_3$: C, 77.12; H, 5.75. Found: C, 77.15; H, 5.75.

Acidification of the sodium bicarbonate solution gave an oily acid which was converted to anhydride by the acetyl chloride treatment. Crystallization from chloroform–petroleum ether[9] yielded 0.120 g. of good material, m. p. 154–155°.

Oxidation of Ethyl 3-Methyl-6,7-benz-1-indone-2-acetate.—A mixture of 0.5 g. of the indoneacetic ester IIIa, 1.5 cc. of water and 2 cc. of concentrated nitric acid was heated in a sealed tube at 190–200° for sixteen hours. The crude product which was filtered on a sintered-glass plate amounted to 0.18 g., m. p. 229–236°. Once recrystallized from concentrated nitric acid, it melted at 232–237°. For benzene-1,2,3,4-tetracarboxylic acid the reported[12] m. p. is 238° with softening at 225°. The methyl ester was prepared with diazomethane. After sublimation and recrystallization twice from methanol, tetramethylbenzene-1,2,3,4-tetracarboxylate was obtained as colorless needles, m. p. 129.5–131° (reported[12] 133–135°).

For comparison a sample of 1-keto-1,2,3,4-tetrahydrophenanthrene kindly supplied by Dr. A. L. Wilds was oxidized in the same way. The crude acid produced therefrom melted at 228–231°, and the purified tetramethyl ester had the m. p. 130–131°. No depression of the m. p. of a mixture of the two samples was observed. When mixed with an authentic specimen of tetramethylbenzene-1,2,4,5-tetracarboxylate, m. p. 137–139°, each of the above products depressed the m. p. to 109–126°.

Lactone (IV) of 3-Methyl-3-hydroxy-6,7-benz-1-hydrindone-2-acetic Acid.—A solution of 1.84 g. of ethyl 3-methyl-6,7-benz-1-indone-2-acetate (IIIa) in 15 cc. of acetic acid and 10 cc. of concentrated hydrochloric acid was boiled under reflux overnight. The hot mixture which had turned from a deep red to a pale yellow color was diluted with water to the point of incipient cloudiness, and on cooling the lactone IV crystallized in straw-colored plates. It amounted to 1.35 g. (81% yield), m. p. 167–168°. An additional 0.14 g. of less pure material, m. p. 164–166°, was obtained from the filtrate. After three recrystallizations from benzene–petroleum ether[9] the lactone was obtained as thick, colorless plates, m. p. 168.5–169°. It is insoluble in, but is cleaved slowly by, dilute alkali.

Anal. Calcd. for $C_{16}H_{12}O_3$: C, 76.18; H, 4.80. Found: C, 76.36; H, 5.01.

An attempt to prepare the semicarbazone of the above lactone (IV) gave a product which after recrystallization from dilute alcohol melted at 244° (dec.) (introduced in bath at 239°). The analysis of this material is compatible with a hydrazide structure which could result from cleavage of the lactone ring by the semicarbazide.

Anal. Calcd. for $C_{17}H_{17}O_4N_3$: C, 62.37; H, 5.24. Found: C, 62.06; H, 5.15.

3-Methyl-3-hydroxy-6,7-benz-1-hydrindone-2-acetic Acid (V).—A suspension of 2.02 g. of the above lactone IV (m. p. 167–168°) in 20 cc. of 5% sodium hydroxide was allowed to stand overnight at room temperature. The clear red solution was filtered, carefully acidified in the cold with dilute hydrochloric acid, and the gummy red precipitate was extracted with ether–ethyl acetate. The organic layer was washed with water, dried over anhydrous sodium sulfate and concentrated. The residue was treated with hot benzene which dissolved all but 0.27 g. of amorphous red material, m. p. 227–235° (dec.) which was not further investigated. The filtrate deposited 0.61 g. of orange microscopic crystals, m. p. 146–150° (dec.). Unlike the lactone this material was soluble in sodium bicarbonate solution. After one recrystallization from benzene it melted sharply at 148.5–150° (dec.). On a second recrystallization the m. p. jumped to 168–169° (dec.) (polymorphic form ?). The best sample was obtained as buff-colored, flat rods, m. p. 169–169.5° (dec.).

Anal. Calcd. for $C_{16}H_{14}O_4$: C, 71.10; H, 5.22. Found: C, 71.20; H, 5.42.

In the crystallizations described above it was necessary to use glassware which had been washed with alkali and thus rinsed free of traces of acid which catalyze the lactonization of the hydroxy acid V. Even with this precaution the dehydration was not eliminated completely, for the more soluble lactone was usually found in the mother liquors.

Ethyl 3-Methyl-6,7-benz-1-hydrindone-2-acetate.—A solution of 1.44 g. of the indoneacetic ester (IIIa) in 25 cc. of ethyl acetate was hydrogenated in the presence of 0.250 g. of 30% palladium-charcoal.[13] After shaking for one-half hour one molecular equivalent of hydrogen was absorbed. The residue obtained after filtration and evaporation was recrystallized from petroleum ether[9] giving 0.803 g. of colorless plates, m. p. 68.5–70°. A second crop obtained from the mother liquor amounted to 0.280 g., m. p. 66–68°, making the total yield 75%. The residue was oily and may have contained the diastereoisomer. Pure ethyl 3-methyl-6,7-benz-1-hydrindone-2-acetate was obtained by two recrystallizations from petroleum ether[9] from which it formed colorless plates, m. p. 70.2–70.6°.

Anal. Calcd. for $C_{18}H_{18}O_3$: C, 76.58; H, 6.42. Found: C, 76.63; H, 6.36.

Cyclization of 3-Carbethoxy-4-(2-naphthyl)-*cis*-3-pentenoic Acid (Ia). (*a*) *By the Acetic Anhydride–Sodium Acetate Method.*—The half-ester Ia (0.512 g.) was treated with 0.14 g. of sodium acetate in 3 cc. each of acetic anhydride and acetic acid just as described above for the stereoisomer Ib. In distinct contrast to the case of Ib, the reaction mixture of Ia, even after the heating was complete, was pale yellow. No trace of the red color which is characteristic of the indone derivative was detected. Acidification of the sodium bicarbonate extracts gave back 0.310 g. (61%) of unchanged half-ester, m. p. 117–118°. The neutral fraction was a yellow oil from which could be crystallized a small amount, 0.019 g., of crude anhydride of I, m. p. 135–142°. One recrystallization brought the m. p. to 149–151°, which was not depressed on mixing with authentic anhydride. No more crystalline material was obtained from the residues, but the lack of red color was considered sufficient evidence for the absence of the indone derivative.

(*b*) *With Hydrogen Fluoride.*—This reagent effects cleavage of the ester group, and therefore promotes cyclization to the expected (see later experiments on the dibasic acid I) lactone IV. Thus 0.44 g. of half-ester Ia after standing in about 20 g. of hydrogen fluoride at room temperature for five hours, yielded 0.291 g. of neutral crystalline material, m. p. 167–168.5°. The m. p. of a mixture with lactone IV was not depressed.

Cyclization of 3-Carbethoxy-4-(2-naphthyl)-*trans*-3-pentenoic Acid (IIa).—When 0.560 g. of the crude oily half-ester IIa was treated with 0.15 g. of sodium acetate in 5 cc. each of acetic acid and acetic anhydride according to cyclization procedures described above, very little (0.016 g.) acidic material remained. The neutral material consisted of ethyl 4-acetoxy-1-methylphenanthrene-2-carboxylate (VIa) obtained by crystallization from ethyl acetate–petroleum ether.[9] The first crop amounted to 0.339 g., m. p. 127–128°, and the second 0.133 g., m. p. 125.5–127°, making the total yield 78%. The analytical sample of VIa formed colorless prismatic rods from dilute alcohol and melted at 127.5–128°.

Anal. Calcd. for $C_{20}H_{18}O_4$: C, 74.52; H, 5.63. Found: C, 74.66; H, 5.72.

Ethyl 4-hydroxy-1-methylphenanthrene-2-carboxylate (VIb) was prepared by acid alcoholysis of 5.00 g. of the above acetoxy derivative (VIa) in 100 cc. of ethanol saturated with hydrogen chloride. After refluxing for five hours, the solution was concentrated, and water was added. The crystalline precipitate amounted to 4.00 g., m. p. 175–178°. An additional 0.21 g., m. p. 174–176°, was obtained by concentrating the filtrate. Recrystallization of the combined crops from dilute alcohol gave 4.01 g. (92% yield) of colorless blades, m. p. 177–179°. Material recrystallized three times from the same solvent had the constant m. p. 178.5–179°.

Anal. Calcd. for $C_{18}H_{16}O_3$: C, 77.12; H, 5.75. Found: C, 76.80; H, 5.76.

Ethyl 4-methoxy-1-methylphenanthrene-2-carboxylate (VId) was prepared in 95% yield by methylaton of the above phenolic ester (5.0 g.) with excess dimethyl sulfate in cold dilute sodium hydroxide. The crude product amounted to 5.0 g., m. p. 70–73°. The analytical sample crystallized from dilute alcohol in the form of colorless needles, m. p. 74–74.5°.

Anal. Calcd. for $C_{19}H_{18}O_3$: C, 77.53; H, 6.16. Found: C, 77.40; H, 5.76.

4-Methoxy-1-methylphenanthrene-2-carboxylic acid (VIc) was obtained by hydrolysis of 5.0 g. of crude VId with 100 cc. of 5% alcoholic potassium hydroxide. After refluxing for four hours the acidic material amounted to 4.29 g. (95% yield), m. p. 222–225.5°. After several recrystallizations from dilute alcohol a sample was obtained as colorless needles, m. p. 225–225.5°.

Anal. Calcd. for $C_{17}H_{14}O_3$: C, 76.67; H, 5.30. Found: C, 76.85; H, 5.33.

4-Methoxy-1-methylphenanthrene (VII).—Attempts to decarboxylate the free phenolic acid VI or the acetate (which are described below) were not successful, because these substances were too sensitive. The more stable methoxy derivative VIc, however, was quite suitable.

The decarboxylation of 1.20 g. of VIc was effected by heating in 5 cc. of quinoline with 0.60 g. of copper powder at 205–210° for one-half hour, then at 215–220° for twenty minutes. On working up the mixture 0.03 g. of unchanged acid was recovered. The neutral fraction was recrystallized from methanol (Norit) to give 0.71 g. of colorless needles, m. p. 76.5–78°. From the mother liquor was obtained an additional 0.09 g., m. p. 74–76°, making the total yield 80%. A sample of the methoxymethylphenanthrene VII after further recrystallizations from methanol melted at 78–79° (reported[6] 78.5–79°). The picrate was prepared in the customary way. It crystallized from the reaction mixture in the form of orange, microscopic crystals, m. p. 183–184° (reported[6] 182–183°).

4-Hydroxy-1-methylphenanthrene-2-carboxylic acid (VI) was obtained by the hydrolysis of VIa (3.00 g.) with 60 cc. of 5% alcoholic potassium hydroxide. The yield of material obtained after three hours of refluxing and recrystallization from dilute acetic acid was 2.25 g. (86%); slightly yellow rods, m. p. 249–251° (dec.) (uncor.). Material having the same appearance and melting at 253–254° (dec.) (uncor.) was obtained after several recrystallizations.

Anal. Calcd. for $C_{16}H_{12}O_3$: C, 76.18; H, 4.80. Found: C, 76.02; H, 5.01.

4-Acetoxy-1-methylphenanthrene-2-carboxylic acid was obtained in 94% yield by acetylation of the phenolic acid

(13) Zelinsky and Turowa-Pollak, *Ber.*, **58**, 1295 (1925).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

VI with acetic anhydride and sulfuric acid. The best material formed almost colorless needles, m. p. 227.5–229°, from ethyl acetate.

Anal. Calcd. for $C_{18}H_{14}O_4$: C, 73.46; H, 4.79. Found: C, 73.48; H, 5.06.

Cyclization of Ethyl 3-Carboxy-4-(2-naphthyl)-*trans*-3-pentenoate (IIb).—The half-ester (0.530 g.) was treated with 0.14 g. of sodium acetate in 5 cc. each of acetic acid and acetic anhydride according to procedures described above. Only a trace of acidic material was recovered. The neutral fraction was crystallized from chloroform–petroleum ether.[9] The first crop amounted to 0.211 g., m. p. 112–115°; and the second 0.078 g., m. p. 108–112°. Both fractions were identified (by mixed m. p.) as the anhydride of II described above. The oily residue was almost all converted to bicarbonate-soluble material after treatment with 5 cc. of ethanol containing a drop of sulfuric acid. This indicated that little, if any, of the phenanthrol derivative VIa could have been present.

Cyclization of 3-Carboxy-4-(2-naphthyl)-*cis*-3-pentenoic Acid (I).—A solution of 0.710 g. of the dibasic acid (I) in about 20 g. of anhydrous hydrogen fluoride was allowed to stand in a platinum vessel in an ice–salt bath for one and one-half hours. The reagent was evaporated in a current of air, and the residue taken up in ether and extracted with 5% sodium bicarbonate solution. Acidification of the latter gave 0.220 g. of crude **3-methyl-6,7-benz-1-indone-2-acetic acid (III)**, m. p. 198–211°. The best sample, obtained as flat, red rods after two recrystallizations from benzene–alcohol, melted at 215.5–219.5°. Attempts to prepare this acid by saponification of the ester IIIa failed.

Anal. Calcd. for $C_{16}H_{12}O_3$: C, 76.18; H, 4.80. Found: C, 75.87; H, 4.88.

The material which remained in the original ether layer amounted to 0.271 g., m. p. 164–166°. It was identified (by mixed m. p.) as the lactone (IV) of 3-methyl-3-hydroxy-6,7-benz-1-hydrindone-2-acetic acid described above.

Cyclization of 3-Carboxy-4-(2-naphthyl)-*trans*-3-pentenoic Acid (II).—The dibasic acid (0.321 g., m. p. 165–166°) was treated with hydrogen fluoride according to the procedure described for the stereoisomer I. The yield of material once recrystallized from ethyl acetate–petroleum ether[9] was 0.246 g. (82%), m. p. 251–253° (dec.) (uncor.). The mixed m. p. with 4-hydroxy-1-methylphenanthrene-2-carboxylic acid (VI) was not depressed.

Analysis of Original Reaction Mixture.—This is a continuation of the procedure described at the beginning of the experimental part for the condensation of diethyl succinate with 2-acetylnaphthalene (part b). The combined residues from the crystallization of the half-ester Ia were dissolved in 400 cc. of alcohol, and a concentrated aqueous solution of barium hydroxide was added with stirring until the mixture was basic to litmus. The crude insoluble barium salt of dibasic acid was filtered, washed with water, alcohol and finally with ether, and was then decomposed with dilute hydrochloric acid. After extraction and drying the crude oily acidic material amounted to 6.9 g. This could not be crystallized. With acetyl chloride at room temperature all but 0.8 g. was converted to neutral material, which also could not be crystallized readily and was not further investigated.

The solution and washings containing the barium salt of the half-ester mixture were combined, acidified with dilute hydrochloric acid, and the organic solvents removed under reduced pressure. The oily residue was extracted with ether and dried over anhydrous sodium sulfate. The ether was removed, and the residue was treated with 11 g. of sodium acetate in 100 cc. each of acetic acid and acetic anhydride. After refluxing for three hours the solvent was removed under reduced pressure and the residue was taken up in ethyl acetate where it was washed with sodium bicarbonate solution. Acidification gave 6.0 g. of crude half-ester. Crystallization from ether–petroleum ether[9] gave 2.2 g. of half-ester Ia, m. p. 116–117°. An additional 1.5 g. of good material was accounted for in the filtrate making the yield of Ia in this fraction 5%. If it is assumed that this represents three-fifths of the amount of Ia which was present before cyclization—the remaining two-fifths presumably having been converted to the anhydride as observed in the experiment described above with pure Ia—an additional 3% of Ia may be accounted for. The neutral fraction in the ethyl acetate solution was concentrated and crystallized by the addition of petroleum ether.[9] In this way 24.1 g. (30% yield) of ethyl 4-acetoxy-1-methylphenanthrene-2-carboxylate (VIa), m. p. 126.5–127.5°, was obtained. No more crystals could be obtained from the oily residue (12.1 g.) which was submitted to acid-catalyzed alcoholysis in order to convert any anhydride of I into the bicarbonate soluble half-ester Ib, and thus to separate any remaining phenanthrene derivative either in the neutral fraction as VIa or in the sodium hydroxide-soluble fraction as VIb. In this way a trace (0.2 g.) of additional VIa was obtained, and the presence of Ib was verified by cyclization of the crude acidic fraction to give the indoneacetic ester IIIa; a small yield of red needles, m. p. 94–96.5°, was obtained. The various oily residues have not been investigated further.

Mixture of Itaconic Di-esters.—The acidic portion of a condensation reaction in which 85 g. (0.5 mole) of 2-acetylnaphthalene was employed was exhaustively esterified with ethanol and hydrogen chloride. Only 2.5 g. of dark, oily acid material was recovered. The distilled yellow mixture of di-esters amounted to 106.7 g. (65% yield) boiling over a 10° range. The main fraction boiled at 203–206° (2–3 mm.).

Anal. Calcd. for $C_{20}H_{22}O_4$: C, 73.60; H, 6.80. Found: C, 73.66; H, 6.75.

The balance of material was accounted for as decomposed residue from the distillation. Since the itaconic di-esters are perfectly stable to distillation, the residue (which may correspond to the uncrystallizable fractions of the preceding experiment) probably contained little, if any, of the itaconic di-esters. The undistillable fraction may contain higher molecular weight substances possibly of the type produced by the condensation of two moles of ketone with one of succinic ester.[14]

Mixture of Itaconic Half-esters.—The partial saponification of 10.17 g. of the above di-ester mixture was effected with 5.10 g. of barium hydroxide octahydrate in 250 cc. of ethanol and 200 cc. of water. After refluxing for seven hours the dibasic acid fraction (1.38 g.) was obtained in the usual way via the insoluble barium salt. An equivalent amount (1.71 g.) of unchanged di-ester fraction was found in the neutral portion. The crude mixture of half-esters amounted to 6.64 g. of brown semi-crystalline material.

Analysis of Mixture of Half-esters.—Crystallization of the above half-ester fraction gave 2.66 g. (40% yield) of colorless half-ester Ia, m. p. 116.5–118.5°. The residues were cyclized with 1.5 g. of sodium acetate in 10 cc. each of acetic acid and anhydride. An additional 4% yield of Ia was accounted for in the small acidic portion which remained. The neutral fraction amounted to 2.97 g. (41% yield) of crude phenanthrene derivative VIa presumably containing about a 3% yield of anhydride of I estimated from the 4% of Ia accounted for above. Purification by distillation under reduced pressure gave 2.06 g. of VIa, m. p. 124–127°. The identity of all crystalline products isolated in the above analyses of mixtures was checked by mixed m. ps. with authentic samples.

Summary

1. The condensation of 2-acetylnaphthalene with diethyl succinate in the presence of sodium ethoxide has been studied.

2. Structures and configurations have been assigned to the resulting itaconic acid derivatives, in the course of which some interesting phenanthrene and 6,7-benzindone cyclization products were encountered.

The Carbonation and Carbethoxylation of Certain Esters Using Sodium Triphenylmethide Reagent[1,2,3]

BY ERWIN BAUMGARTEN AND CHARLES R. HAUSER

In the present paper, the synthesis of certain malonic acid derivatives by means of the carbonation or carbethoxylation of the anions of esters (prepared by the action of sodium triphenylmethide) is reported.

Carbonations.—The carbonation of esters to form half malonic acid esters has previously been carried out apparently only with methyl diphenylacetate,[4] the reaction being effected by means of sodium triphenylmethide. In the present investigation, four aliphatic esters have been carbonated using this reagent.

The carbonation of *t*-butyl acetate gave mono-*t*-butyl malonate as a slightly impure oil in 57% yield, while the carbonation of *t*-butyl isobutyrate gave mono-*t*-butyl dimethylmalonate as a crystalline solid in 81% yield. Such half *t*-butyl esters of malonic acids have apparently not been reported previously. The general reaction may be represented as

$$\mathrm{HCCOOC(CH_3)_3} \xrightarrow[\text{by } CO_2 \text{ and acid}]{(C_6H_5)_3CNa \text{ followed}} \mathrm{HOOCCCOOC(CH_3)_3}$$

In contrast to malonic acids and their ethyl esters (which undergo decarboxylation when heated),[5] mono-*t*-butyl malonate and mono-*t*-butyl dimethylmalonate undergo mainly the elimination reaction to form isobutene and the corresponding malonic acid on pyrolysis.

$$\mathrm{HOOCCCOOC(CH_3)_3} \longrightarrow \mathrm{HOOCCCOOH} + \mathrm{CH_2{=}C(CH_3)_2}$$

The ease with which this elimination reaction occurs is probably due to an acid catalysis, since ordinary *t*-butyl esters, such as *t*-butyl cinnamate and *t*-butyl isovalerate, are stable at these temperatures.[6] It should be pointed out, however, that *t*-butyl esters undergo the elimination reaction more readily[7] than the corresponding ethyl esters.

The carbonation of ethyl acetate and ethyl isobutyrate formed presumably the half-ethyl esters of the corresponding malonic acids (in the form of their sodium salts). In the present study, these intermediates were allowed to hydrolyze to the corresponding malonic acids; this reaction occurred readily. There were obtained from ethyl acetate, a 34% yield of malonic acid and from ethyl isobutyrate, a 73% yield of dimethylmalonic acid.

$$\mathrm{HCCOOC_2H_5} \xrightarrow[\text{by } CO_2]{(C_6H_5)_3CNa \text{ followed}} \mathrm{NaOOCCCOOC_2H_5} \xrightarrow[\text{and acid}]{\text{hydrolysis}} \mathrm{C(COOH)_2}$$

The mechanism of the carbonation of esters by means of sodium triphenylmethide reagent is analogous to that for the carbonation of ketones reported in the preceding paper.[1]

Carbethoxylations.—The carbethoxylation of ethyl acetate with diethyl carbonate to form diethyl malonate has previously been effected with sodium ethoxide.[8] This reaction has now been effected by sodium triphenylmethide. The carbethoxylation of ethyl isobutyrate to form diethyl dimethylmalonate, which has been effected previously with ethyl chlorocarbonate[9] in high yield using sodium triphenylmethide, has now been effected in even higher yield with ethyl 4-phenylphenyl carbonate using the same base.

The carbethoxylation of *t*-butyl acetate with diethyl carbonate using sodium triphenylmethide, which has been carried out previously[10] and confirmed in the present investigation, gives ethyl *t*-butyl malonate in more than 50% yield. It has been found, however, that when ethyl 4-phenylphenyl carbonate is used instead of diethyl carbonate, the yield of ethyl *t*-butylmalonate is only 23% after one and one-half hours, and negligible after twelve hours. Apparently, in the presence of the reactive diphenyl ester, the ethyl *t*-butylmalonate first formed undergoes further carbethoxylation to give the di-carbethoxylation

product. Analogous reactions have been observed previously.[8,9]

Experimental[11]

General Procedure.—Ester anions were prepared from equivalents (0.2 mole) of ester and sodium triphenylmethide reagent essentially as described for the preparation of ketone anions.[12] When formation of the anion was indicated by the disappearance of the characteristic color of the reagent, the anions were carbonated or carbethoxylated as described for these reactions with ketones.[12]

Dimethylmalonic Acid.—The anion of ethyl isobutyrate prepared at room temperature from 23.2 g. (0.2 mole) of ethyl isobutyrate was carbonated after fifteen minutes. After the Dry-Ice had evaporated, 400 ml. of water and 200 ml. of ether were added and the resulting ether phase extracted with 50 ml. of 10% sodium hydroxide solution. The combined aqueous phases (washed with ether) were left for twenty-four hours at room temperature (to permit hydrolysis of the half ester) prior to neutralization with dilute sulfuric acid. Extraction of the acidic solution with ether followed by evaporation of the solvent gave 19 g. (73%) of dimethylmalonic acid, m. p. 193–194° (dec.) (reported,[13] 192–193°).

Malonic Acid.—The anion of ethyl acetate prepared at 0° from 10.55 g. (0.12 mole) of ethyl acetate was carbonated immediately and the mixture worked up as in the preceding experiment. The aqueous solution of malonic acid was saturated with sodium chloride prior to the final ether extractions. There was obtained 4.3 g. (34%) of malonic acid, m. p. 131–133°. Recrystallization gave 3.4 g. of pure product, m. p. 133.5–134.5° (dec.) (reported,[14] 134.8–134.9°).

Mono-*t*-butyl Dimethylmalonate.—The anion of *t*-butyl isobutyrate prepared at room temperature from 28.8 g. (0.2 mole) of *t*-butyl isobutyrate[6] was carbonated after five hours. The alkaline solution of the reaction product, obtained as described above, was immediately acidified with iced sulfuric acid. Evaporation of the ether extract of the acidic solution yielded 30 g. (81%) of mono-*t*-butyl dimethylmalonate, m. p. 78–81°; from petroleum ether (b. p. 30–60°), m. p. 80.0–80.9°.

Anal. Calcd. for $C_9H_{16}O_4$: C, 57.43; H, 8.57; neut. eq., 188.2. Found: C, 57.64; H, 8.26; neut. eq., 188.5.

Mono-*t*-butyl Malonate.—The anion of *t*-butyl acetate prepared at 0° from 23.2 g. (0.2 mole) of *t*-butyl acetate[6] was carbonated immediately. After removal of low boiling impurities from the crude acidic material, 18 g. (57%) of slightly impure mono-*t*-butyl malonate was obtained. Neutral equivalent: calcd. for $C_6H_{12}O_4$: 160.2. Found: 154. The compound could not be distilled at a pressure below 1 mm.

Pyrolysis of Mono-*t*-butyl Malonates.—Pyrolysis of mono-*t*-butyl dimethylmalonate at 140–150° for two hours gave dimethylmalonic acid, m. p. 180–182.5°; from ether–petroleum ether, m. p. 190–192°.[13] The characteristic odor of isobutyric acid, arising from decarboxylation of dimethylmalonic acid, was observed after pyrolysis. A gas evolved during the pyrolysis and condensed in a Dry-Ice trap absorbed bromine in carbon tetrachloride solution. The gas was presumably isobutene.

The pyrolysis of mono-*t*-butyl malonate at 120° proceeded with the evolution of a gas. The residue was malonic acid, m. p. 133.5–134.5° (dec.).[14]

Diethyl Malonate.—The anion of ethyl acetate was prepared from 17.2 g. (0.2 mole) of ethyl acetate and carbethoxylated immediately with 23.6 g. (0.2 mole) of diethyl carbonate. A precipitate formed and after four hours 20 ml. of glacial acetic acid in 80 ml. of ice-water was added to the reaction mixture. The ether phase (extracted with iced sodium hydroxide solution) was dried (sodium sulfate followed by "Drierite") and distilled. The material, b. p. 40° (atm.) to 150° (15 mm.), was redistilled, yielding 6.6 g. (41%, based on sodium triphenylmethide) of diethyl malonate, b. p. 94–97° (19 mm.). From the alkaline extract of the original reaction mixture, 1.5 g. (12%) of ethyl acetoacetate, b. p. 76–79° (19 mm.), was isolated.

Diethyl Dimethylmalonate.—The anion of ethyl isobutyrate was prepared from 23.2 g. (0.2 mole) of ethyl isobutyrate and carbethoxylated with 36.3 g. (0.15 mole) of ethyl 4-phenylphenyl carbonate.[15] The mixture was worked up after one and one-half hours as in the preceding experiment (omitting alkali extraction of the ether phase), yielding 23 g. (83%, based on ethyl 4-phenylphenylcarbonate) of diethyl dimethylmalonate, b. p. 87–88° (15.5 mm.[9]). Diethyl dimethylmalonate did not absorb bromine in carbon tetrachloride solution and was hydrolyzed in 90% yield to dimethylmalonic acid, m. p. 193–194°.[13]

Ethyl *t*-Butyl Malonate.—The carbethoxylation of 0.2 mole of *t*-butyl acetate[6] with ethyl *p*-diphenylcarbonate[15] gave 4.4 g. (23%, based on sodium triphenylmethide) of ethyl *t*-butyl malonate, b. p. 100–101° (18.5 mm.[10]), after one and one-half hours. No ethyl *t*-butyl malonate could be isolated after twelve hours reaction time.

Summary

1. The carbonation of certain *t*-butyl esters has been effected by means of sodium triphenylmethide to form the corresponding mono-*t*-butyl esters of malonic acids. The carbonation of certain ethyl esters, followed by hydrolysis, has given the corresponding malonic acids.

2. The carbethoxylation of certain esters with diethyl carbonate has been effected using sodium triphenylmethide to form the corresponding malonic esters. Carbethoxylation with ethyl 4-phenylphenylcarbonate appears to give partly the dicarbethoxylation product.

3. Half *t*-butyl malonates on heating were found to undergo mainly the elimination reaction instead of the more common decarboxylation reaction.

NOTES

t-Butyl Trichloroacetate

By Warner E. Scovill, Robert E. Burk and Herman P. Lankelma

Of the four butyl esters of trichloroacetic acid only the tertiary isomer has not been described. We find that it is readily prepared in 95% yield from trichloroacetyl chloride in the presence of pyridine, following the method used by Bryant and Smith[1] in the preparation of the corresponding acetate. No solvent was added, however, and heating was unnecessary. It was purified by distillation at 1 mm. pressure.

It may also be prepared from trichloroacetic acid and isobutylene, following the method used by Timofeev and Andreasov[2] for the preparation of the corresponding amyl ester. The isobutylene is rapidly absorbed in the trichloroacetic acid at 60°, the absorption being complete in three hours. The resulting brown, oily liquid crystallized on cooling with ice. It recrystallized well from both pentane and methanol at 0°, a yield of 80% being obtained from the former.

The following physical properties were determined: m. p. 25.5°; b. p. 37° at 1 mm. pressure; d^{25}_4 1.2363; n^{25} 1.4398.

Anal. Calcd. for $C_6H_9O_2Cl_3$: C, 32.83; H, 4.13; Cl, 48.46. Found: C, 32.50; H, 4.05; Cl, 48.65.

An Apparatus for the Manipulation of Sodium Triphenylmethide Reagent

By Erwin Baumgarten and Charles R. Hauser

Sodium triphenylmethide in ether solution is a useful reagent to bring about certain condensation reactions.[1] The present note describes a simple apparatus[2] for the manipulation of the reagent permitting the withdrawal of analyzed aliquots from a single large scale preparation of the reagent so that a series of relatively small scale experiments may be carried out conveniently.

The analyzed solution of sodium triphenylmethide, prepared[3] in a two-liter bottle from one mole of triphenylchloromethane,[4] is divided into desired aliquots by means of the buret assembly illustrated in Diagram I, the essential features of which are a mercury-filled pressure release and a three-way stopcock, connected as shown. The system is swept with nitrogen[5] before use. In operation, a constant pressure of nitrogen is maintained in the system sufficient to push the reagent from the storage bottle to the buret. Transfer of the reagent from the storage bottle to the buret is effected by adjusting stopcock A to position (a), applying a positive pressure on the storage bottle while the buret communicates with the atmosphere. Transfer is stopped by adjusting stopcock (A) to position (b), equalizing the pressure between the storage bottle and the buret. The buret may now be drained into the receiver, previously filled with nitrogen.

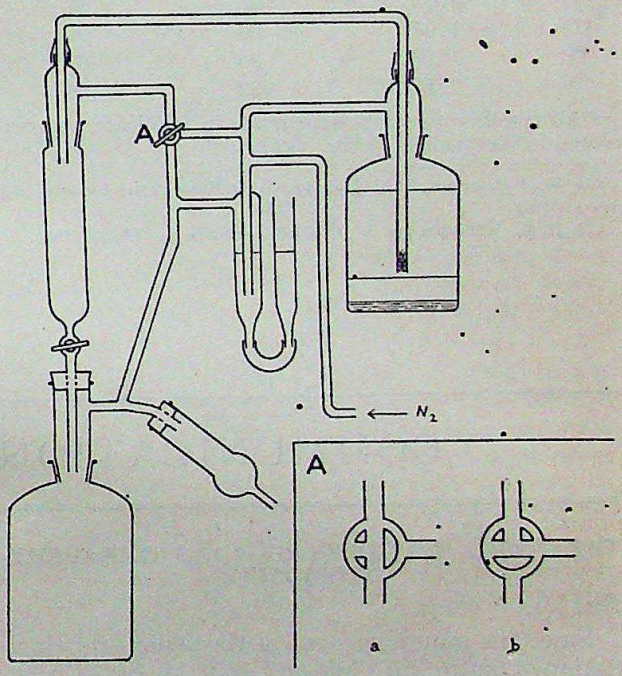

Fig. 1.

It should be noted that this apparatus maintains the reagent at all times under a small positive pressure of nitrogen preventing contact with moisture or oxygen.

Photochemical Destruction of Vitamin B_2 in Milk

By John A. Ziegler

The results of experiments carried out [illegible] March, 1944, on the destruction of riboflavin with

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

milk independently confirm those recently reported by Peterson, Haig and Shaw.[1] Preliminary experiments have also indicated that the destruction by radiation increases with temperature, as previously reported by Williams and Cheldelin.[2]

Samples of so-called "raw" milk (I), homogenized raw milk (II), pasteurized milk (III), homogenized pasteurized milk (IV), and irradiated vitamin D-containing milk (V), were freshly obtained. All samples were stored in the dark in the usual capped quart bottles and were refrigerated until the experiment was begun. Exposures were made within twenty-four hours of bottling to direct mid-morning spring sunshine in the open air for periods up to two hours during which the atmospheric temperature was 16.7 to 20.6°.

TABLE I

Sample	Riboflavin concentration,[a] γ/ml.	Destruction of riboflavin after 1 hr. exposure,[a] %	2 hr. exposure[a] %
I	2.07	36	59
II	2.05	27	54
III	1.97	26	54
IV	1.86	39	68
V	1.89	32	66

[a] All riboflavin assays were made in triplicate and corrected for the values of the blank.

Riboflavin assays were made by the microbiological method of Snell and Strong[3] and frequent recovery experiments were made by adding known amounts of the pure crystalline vitamin to samples of milk to check the accuracy of the method. Recoveries amounted to 94–102%. In addition, samples of milk were withdrawn at the same time as those for assay, made alkaline to *p*H 10 with 1 *N* sodium hydroxide, and exposed to the light from a 750-watt bulb at 50 cm. for twenty-four hours in order to destroy all riboflavin present. The photolyzed milk was then neutralized to *p*H 6.8 and added separately to the basal medium in identical amount to the samples being assayed. The results of these blanks were subtracted from the values of the actual assays to give the riboflavin concentrations reported in Table I.

Since milk after delivery to the consumer frequently remains on an open porch in direct sunlight, it is apparent that during this period from one-third to two-thirds of the riboflavin may be destroyed.

COMMUNICATIONS TO THE EDITOR

THE TOTAL SYNTHESIS OF 2,3,4,5-TETRADEHYDROBIOTIN

Sir:

Since the announcement of the structural elucidation of biotin [du Vigneaud, *et al.*, *J. Biol. Chem.*, **146**, 475, 487 (1942)], the quest for a practical synthesis of the vitamin in this Laboratory has led to the development of a seventeen-step synthesis of 2′-keto-3,4-imidazolido-2-thiophenevaleric acid, the aromatic analog of biotin. Experiments are now in progress on the nuclear reduction of this compound to biotin.

The starting materials were trimethylene chlorobromide and ethyl malonate, from which was obtained ethyl 3-chloropropylmalonate by the method of Fischer and Bergmann [*Ann.*, **398**, 120 (1913)]. Hydrolysis and decarboxylation followed by esterification gave ethyl 5-chlorovalerate, described by Mellor [*J. Chem. Soc.*, **79**, 132 (1901)]. This compound reacted with ethyl malonate to duce ethyl pentane-1,1,5-tricarboxylate (b. p. –170° (4 mm.), for $C_{14}H_{24}O_6$—Calcd.: C, 58.32; H, 8.37. Found: C, 58.49; H, 8.54). Hydrolysis yielded pentane-1,1,5-tricarboxylic acid (m. p. 82°, for $C_8H_{12}O_6$—Calcd.: C, 47.05; H, 5.92. Found: C, 47.11; H, 5.88). Treatment with sulfuryl chloride followed by decarboxylation gave 2-chloropimelic acid (m. p. 89–90°, for $C_7H_{11}O_4Cl$—Calcd.: C, 43.25; H, 5.70. Found: C, 43.27; H, 5.78) which after reaction with β-mercaptopropionic acid and esterification yielded 2-carbethoxyethyl 1,5-dicarbethoxyamyl sulfide (b. p. 210–213° (3 mm.), for $C_{16}H_{28}O_6S$—Calcd.: C, 55.14; H, 8.10. Found: C, 55.14; H, 8.15). Cyclization by the Dieckmann reaction gave ethyl 4-carbethoxy-3-keto-2-tetrahydrothiophenevalerate (for $C_{14}H_{22}O_5S$—Calcd.: C, 55.60; H, 7.33. Found: C, 55.53; H, 7.36). The oxime of this keto ester was converted to ethyl 3-amino-4-carbethoxy-2-thiophenevalerate (m. p. 43–44°) by means of dry hydrogen chloride followed by decomposition of the resulting amine hydrochloride with a suitable base. Selective hydrolysis produced 3-amino-4-carbethoxy-2-thiopheneval-

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

eric acid (m. p. 97–97.5°, for $C_{12}H_{17}O_4NS$—Calcd.: C, 53.12; H, 6.32. Found: C, 53.14; H, 6.32) which was converted to the N-benzoyl derivative (m. p. 126.5–127.5°, for $C_{19}H_{21}O_5NS$—Calcd.: C, 60.77; H, 5.63. Found: C, 60.70; H, 5.53). The Curtius degradation through the hydrazide (m. p. 140–141°, for $C_{17}H_{19}O_4N_3S$—Calcd.: C, 56.49; H, 5.30. Found: C, 56.40; H, 5.57), and the azide (dec. 99–100°, for $C_{17}H_{16}O_4N_4S$—Calcd.: C, 54.83; H, 4.33. Found: C, 55.11; H, 4.53) gave 3-benzoylamino-4-carbethoxyamino-2-thiophenevaleric acid (m. p. 156.5–157.5°, for $C_{19}H_{22}O_5N_2S$—Calcd.: C, 58.44; H, 5.68. Found: C, 58.88; H, 5.72) when the azide was refluxed with absolute alcohol. The final product, 2′-keto-3,4-imidazolido-2-thiophenevaleric acid (m. p. 253–254° with decomposition, for $C_{10}H_{12}O_3N_2S$—Calcd.: C, 49.98; H, 5.03. Found: C, 50.33; H, 5.25) was prepared from the urethan by hydrolysis to the diamine and immediate treatment with phosgene.

Ultraviolet absorption curves prepared by Dr. J. M. Vandenbelt show that the compound has strong absorption in the region 250 to 270 mμ, with the peak value at 260 mμ having a molar extinction coefficient of approximately 17×10^{-3}. The curve closely corresponds with the curves for 2′-keto-3,4-imidazolido-2-γ-phenoxypropylthiophene (m. p. 174–174.5°), 2′-keto-3,4-imidazolido-2-γ-benzyloxypropylthiophene (m. p. 127–127.5°) and 2′-keto-3,4-imidazolido-2-γ-hydroxypropylthiophene (m. p. 138–139°), all of which have been prepared and characterized during this work.

The authors gratefully acknowledge the assistance of A. W. Spang who did the microanalyses. Details for the preparation of all compounds and the results of biological tests for biotin and antibiotin activity will be forthcoming.

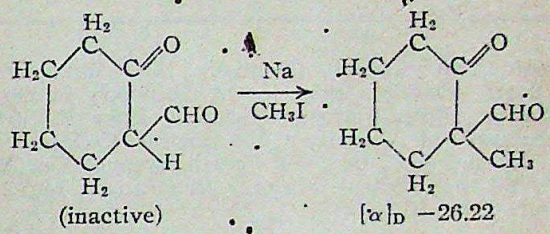
ATTEMPTED REPETITION OF A REPORTED TOTAL ASYMMETRIC SYNTHESIS

Sir:

In a recent letter to the editors of *Nature*, Paranjape, Phalnikar, Bhide and Nargund[1] report the synthesis of several optically active substances from inactive starting materials without the use of any asymmetric reagents or catalysts. They report that the asymmetric synthesis occurred at the following step in their series of reactions



(inactive) $[\alpha]_D$ −26.22

The reported activity was determined on the crude material, since the methylated-formylcyclohexanone was reported to be an unstable liquid, impossible to purify by distillation.

An attempt has been made in these Laboratories to repeat this extraordinary result, which would not be predicted on the basis of any known theory of optical activity.

Inactive formylcyclohexanone was prepared according to the method of Rupe and Klemm,[2] and the methylation was carried out using two different techniques.

In the first trial, formylcyclohexanone was added to a 10% ethanolic solution of sodium ethylate and refluxed with methyl iodide. This yielded, after evaporation of the solvent and washing with water, a reddish liquid, a portion of which darkened and resinified when an attempt was made to distill it. The crude material had a specific rotation of zero, with an error of ±0.7° due to the difficulty of taking readings on such a comparatively strongly colored material.

In the second synthesis, the sodium salt of the formylcyclohexanone was suspended in toluene and allowed to react with methyl iodide. This procedure yielded a much clearer product after removal of the solvent, and it was possible to determine that the material was totally inactive within the 0.01° accuracy of the Zeiss polarimeter. Readings were taken on the material itself as well as on chloroform solutions of it as reported by the Indian authors.

Considerable speculation on possible sources of their reported results has yielded no reasonable explanation.

NEW BOOKS

Second Year College Chemistry. By WILLIAM H. CHAPIN, Emeritus Professor of Chemistry in Oberlin College. Fifth edition, revised, by Luke E. Steiner, Professor of Chemistry in Oberlin College. John Wiley and Sons, Inc., 440 Fourth Avenue, New York, N. Y., 1943. viii + 575 pp. Illustrated. 14.5 × 22 cm. Price, $3.75.

The passage of five years has brought the fifth edition of this popular and old reliable text, steadily changing in content to better serve its original purpose of extending the frontiers of elementary chemistry. Unfortunately, there is no place in many college programs for the lessons it could teach. In the Preface, Dr. Steiner writes: ". . . Liquids and solutions are discussed more fully and more exactly. A new chapter on crystalline solids relates the dimensions of atoms, ions and molecules to the structure of crystals and chemical behavior, and serves as an introduction to crystal chemistry and to structural chemistry. Similarly, the chapters on liquids and solutions correlate their properties more closely, with chemical behavior. . . . Early chapters place greater emphasis on mathematics, . . . but the kinetic point of view is maintained."

The revision has been extensive, thirteen of the twenty chapters showing an increase of three pages or more, and two chapters only having been shortened. The net increase in pages is 168, including a block of miscellaneous problems at the end. The typography is unchanged, but in keeping with war-time necessity the paper is thinner and the margins are narrower, giving a book no larger than the previous edition.

ALLEN D. BLISS

Laboratory Manual of Explosive Chemistry. By ALLEN L. OLSEN AND JOHN W. GREENE, Kansas State College. John Wiley and Sons, Inc., 440 Fourth Avenue, New York 16, N. Y., 1943. vi + 106 pp. Illustrated. 14 × 22 cm. Price, $1.75.

This laboratory manual is designed for a short course on explosives such as that set up by the Engineering, Science and Management War Training Program, the purpose of which is to provide training in the chemistry of explosives for persons planning to work in explosives and loading plants as (1) inspectors for the Ordnance Department and (2) operators for the manufacturers having contracts in this field. It consists almost entirely of directions for testing, which are taken directly from the War Department Technical Manual 9-2900 (August 29, 1940). Suitable acknowledgment is made to the Technical Manual and no pretense of originality is made.

From the standpoint of a course such as that mentioned above, limitation to the specification procedures of the Ordnance Department is well advised. In evaluating this book, it should be emphasized that the procedures, as given, represent the standard procedures of the Ordnance Department and not the best possible procedures which might be worked out for the various tests. The authors have exerted commendable restraint in avoiding the temptation to devise more elaborate and perhaps more accurate tests.

Since it is mostly a duplication of Technical Manual 9-2900, it may, perhaps, be useful to compare the scope of the Technical Manual with this book. In the latter the details of the manufacture of explosives are omitted, but the methods are illustrated by small-scale laboratory directions. The chief contribution of the Laboratory Manual over the information available in the Technical Manual is the inclusion of a number of explanatory notes summarizing the reasons for various operations and mentioning additional precautions. Another useful feature is a chapter on "Safety," which would answer many of the questions occurring in the minds of people inexperienced in this field who might be given the responsibility for organizing a course on the testing of explosives. The substances for which methods of testing are given are the same as those included in Technical Manual 9-2900. No classified information is included in this book.

The book contains a few errors, but these are not serious and would generally be fairly obvious to the user. The book is not intended to cover the entire field of explosives but is intended, primarily, for those interested in the routine testing of products in current manufacture. It will be of interest and helpful to those participating in courses of this type.

RALPH CONNOR

Quantum Chemistry. By HENRY EYRING, Frick Chemical Laboratory, Princeton University, JOHN WALTER, Palmer Physical Laboratory, Princeton University, and GEORGE E. KIMBALL, Department of Chemistry, Columbia University. John Wiley and Sons, Inc., 440 Fourth Avenue, New York 16, N. Y., 1944. vi + 394 pp. Illustrated. 14.5 × 22 cm. Price, $5.00.

Into this book, just over an inch between the covers, the authors have packed a large amount of basic theoretical material, much of it not elsewhere available except in special monographs and reviews. In addition to the standard contents of an elementary text on quantum mechanics there are chapters on group theory, statistics reaction rates, and other applications of interest to the modern theoretical chemist. The presentation is of necessity condensed in style, but is skilfull and accurate (except for an occasional misplaced index or average sign), and no essentials have been omitted. The work will be valuable as a convenient general reference book for the student, and for this purpose has the merit that each chapter can be read by itself, sufficient back references being supplied to indicate where the necessary preliminary material may be found. As an aid to further study, a good bibliography is appended.

A. S. COOLIDGE

Enzyme Technology. HENRY TAUBER. John Wiley and Sons, Inc., New York, N. Y.; Chapman and Hall Ltd., London, 1943. vii + 275 pp. 46 figures. Price, $3.50.

The purpose of this book, according to the author, is to present practical information concerning the role and use of enzymes in industry, their preparation, and their use in medicine. These objectives are achieved, although many of the subjects are not discussed in great detail. Fortunately, there is a generous bibliography included at the end of each chapter, enabling one to refer to the original material. In some cases the author has not followed his original objective. This is true in the discussion on the use of yeast in medicine.

There are sixteen chapters covering the following material:

Yeast: Production and Utilization and the Enzyme Systems
Production of Ethyl Alcohol by Fermentation
The Role of Enzymes in Brewing
Mold Fermentations
Bacterial Fermentations
The Production of Enzymes and Methods of Their Estimation
Enzymes for Medical Use
Enzymes of Grains and Malt and the Role of Enzymes in Bread Making

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri
48545

Enzymes in Dairy Products
Enzymes in the Meat, Egg, Vegetable, and Fruit Industries
Pectin-Decomposing Enzymes and Their Use in the Fruit Juice, Wine, and Jelly Industries
Vitamin-Destroying Enzymes
Enzymes in Textile, Paper, and Related Industries
The Use of Enzymes in the Manufacture of Leather
Enzymes in Other Industries
Microbiological Methods for the Estimation of Vitamins

The individual chapter headings do not always give a reliable index of the contents within the chapter. For example, Chapter VI: "The Production of Enzymes and Methods of Their Estimation," contains methods for the preparation of diastatic enzymes from molds, bacteria and pancreas, and also proteolytic enzymes, whereas the preparation of yeast enzymes, malt diastase, and some other preparations are described in other chapters. The only methods included in this chapter are those covering proteolytic activity, lipolytic activity, and one method for saccharogenic amylase activity. Some of the other methods are given in the respective chapters describing specific enzymes in more detail.

It is believed that it would have been preferable to group the chapters containing material on the amylases together, thereby enabling the author to make possible a more unified treatment of the subject.

The author has confused the starch liquefying property of α-amylase and the as yet unverified amylophosphatase of Waldschmidt-Leitz and Mayer. It is also unfortunate that the models of Hanes for the structure of the starch molecule are given, since it is quite well-established that starch consists of straight-chain amylose and branched-chain amylopectin and the simple Haworth structure is no longer tenable.

The last chapter contains a description of the microbiological assay methods for the six B vitamins.

There are relatively few errors and the binding and printing are quite good. The book is a useful contribution to the growing field of enzyme technology. It covers a broad scope, possibly too broad, but the reader can cover the field more thoroughly with the help of the excellent collection of references given after each chapter.

CHARLES N. FREY
SUTTON REDFERN

General Chemistry. A First Course. By L. E. YOUNG, Professor of Chemistry, Mills College, and C. W. PORTER, Professor of Chemistry, University of California. Revised edition. Prentice-Hall, Inc., 70 Fifth Avenue, New York, N. Y., 1943. xi + 527 pp. Illustrated. 15.5 × 23.5 cm. Price, $3.75.

This book is, in many ways, better than most texts that have been written lately for beginners. Many glaring faults to be found in texts much used in High Schools and Academies have been corrected. Thus *nascent* hydrogen is not mentioned and a correct explanation is given of the electrolysis of brine. Equation balancing, solving of problems, oxidation–reduction, etc., are explained intelligently and the student is not encouraged to follow the German practice of expressing all chemical arithmetic in terms of ratio and proportion. The book is intended to be used in colleges but it is well suited for use in High Schools although no attempt is made to satisfy the requirements of College Entrance Boards, and it is not a reference book.

As stated in the preface, "The attempt is made to explain the fundamental principles of chemistry in simple language and illustrative matter is drawn from the experiences of daily life." In teaching beginners, the chief difficulty is the approach to the subject because no single element, except perhaps the rare gases, can be studied adequately without reference to other elements. For this reason, the first quarter of the book is rather conversational in style and easy to understand although the reader is expected to swallow considerable dosage about as one takes a pill. Thus on page 3 it is shown that a single molecule of sodium chloride would weigh so little that it would have to be a gas and after stating that matter cannot be created or destroyed a foot-note is inserted which states that the "escape or absorption of heat results in a corresponding loss or gain in matter" and a little later the student is taught that when 20 million tons of coal are burned one pound of it is converted into heat and light. This will almost lead some beginners to think that heat and light can be weighed, which agrees pretty well with conceptions that prevailed in the Middle Ages. In this connection, it may be stated that Physicists often have claimed that Chemists don't understand the difference between *mass* and *weight*.

Subjects such as *isotopes*, *deuterium*, *electrons*, *neutrons* and the *Periodic Table* are discussed early in the book when hydrogen is the only element that has been studied. This rather pleases the reviewer although some may think that this leads to over-emphasis of theory. The elements of crystallography are given on pages 20–22, which leads to the discussion of *space lattice* and the crystal lattice of sodium chloride is shown on page 24.

In general, the descriptive matter concerning the elements and their compounds is adequate for a course given beginners, but some modern ideas concerning acids, bases, salts and the hydronium ion are not mentioned, which will probably displease some good chemists. The law of chemical mass action and the reversibility of most reactions is not discussed adequately and the chapter on the *Electromotive Series* is unsatisfactory because no attention is paid to the concentrations of the ions in solution. In fact, a table of twenty oxidation-potential potentials is given in the Appendix and is stated to pertain to "infinite dilution" although the values given are identical with those usually given for molar concentrations. It is quite likely that the authors themselves do not entirely understand the application of the *Nernst rule* to oxidation–reduction potentials.

The sections on *Organic Chemistry* are excellent and the reviewer is greatly pleased to find the conception that the carbon is negative in CH_4 but positive in CCl_4.

In examining a book for review, one is inclined to overemphasize the things he does *not* like and in reading a text is more likely to underline false statements and misprints than to note excellent points. This book is well-published, is well-written and contains very few false statements or misprints. It might be better if, in the *Table of Contents*, the reference to the *Metric System* were given as page 511 instead of 504, that the definition of *amphoteric* substances be restricted to oxides and hydroxides and that *amorphous* substances be recognized as being in a state of extreme fineness of the particles rather than due to lack of any crystalline form, but enumeration of such things is more or less captious and the reviewer hopes he has made it clear that he likes the book.

WILLIAM T. HALL

The Physical Chemistry of Electrolytic Solutions. By HERBERT S. HARNED, Professor of Chemistry, and BENTON B. OWEN, Associate Professor of Chemistry, Yale University. (American Chemical Society Monograph Series.) Reinhold Publishing Corporation, 330 West 42nd Street, New York, N. Y., 1943. xi + 611 pp. Illustrated. 15.5 × 23.5 cm. Price, $10.00.

Appearing twenty years after the publication of both Debye and Hückel's first papers on the interionic attraction theory and Lewis and Randall's "Thermodynamics," "The Physical Chemistry of Electrolytic Solutions" rounds out one period in the development of solution theory. This is the period in which the physical chemists have been taught to use exact thermodynamics in the treatment of solutions and to use the Debye theory for extrapolation to solutions too dilute for accurate experimental measurements. The authors consider the Debye theory sufficiently established so that they take the first five chapters to develop the theory before making any comparison with experiment to check its validity. The second group of fi-

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

chapters discusses experimental methods beginning with the irreversible effects and ending with electromotive force measurements, which make a smooth transition to the last group of five chapters which discuss the equilibrium properties of various types of solutions, particularly those studied in the Yale laboratories.

During this period it has been necessary to make a large number of measurements upon simple systems to verify the theory, to discover the nature of the transition from solutions so dilute that the theory is exact and measurements are impossible to those so concentrated that the theory becomes too complicated but measurements are relatively easy, and to obtain a body of correlated data for the study of concentrated solutions. Most of the more accurate results are presented in the last ten chapters.

Theoretical studies are much less well presented than experimental work. So much of the book is based upon the Debye theory that one might expect a thorough discussion of its derivation. However, the investigations of the statistical basis are limited to a footnote citation, and there is no discussion at all of the fact that the Debye equations are derived for a very special model with all the ion spheres of the same size, and no mention of the attempts to determine the deviations to be expected when these conditions are not fulfilled.

The book is weak in a few places where we might expect it to be strongest. The equation which is the basis of the treatment of the thermodynamics of "The Reversible Galvanic Cell," equation 1-5-1, cannot be derived from equation 1-2-6 by any method known to me. Equation 1-5-5, which is called "the equation for concentration cells," is not used as such either in this book or elsewhere as far as I know. In the "General Statement of the Interionic Attraction Theory" (Chapter 2) an outline of the complicated mathematical framework of the Onsager–Fuoss treatment of irreversible processes is followed by a simplified derivation of the Debye potential, neglecting the ionic diameter. The mathematics of the proper derivation, which has to be given in the next chapter, is so much simpler than that of the preceding sections that there seems no excuse for an approximate derivation here. The case is aggravated by two errors in the derivation. From the fact that κA is not a function of r, it does not follow that κA must vanish as κ approaches zero; even if this were true, it would not follow that A is not a function of κ.

The authors have a difficult problem in the treatment of non-reversible processes. The mathematics is so complex that it cannot be presented completely, yet there should be enough to illustrate the methods. How much should be presented? Although my own taste would have been for more space devoted to a physical picture and less to the mathematics, I think the compromise chosen by the authors is a good one.

Their treatment of numerical results involves another problem which is not so wisely handled. The data from the Yale laboratories are computed with the Lewis and Randall "International Critical Tables" values of fundamental physical constants, like most data in the literature, and with values for the fundamental hydrochloric acid concentration cell based on smoothing less skillful than the present practice. These values are given in the book with the explicit excuse for the incorrect constants that the errors "are generally less than the errors in the physicochemical data with which they are combined." Hanging on to erroneous quantities is much like drug addiction. Each paper published with the old values makes it more difficult to give them up for the new. The better the paper, the worse is its effect. A book like the present makes the recovery of the authors almost impossible, and the publication of many convenient tables in chapter 5 tempt others to the same bad habits. This chapter should not have been allowed to appear without a poison label. For freezing point measurements the discrepancy is greater though not used so much. Attention should be called to the fact that the most probable value of the constant for water is 1.860 and not 1.858.

The most valuable part of the book is the bringing together of experimental work. Chapter 6 presents and discusses data on the conductance, transference, viscosity and diffusion. Chapter 7 treats the relation of conductance to the electrostatic formation of ion pairs and higher complexes and to the association of weak electrolytes, the effect of frequency on conductance and dielectric constant, and the effect of field strength on the former. In Chapter 8 are presented thermochemical quantities, partial molal volumes and coefficients of expansion and compressibility. Chapter 9 discusses freezing points, boiling points and vapor pressures. Chapter 11 treats hydrochloric acid; chapter 12 covers other strong 1-1 electrolytes in aqueous solution, including their effect on non-electrolytes. Chapter 13 is devoted to polyvalent electrolytes in aqueous solution. Mixtures of strong electrolytes are discussed in Chapter 14, and weak electrolytes in Chapter 15. The appendix collects tables which would have spread out the text too much if included earlier. These later chapters are, quite properly, built around the electromotive force measurements in the Yale laboratories and emphasize those electrolytes which can be studied by this method. The only chemical reaction discussed is the acid-base equilibrium. Every worker in the field will be grateful to the authors for the labor they have spent collecting and coördinating this material, and will need to have a copy easily accessible.

A glossary of symbols at the beginning is very helpful. The convenience as a reference book could have been increased greatly by having the chapter and section numbers at the top of each page. Trivial slips like typographical errors, split infinitives, and stabilization energy from proton resonance have been kept infrequent, though they have not been entirely eliminated.
